with the local application of bacteriophage in the form of moist dressings. Usually two injections, each of which may vary from 0.5 c.cm. to 3 c.cm., have been given with an interval of from 24 to 48 hours. In the case of *Bact. coli* infection of the bladder, this method is said to have given very encouraging results. Larkum (1926) demonstrated the existence of bacteriophage in most acute urinary infections and he later tried this method of treatment in suppurative conditions and found it satisfactory.

Certain general principles must be borne in mind for the clinical use of bacteriophage in these conditions. It must come into direct contact with the infected tissues and external application, direct injection and circum-injection are employed according to the type of lesions to be dealt with. Care should be taken during injection of bacteriophage inside a closed cavity, so that the tension is not thereby increased. It is, therefore, always safer to aspirate such pus as may be present in it, before injecting the phage.

Though bacteriophage treatment by localised injections has given a certain measure of success, it is not at present possible to evaluate its importance in clinical practice. In these conditions there is direct contact between the invading organism and the therapeutic agent in the shape of bacteriophage, and it is not possible to say how far the results are due to bacteriophage therapy or other bacterial products that are present.

CHAPTER III

BOWEL DISEASES

The varying conditions of oxygen tension and reactions, physical and chemical, in different levels of the alimentary canal favour the growth of different types of organisms at these various levels of the intestines. The mouth offers an aerobic area, although the various crevices between the teeth, in the folds of the mucous membranes and the crypts of the tonsils, anærobic organisms flourish. In the stomach, if the acidity of the gastric juice is normal, most bacteria are killed unless otherwise protected. In the duodenum oxygen tension is low and from here onward to the colon, more or less anærobic conditions prevail. In the colon and rectum conditions are favourable for the growth of aerobic organisms. Certain conditions influence the normal bacterial flora of the intestine, *e.g.*, the degree of digestion of the food, the proportion of unaltered carbohydrates and protein at different levels of the gut, etc. The products of bacterial growth at one level of the colon will also influence the growth of other types of organisms in the same level and further down. Although a new invader may sometime succeed in establishing a foot-hold at some level in the gut, it has to encounter other bacteria at lower levels, and unless conditions are particularly favourable, it will be readily overpowered by the more adapted intestinal bacteria. In the colon and rectum many of the bacteria die out as a result of the gradual loss of water. The presence of bacteriophage also helps to maintain an equilibrium between man and his intestinal bacteria.

At birth there are no bacteria in the intestine, the meconium is sterile unless infection has taken place as a result of some general infection in the mother. Shortly after birth bacteria make their appearance. They are chance contaminations, from kissing, feeding bottles, milk, etc., and are of various kinds (staphylococcus, streptococcus, coliform organisms, yeasts, etc.). In a few days after birth the characteristic intestinal flora is

established which is modified under different conditions, such as administration of cathartics, changes in diet, intestinal infections. The principal types of intestinal flora are, *B. bifidus*, *Lactobacillus acidophilus*, *Streptococcus faecalis*, certain spore-bearing aerobes and anærobies, coliform and other allied organisms. The intestinal flora varies with the conditions of life. In breast-fed infants the duodenum contains streptococcus, while in the rest of the gut coliform organisms and *B. bifidus* are common. In the artificially-fed infants Gram-negative organisms are numerous and putrefactive bacteria are relatively more common. The duodenum of a normal person is relatively sterile except during digestion. In the upper part of the small intestine cocci predominate and the lower part contains an abundance of coliform organisms and spore-bearing proteolytic aerobes. The large intestine contains certain proteolytic anærobies and aerobes, yeasts, moulds and spirilli.

The intestinal flora is, however, subject to wide variations. In infections with cholera and dysentery the specific infecting organisms may dominate the intestinal flora. Changes in diet, such as increase of carbohydrates may lead to a preponderance of intestinal flora of *Lactobacillus acidophilus* type. Meat protein leads to an increase of the putrefactive bacteria; milk and vegetable proteins produce much less putrefaction. Purgatives and the so-called intestinal antiseptic group, have no appreciable effect on the intestinal flora. Though direct entrance of the bacteria to the gastro-intestinal canal is no doubt the most important route by which infection occurs, it has been argued that infection may occur also through other channels. If bacteria are injected parenterally they can be found in the bile, and if the bile duct is tied, certain bacteria are eliminated through the intestinal mucosa.

Foster and his co-workers (1908) in their study of the mode of infection of the intestinal canal with typhoid bacilli put forward the view that the bacilli enter the circulation possibly through the tonsils. They multiply in the blood, pass through the liver and gain access to the gall bladder where they set up a catarrhal inflammation, and thence infect the intestine. They showed that when typhoid bacilli were injected intravenously

into animals the organisms were found mainly in the gall bladder where they persisted for weeks. *Bact. typhosum* could be isolated from the blood in the later parts of the incubation period before any manifestations of disease appeared and before they could be isolated from the intestine. On autopsy, the bacilli were always present in the gall bladder and the upper parts of the intestine, but were frequently absent in the lower part of the intestine.

Recently, Teal (1934) has investigated the problem of bacterial infection of the intestinal canal. He administered the bacteria to animals by different channels and noted the results. It was found that bacteria can find their way to the tissues through the bucco-pharyngeal mucous membrane without any breach occurring on the surface. They multiply in the neighbouring lymphatic glands, enter the blood stream and from there reach the intestinal mucosa and are excreted along its entire length. Most of the organisms when given by the mouth are destroyed by the gastric juice because the intestinal bacilli are incapable of long survival in an acid medium. When the pH is considerably lower than 3 or 4, death of bacteria occurs rapidly. A small number may however pass alive through the pylorus and reach the intestine. When the organisms are injected directly into the intestine at places where the acidity is neutralised, the bacteria may survive for a considerable time, but the normal healthy mucosa as a rule does not allow their passage readily and those that pass through are rapidly destroyed in the lymphatic glands. Loudon and Sanarelli showed that germicidal activity in these cases is not due to the acidity of the gastric juice but to other factors, *e.g.*, the sterilizing effect of the succus entericus; the presence of normal non-pathogenic organisms in the gut, however, plays an important part in inhibiting the growth of pathogenic bacteria.

Another important consideration in this connection is the impermeability of the healthy mucosa to intestinal organisms. This property probably comes into play in nearly all cases. If, however, the mucous membrane is injured, the passage of organisms through it is facilitated. Besredka was able to

demonstrate the passage of bacteria through the mucous membrane of the intestine after damaging it with large quantities of ox bile. It thus appears that sufficient protection exists in nature for the prevention of intestinal infections. In cases of typhoid fever infection is caused by the bacteria escaping the action of hydrochloric acid in the stomach. This occurs when they are hurried through the stomach in a large quantity of water, or in the presence of some organic envelope, or by hypochlorhydria, temporary or permanent. In the intestine some alteration in the permeability or resistance of the mucosa brought on by such factors as injudicious diet, contaminated food and conditions reflexly altering the circulation of the mucosa, also favour the development of an infection. In addition, it has been suggested that in some cases infection takes place by passage of the bacilli through the bucco-pharyngeal mucosa followed by invasion of the blood stream. In bacillary dysentery, infection occurs through the oral route. The toxins of *Bact. shigæ* are not destroyed in the gastro-intestinal tract. The exotoxin is absorbed into the blood stream and can cause typical damage to the capillary endothelium, the central nervous system and the endocrine glands; the endotoxin which causes intestinal lesions is eliminated by the large intestine. The living bacilli can produce toxins sufficient to cause damage to the mucous membrane, and allow multiplication of the organisms. In the case of cholera, ingestion of the bacilli is necessary for the production of the disease. Although this is true, there seem to be certain conditions which modify an infection. The state of health of an individual and the degree of acidity of the stomach contents determine, to a great extent, the susceptibility or otherwise to an infection.

General management. The rationale of the treatment of bacterial infection of the intestine, properly considered, is the management of the patient rather than of the disease. Every attempt should be made to increase the patient's resistance. Constipation is to be particularly avoided. Anything which lowers the neuro-muscular tone of the intestinal wall will contribute to the development of constipation. Seasonal changes, lack of essential food factors, want of exercise, excess of tobacco,

lack of efficient mastication and deficiency in the intake of fluid are important contributory factors. Undoubtedly the nature of the dietary is of utmost importance. So far as the food factor is concerned, an adequate supply of fresh foodstuffs including an ample supply of vegetables and fruits is essential. The nature of the diet is dependent upon the specific illness, but in general, it may be said that rough fibrous meat and fish and the coarser and harsher vegetables and fruits should be forbidden. The softer forms of meat and fish and the simpler fruits and vegetables are permissible. Sugars and sugar-producing foods, by reason of their fermentable qualities should be reduced. The main articles of consumption should be restricted to milk (citrat-ed if necessary), raw or lightly boiled eggs, butter and cheese in moderate quantity which provide both protein and fat. The important point in the management of a case should be to soothe and not to stimulate the intestine, and such an effect can only be attained by presenting the intestine with a small and innocuous mass of food which it can easily digest.

In cases where the intestine is sluggish some laxative may be prescribed to empty the bowel. The choice of laxatives in cases of stasis is not always easy, because most of these drugs have no effect. Liquid paraffin is suitable in some cases; it should not, however, be used indiscriminately or persisted with too long, because besides being useful as a lubricant it can do harm by retarding absorption. Some general metabolic stimulants do good in asthenic cases; thyroid extract may be prescribed as a general stimulant. Autogenous vaccine prepared from any pathogenic organisms isolated from the fæces may be employed in conjunction with other remedies.

Intestinal antiseptics in bacterial infection. It is now generally admitted that intestinal antiseptics are of no value and there is no drug known which, when administered by the mouth, will reduce the number of living bacteria in the stools. Nevertheless, it is possible that some drugs may check or diminish the growth of bacteria in the upper part of the intestine and thereby lessen the absorption of toxic products. With this idea disinfection of the alimentary canal has been advocated in many diseases such as cholera, typhoid, dysentery, etc.

Normally the lower one-third of the small intestine and the upper part of the large intestine contain the largest number of bacteria, and the number of living bacteria steadily diminishes further down in the colon. Many experiments have been conducted to determine the bactericidal effect of various drugs on the intestinal flora. Rogers (1913) tested the efficacy of certain inorganic and organic compounds of silver, copper and mercury and some other antiseptics on Shiga's bacillus and concluded that silver compounds such as albeigin, gave the best results, mercury and copper compounds being non-effective. Of the other antiseptics, cyllin and izal are effective both in broth and in distilled water and are worthy of further trial. Phenol and the higher coal-tar products have also an antiseptic property, but most of them lose their activity in the presence of faeces and thus fail to exert any influence on the intestinal bacteria. This can be readily understood if we consider the large number of bacteria present in the colon and the large mass of material in the intestine which tend to weaken the antiseptic property of the drugs. Besides many of the so-called intestinal antiseptics produce toxic symptoms in doses necessary to produce any bactericidal effect.

There is another important point to be considered in this connection. The normal defensive power of the healthy mucosa is always brought into action to deal with the bacteria present in the gut. These drugs therefore may on the contrary do harm by injuring the intestinal mucosa. This has been demonstrated by Schutz (1901) who found that after large doses of calomel the cholera vibrio persists in the intestinal canal of dogs for a longer period than when no drug is given.

Although complete intestinal asepsis is not practicable, a relative asepsis is not inconceivable though it has not been demonstrated satisfactorily. The use of antiseptics, at best, is inferior to other methods, such as suitable modifications of diet and evacuation of the bowel. Whenever any drug is used those antiseptics should be preferred which are sparingly soluble in water so that they will not be absorbed from the intestine to any appreciable extent. In order that a drug may be useful as an intestinal antiseptic it must exert

the maximum effect on the colon where the action is desired without its action being hampered in the presence of organic matter. It must at the same time be non-irritant to the gastric and intestinal mucosa and should not be absorbed to an extent sufficient to produce toxic symptoms. The following are some of the drugs commonly used:—

Potassium permanganate. It is an oxidising agent and disinfectant but its action is weakened by the presence of organic matter. As a disinfectant to the intestinal canal it was used by Rogers in cholera. In order to destroy the toxins in cholera the doses recommended are as much as 50 gr. a day. This is given in the form of pills made up with vaseline in doses of 2 gr. every fifteen minutes for two hours, then every half-hour till the stools are coloured green. Large doses of the drug produce toxic symptoms and hence it should always be used with caution.

Kaolin. This compound is the native white aluminium silicate purified by elutriation from sandy matter; another variety of it is known as Fuller's earth. Kaolin and Fuller's earth are adsorbents and as such have the power of absorbing various soluble substances and suspended matters. The drug has been largely used in diarrhoea, dysentery and cholera. It is not a direct disinfectant of the alimentary canal but is believed to adsorb bacterial toxins and affords a mechanical protection for the inflamed mucous membrane.

Salicylic compounds. Of these salol (phenyl salicylate) is largely used as an intestinal antiseptic. It is non-irritant to the stomach and is broken up liberating phenol and salicylic acid. The phenol component is thought to be valuable from the point of view of its effect on the disinfection of the gut, but the decomposition is so slow and the absorption of phenol is so rapid that its usefulness is very limited. When given by the mouth nearly 10 per cent. or more is excreted unchanged in the faeces; when administered in a capsule it may be found in the faeces as crystals, formed by partial fusion and recrystallisation of the drug. It is therefore advisable to give it in the form of an emulsion or with some indifferent powder. The dose is 5 to 20 gr. by the mouth. It has been largely prescribed in typhoid fever, but it is doubtful whether it has any effect on the disease.

Phenol and its derivatives. The substances of this group are highly bactericidal. The higher coal tar products have great germicidal power and they have a much feebler toxic action when given by the mouth as compared with phenol. Some of these compounds such as tetrachlor-phenol, o-cresol, tetra-brom-o-cresol have very high phenol co-efficients, but they lose their disinfectant property in the presence of organic matter and hence are not used therapeutically.

A few benzol derivatives have been used internally. Naphthalene and the less-irritating related compounds are among the most effective. Alpha-naphthol is highly toxic and is not employed; beta-naphthol acts similarly to phenol but is more germicidal. It is given in doses of 3 to 10 gr. and as much as 10 to 15 gr. may be given in a single dose, but it is liable to set up gastric disturbances and upset digestion. Other preparations such as benzo-naphthol and naphthol-bismuth have also been used.

Miscellaneous drugs. Insoluble salts and slightly soluble salts of the heavy metals are also available as indirect intestinal antiseptics. Large doses of bismuth are used in diarrhoea and intestinal disorders. The action of bismuth is partly mechanical by virtue of its power of forming a protective covering on the inflamed mucous membrane and many insoluble salts will do it. A small amount may however be dissolved and exert an astringent and mild antiseptic action. Bismuth carbonate and subnitrate are generally used and may be prescribed either in the form of a powder or suspended with mucilage.

Insoluble salts of mercury especially those which have a cathartic action have also some antiseptic property. Calomel is a cholagogue purgative and is therefore useful in conditions of intestinal putrefaction, *e.g.*, in dysentery, early cases of typhoid. Asiatic cholera has been treated in the early stage with divided doses of calomel. Bile is another substance which has been used as an antiseptic. It is not a direct disinfectant of the gut contents but an indirect one by aiding digestion, and helping absorption of foodstuff. In cases of biliary obstruction with offensive stools, bile is said to be useful. Ox-bile is a dark greenish brown substance somewhat bitter in taste. It is prescribed in doses of 5 to 15 gr.; the antiseptic value is however doubtful.

Charcoal has been used as an intestinal antiseptic. It has the power of adsorbing gases and this has led to its use for flatulence and indigestion. In acute bacterial dysentery, large doses are given, 30 to 45 gm., three times daily, mixed with hot tea. *Carbo animalis* or bone black is preferred for this large dose, because the sharp particles of the vegetable charcoal act as an irritant. It has been experimentally shown that both diphtheria toxin and antitoxin are absorbed by animal charcoal. In general the toxins of the Gram-positive bacteria are said to be more readily absorbed than those of Gram-negative ones. It may therefore be advantageously prescribed in those cases associated with much bacterial fermentation in the intestinal canal.

ENTERIC FEVER

Enteric fever constitutes a group of continued fevers caused by *Bact. typhosum* and a group of closely related organisms amongst which the most important are *Bact. paratyphosum*. A

and *Bact. typhosum* is the causative organism of typhoid fever and the other organisms of paratyphoid fevers; the term enteric fever is commonly employed to include the continued fevers due to these organisms.

The generic name enteric fever is also a convenient name as it is often impossible to distinguish these fevers clinically. Generally infections due to the paratyphoid group of organisms are milder and less fatal than typhoid fever; but recent work has shown that some of the fevers due to the so-called paratyphoid group of organisms are of more serious import than the classical typhoid fever. During recent years considerable data has accumulated concerning the distribution of various types of enteric infection and without entering into the details of the distribution of the different types it may be said that these fevers have a world-wide distribution. The more the attention of workers is directed to the study of these fevers the more it is being realized that a number of organisms, more or less related to one another, are implicated in the causation of these fevers and that they have a much larger area of distribution than was formerly believed.

The enteric group of fevers occur throughout the year in the tropics and during the hot and moist periods of the year they tend to occur in epidemic form. Wherever sanitation is deficient and there is neglect of the proper disposal of faeces, and wherever there is a lack of safeguarding of the water supply, there is a danger of an outbreak. The bacilli may reach the mouth by means of infected fingers or by the intake of infected food and water. Outbreaks have been traced to the eating of raw contaminated oysters, to food contaminated by flies and to the use of contaminated ice.

In every case, however, the infection is from the urine or faeces of a typhoid case, or to carriers who play an important part in the spread of the disease as will be realised when it is remembered that some 2 to 5 per cent. of those who contract the disease become more or less permanent carriers and continue to excrete the organisms for many years.

Typhoid fever, due to *Bact. typhosum*, may be taken as a representative of the group of enteric fevers as a whole. The

paratyphoid infections are milder and will not be considered separately. The basis of therapy is the same in all the enteric fevers.

Bact. typhosum the causative organism of typhoid fever is a motile flagellated bacillus and produces an intracellular toxin. It gives a specific agglutination reaction which is of great value in the diagnosis of a case of typhoid fever. The bacillus does not withstand high temperature, being killed at a temperature of 60°C. It is however resistant to cold and can live for about three months in ice, but in ordinary tap water it usually disappears within two to three days. The duration of life of the bacteria is of great practical importance, though it must be remembered that it varies with the amount of movement of water, the chemical substances present and various other factors, such as the existence of saprophytic organisms. The bacilli have been obtained from the soil. In faeces their duration of life is variable, being dependent on the chemical character of the stool and other bacilli present. In man the infection occurs through swallowing contaminated material. The bacteria pass the acid barrier in the stomach, multiply in the upper part of the small intestine in bile, pass through the lymph follicles with resulting hyperplasia, and in severe cases, ulceration, sloughing and necrosis may occur. The bacilli then gain entrance *via* the lacteals to the posterior abdominal lymph glands any lymph glands of the mesentery which become enlarged. Later, they invade the blood stream with transitory or intermittent primary bacteraemia, and formation of foci in the spleen, liver and bone marrow where they grow. From these foci the bacteria invade the blood again, causing secondary bacteraemia and this occurs in the first week of the disease and later a secondary invasion of the intestines occurs. The bacilli are excreted from the blood into the bile and in the urine in nearly all cases. The duration of the organisms in the blood varies, they can be occasionally cultivated after the first week of illness. In many other sites their occurrence has been observed, e.g., in the rose spots, in the abscesses in the skin, subcutaneous tissues and suppuration in various parts of the body. Their occurrence in the urine is important and it has been observed that in about 25 per cent. of cases the bacilli may be found in the urine but not until the third week and in some patients not until convalescence. The stage of recovery coincides with the period when the patient shows antibodies in the blood. Gradually the various foci of infection, gall bladder, spleen and kidney clear up, but in some cases if a focus is left behind the carrier condition develops and the patient becomes a source of infection to others.

The paratyphoid bacilli are closely related to *Bact. typhosum*. There are several varieties of which A and B are the common types. Though the clinical features of paratyphoid fever are much the same as those of typhoid fever, the essential difference lies in the course

being varied and irregular and the infection, as a rule, is milder with a low mortality. In paratyphoid fevers the intestines frequently show no change, although in some cases they may be acutely inflamed throughout their length.

Carrier. The rôle of the 'carrier' in the spread of infection is important. Some 2 to 5 per cent. of those who have recovered from an attack of enteric fever, continue to pass the specific organism in the excreta sometimes for years. In some individuals the bacilli may be found in the excreta without the patient having, at any period of his life, suffered from the disease. The carriers are a grave danger to the community. They contaminate the food or water supply and spread infection. The main conclusion which emerges from the mass of evidence on record is that the ultimate source of infection would appear in all cases, to be the excreta of an infected human being and this source is seldom remote. These observations and similar ones in different parts of the world go to prove the importance of isolating typhoid convalescents until they are found to be no longer excreting typhoid bacilli in the stools. It is a difficult matter to treat these carriers. The intestinal antiseptics, such as hexamine, usually fail to cure them and similarly vaccine treatment is also uncertain. The removal of the gall bladder has been advocated but this is a serious procedure and very few will submit to such a major surgical interference.

Laboratory diagnosis. The actual isolation and identification of the infecting organism is the best direct evidence of typhoid fever. All immunological methods, such as agglutination test, are strongly corroborative, but should be considered as subsidiary to the isolation of the organism by blood, stool and urine culture. Within the first few days of fever (chances are less after the 5th or 6th day) culture of the blood generally gives positive results. The blood is cultured in ox bile at 37°C. (5 c.cm. blood to 25 c.cm. bile) sub-cultured on solid media and the organism identified by biochemical and agglutination tests; culture can also be done in 10 per cent. glucose broth (10 gm. to 100 c.cm. broth). The stool may give positive results within 3 or 4 days of the onset of the disease but more frequently after the second week. A fresh stool should be examined or it may be preserved in Teague and Churmma's solutions; malachite green, china green, etc., if added to the stool inhibit the growth of other coliform organisms. The stool is emulsified in peptone water and then plated on MacConkey's medium. Isolation of the organisms from urine is possible during the second and third week and is done in the same way as for stools. The agglutination reactions (better known as Widal's test) may be performed by the macroscopic or the microscopic method, but the former is preferable. The principle of the reaction is to mix increasing dilutions of the serum with the bacterial emulsion and examine for agglutination. The agglutinins usually appear during the first week and attain their highest titre from the 10th to 15th

day and then gradually fall. It is necessary to determine the 'O' as well as the 'H' agglutinins. Some typhoid patients develop somatic but not flagellar agglutinins and this may be missed if both are not looked for. 'O' agglutinins may appear early but negative results in the first week are of little importance. It may be noted in this connection that inoculated cases show much higher titre for H than O whereas in un-inoculated cases positive results with 'O' at 1 in 20 to 1 in 50 are more common than with H. To do a complete test according to the present state of our knowledge nine suspensions should be used and these are :

- | | | | | | |
|-----|------------|-------|------------|----|---|
| (1) | Formolised | broth | suspension | of | <i>Bact. typhosum</i> . |
| (2) | " | " | " | | <i>Bact. paratyphosum A</i> |
| (3) | " | " | " | | type phase of <i>Bact. paratyphosum B</i> |
| (4) | " | " | " | | " <i>Bact. paratyphosum C</i> |
| (5) | " | " | " | | " <i>supestifer</i> . |

The above are H suspensions

- | | | | | |
|-----|-------------|------------|----|-----------------------------|
| (6) | Alcoholised | suspension | of | <i>Bact. typhosum</i> . |
| (7) | " | " | " | <i>Bact. paratyphosum A</i> |
| (8) | " | " | " | <i>Bact. paratyphosum B</i> |
| (9) | " | " | " | <i>Bact. paratyphosum C</i> |

These are O suspensions

The ideal test for the enteric group of fevers should include all these, but for routine purposes, the first three, or better still, the first six may be used, repeating the test with the others later, if necessary. Only smooth cultures must be used for preparing the emulsions. The occurrence of a positive Widal reaction after the first week of illness and its maximum about the twenty-first day, is diagnostic. Interpretation of the results is as follows. In the un-inoculated cases of typhoid fever a positive reaction up to a titre of 1 in 100 is highly suggestive, and 1 in 500 is almost a certain indication ; positive reaction may be obtained up to a titre of 1 in 50,000. In case of infection with *paratyphosum B* the results are similar, but agglutination may occur up to a titre of 1 in 500,000. For *paratyphosum A*, positive reaction in 1 in 20 is significant and in 1 in 100 almost certain. It is rare in higher dilutions. In the inoculated cases serial tests should be done ; a four-fold rise in titre in the early stage is not of much value but a ten-fold rise is strongly suggestive. A positive reaction in an 'O' titre of 1 in 100 or higher is of important diagnostic significance and in 'H' titre of 1 in 1000 to 1 in 2000 is also suggestive.

Diarrhoea reaction. The reaction is present from the fourth to the fourteenth day in typhoid. A negative reaction is of more value against the diagnosis than a positive reaction is in favour of it. It is of more import in distinguishing between a relapse and a complication. The

reaction is present in measles but not usually in German measles. It is very constantly present in tuberculosis which is advancing very rapidly. The test is done in the following way. Equal parts of the diazo-reagent and urine are placed in a test tube and covered with a little ammonia. If the liquid becomes deep red in colour at the junction of the two fluids and upon shaking a pink colour be imparted to the foam, it is positive. Any trace of yellow or orange colour denotes a negative reaction.

Prophylaxis. The prophylactic measures in enteric fevers consist in the prevention of dissemination of excreta from patients, convalescent or healthy carriers, so that they do not convey infection into the system of sewage disposal. Secondly, the disposal of infected sewage should be such as not to reach and contaminate the water supply or be accessible to flies. Where the disease is endemic, or during the period of an epidemic, special precautions should be taken to avoid all predisposing factors. Drinking water should always be boiled and special attention is necessary to ensure the purity of milk, butter or other food-stuff that might directly or indirectly be exposed to infection. Typhoid patients should be isolated as early as possible. The excreta must be disinfected, as well as all objects used by the patient, *viz.*, linen, utensils, thermometer, etc. The advent of prophylactic inoculation has greatly reduced the incidence of both typhoid and paratyphoid infections. Statistical evidence of the use of vaccine in epidemic and endemic areas shows that it considerably reduces the susceptibility of the individual to the disease and the case mortality shows a marked decrease after the use of this prophylactic inoculation. The vaccine which is generally known as T.A.B. vaccine, contains 1,000 million of typhoid bacilli, 500 millions each of paratyphoid A and B in each c.cm. Two doses of 0.5 and 1.0 c.cm. are given at an interval of about ten days. For details see vaccine therapy.

General management. Rest in bed, strictly regulated diet and good nursing are the principal points to be aimed at. The patient should be kept in a well ventilated room and confined to bed from the beginning of his illness. Intelligent and careful nursing is essential and all the specific instructions should be clearly written in the form of a chart and the condition recorded as it varies from day to day. The care of the mouth

is a matter of great importance. A combination of borax with glycerine is an efficient means of securing cleanliness of the mouth and gums ; a solution of sodium bicarbonate may be alternated with it to dissolve sticky mucus.

The idea underlying the treatment is to help elimination of the toxins from the body by the principal channels of excretion such as faeces, urine and sweat. With this end in view the treatment should be directed along the following lines :

Hydrotherapy. The use of water is of great importance. It may be utilised for sponging, tepid or cold, and a bath. Whenever the temperature rises above 103.5°F., the patient should be sponged with water at a temperature of about 70°F. About 15 to 20 minutes are necessary to sponge a patient efficiently. If a bath is required it should be given in a tub big enough to keep the patient under water except his head. The temperature of the water in the bath varies between 75 to 85°F., and the patient remains there for 10 to 15 minutes. The bath in most cases brings about distinct improvement in the condition ; it markedly lowers the temperature, brings about an improvement in circulation, lessens the excitability and helps in the elimination of toxins.

Diet. The importance of diet in the treatment of enteric fevers cannot be too strongly stressed. It should be nourishing and liberal in order to maintain the strength of the patient. A good deal of controversy exists over diet. Some give milk with the addition of a little quantity of sugar or cream while others give a much more liberal diet. It is to be understood that there is an increase of about 40 per cent. in the basal metabolism in enteric fevers with marked protein breakdown. This is due to the toxic decomposition of protein of the body and is not due to raised body temperature. Experimentally it has been shown that a large amount of carbohydrates with a moderate quantity of protein helps to maintain the patient in equilibrium ; protein diet alone fails to keep the body metabolism in equilibrium. If too much food is given there is likelihood of development of abdominal pain, discomfort, meteorism, haemorrhage or perforation. On the contrary, too little food will

starve the patient, delay convalescence and often the temperature will remain at a higher level until a larger quantity of food is given. The condition of the patient must be taken into consideration ; in a severe case it is difficult to give even a moderate quantity of milk without producing some discomfort, while a mild case requires more food.

In general, the diet given should have a caloric value of 2,000 to 2,500 calories, chiefly composed of carbohydrate and protein, the latter amounting to about 70 gm. in 24 hours. The proteins prevent excessive loss of weight, the carbohydrates give the necessary heat and energy and also oxidise the fats and thereby prevent acidosis.

The bulk of the food should be liquid, milk or its modifications, such as peptonised milk, malted milk, butter milk or whey are given. If there is diarrhoea and much fermentation in the intestine, the diet should be very simple and consist entirely of whey or glucose. Water may be given freely and as much as 3 to 4 litres of water should be consumed in a day. Barley water, lemonade, soda water are also useful. Glucose and lactose may be advantageously given frequently. An efficient drink can be prepared by the addition of some alkali such as bicarbonate of soda and lactose to water ; it should be given as often as the patient feels thirsty and is an efficient diuretic. See diet in disease, page 166.

Medicinal treatment. There is no specific drug treatment and medicinal treatment is indicated only to control symptoms and give the patient as much relief as possible. The various antiseptic drugs that have been tried intravenously do not seem to alter the course of the disease in any way ; the use of the intestinal antiseptics so as to alter the bacterial flora of the intestine is likewise without effect.

Abdominal pain and distension are often troublesome complications ; these are best treated with fomentations and turpentine stupes. Oil of cinnamon is recommended for the relief of such conditions and good results have followed its use in many cases. For meteorism, the rectal tube may be passed and a turpentine enema may be given. The diet should

at the same time be reduced and food should be liquid ; whey and albumen water should be substituted for milk and given at longer intervals.

Diarrhoea is due either to intestinal fermentation or to irritation caused by ulceration. It is, therefore, unwise to attempt to check diarrhoea so long as pain, distension and flatulence exist. As regards drugs, salol is largely used with a view to deodorizing the stools by inhibiting putrefaction and fermentation. But it is to be noted that intestinal antiseptics such as salol, beta-naphthol, chlorine mixture, etc., do not in any way alter the bacterial flora of the intestine. If the number of stools is very large, bismuth is useful either alone or in combination with Dover's powder. The amount of food should be reduced, and whey and albumen water in small amounts substituted for milk. Constipation occurs in many cases but it is unsafe to use purgative drugs to relieve it. In such cases an ordinary soap-water enema every alternate day or liquid paraffin may be given. For sleeplessness, see page 223.

A very serious strain is put on the heart and weakness of the cardiovascular system is obvious. Whatever be the immediate condition, the possibility of the heart being exhausted must be well recognised. In order to preserve the cardiac muscle from exhaustion, digitalis in the form of tincture should be given at the earliest evidence of myocardial weakness. With signs of failure of the circulation, strychnine (1/32 to 1/8 gr.) hypodermically or 1 c.cm. of camphor in ether or strophanthin (1/240 to 1/60 gr.) intravenously should be tried. See cardiac tonics, page 241.

Hexamine in doses of 10 gr. three times daily is largely used during the third week of enteric fevers. The antiseptic value of the drug especially in bacilluria which occurs between the second and the third week, is well recognised. Attendant complications such as cholecystitis, pyelitis and cystitis are also treated with large doses of hexamine.

The treatment of hæmorrhage requires the greatest care. Hæmorrhage is most likely to occur after the second week and

in the majority of cases a history of persistent diarrhoea may be traced. In hæmorrhage absolute rest is essential and an injection of morphine should be given. An ice-bag should be placed on the abdomen and food withheld for eight to twelve hours and the stools watched for blood. The use of normal horse serum (10 to 20 c.cm.) or hæmoplastin in 2 c.cm. doses is of proven value; calcium chloride 5 to 10 c.cm. of a 10 per cent. solution may be given intravenously; defibrinated blood in doses of 10 to 20 c.cm. given intramuscularly has also been used with success. In serious cases transfusion of blood may be necessary. There is no unanimity of opinion regarding the use of morphine. It is however the usual practice with many to give opiates by the mouth or an injection of morphine in order to give rest to the bowel and thereby check hæmorrhage. If perforation occurs, the only means of saving the life of the patient is by doing immediate laparotomy.

Serum treatment. See serum therapy, page 791.

Specific and non-specific vaccines: Conflicting results have been obtained with subcutaneous and even intravenous injections of typhoid vaccine in the treatment of the disease. The study of the records shows that this method of treatment is of doubtful value. Vaccine given for protection will not check an infection already installed and incubating, and likewise the statistical record of cases treated with vaccines does not show that this has a material advantage over other forms of treatment. Moreover in some cases it has been stated that the use of vaccines may predispose the patient to hæmorrhage. For specific vaccine treatment see vaccine therapy, page 773.

Non-specific vaccines have been tried in enteric fever and are said to have given good results in many cases especially those complicated with bone lesions. The treatment consists in giving intravenously foreign proteins, *e.g.*, *Bact. coli* vaccine in doses of 10 to 20 million organisms per c.cm. A reaction is produced which is characterised by fever, chill and leucocytosis after an injection. In no case should the vaccine used be old and stored for a long time. Whenever possible freshly pre-

pared vaccines should be given a trial as early in the course of the disease as possible.

Bacteriophage. The value of the administration of bacteriophage in the treatment of enteric fevers has not as yet been established. *In vitro* lytic principles may be obtained which have a marked effect on *Bact. typhosum*. It is therefore preferable if possible to obtain phage that will lyse the specific bacteria. The doses are 2 c.cm. every four hours for five or six days. It can be similarly employed as a prophylactic during an epidemic. See also bacteriophage therapy, page 808.

Convalescence. The management of the period of convalescence is very important. The diet should be gradually increased, and it is best to wait for a week or ten days after the temperature is normal before resorting to solids. The patient should be allowed to get up gradually; all strain and over-exertion are to be avoided. Constipation is to be particularly avoided and it is best treated by liquid paraffin and enemas. After an attack of typhoid fever the patient should have, if possible, a period of rest in the country or to some health resort before returning to his ordinary mode of life.

The treatment of typhoid carriers presents innumerable difficulties. In such cases hexamine should be given continually in large doses. Autogenous vaccines offer a good chance of success for the treatment of these carriers; particular care should be taken to dispose of their urine and fæces and they should not be allowed to handle food.

BACILLARY DYSENTERY

Bacillary dysentery occurs over the whole world but is more common in the tropics, and may become epidemic when conditions such as over-crowding and bad sanitation exist. Infected persons and carriers are mainly responsible for its spread. Infection may be direct or through contamination of food and water. Milk is one of the common articles of diet implicated and flies play an important part in the spread of the disease. The incidence of the disease is at its minimum in the cold weather, and increases when the hot weather sets in.

Recent work has shown that bacillary dysentery is far more common than the amœbic form, even in tropical climates.

There are two main types of the disease :—

(a) *Bacillary dysentery due to non-mannite-fermenting bacilli of the Shiga type.* In these cases collapse may be present and pyrexia is usually marked. The stools are very frequent, 16 or more a day, but may vary from none at all, in the acute gangrenous type with paralysis of the gut, to the incessant passage of stools resembling the rice water stools of cholera, but containing flakes of blood-stained mucus. The Shiga bacillus produces both an intracellular and an extracellular toxin, and also produces poisonous pressor bases from animal proteins.

(b) *Bacillary dysentery due to mannite-fermenting bacilli of the Flexner group.* In these cases collapse does not occur as a rule, pyrexia is less marked, and the stools are usually less than 16 a day. The blood and mucus in the stool may not be visible to the naked eye, and many cases present the symptoms of mucous diarrhoea, the stools being faecal-coloured or pale. The so-called 'hill diarrhoea' is usually due to infection with a bacillus of the Flexner group. This group of bacilli produces an intracellular, but no extracellular toxin. They produce indol and ferment carbohydrates but do not ferment lactose.

The cases of bacillary dysentery range in severity from very mild to fulminating choleraic types. The onset is usually sudden with rise in temperature, abdominal pains, tenesmus and diarrhoea with blood and mucus in the stools. In severe cases there are marked symptoms of toxæmia and dehydration. The colon and the lower part of the ileum are inflamed and there may be ulceration. The isolation of the dysentery bacilli is the most reliable method of diagnosis. Stools containing no mucus very rarely yield positive results; these should therefore not be selected for examination. If the material has to be sent any distance an equal quantity of Teague's solution should be added and the material kept in a cool place. It is only in the first seven days of the acute attack that positive bacteriological results are possible. In chronic bacillary dysentery it is difficult to isolate the causative organisms and repeated examination of the stool is necessary.

Agglutinins develop in the blood of dysentery cases usually after seven days from the onset. Positive agglutination in a dilution of 1 in 25 in Shiga infection, and of 1 in 50 or over in Flexner, are highly suggestive of recent infection. Carriers have been detected by their blood agglutinating dysentery bacilli. A cutaneous reaction on the lines of the Schick test for immunity to diphtheria has been described. Cellular exudates and macrophage cells in the stools are helpful in diagnosis. In early acute bacillary dysentery there are numerous desquamated epithelial cells and degenerated polymorphonuclear cells. Columnar epithelial cells are more numerous than in amœbic dysentery.

in which the cells are mainly mononuclear leucocytes with well defined nucleus.

Carriers. Healthy carriers particularly of the Flexner group of organisms do exist. The carriers of Shiga bacilli are usually persons who are ill.

Bacillary dysentery occurs very frequently in children and young adults. It prevailed on all fronts during the War. In many countries bacillary dysentery comes in severe epidemics and is responsible for a high case mortality which may range between 2 to 80 per cent. The Shiga bacillus is much more toxic than the organisms of Flexner group. The Shiga toxins have been shown to act on the central nervous system of rabbits. The high degree of toxicity of Shiga's bacillus has militated against the successful use of vaccines made from it. Anti-toxins have been prepared which given subcutaneously have proved invaluable, and prophylactic vaccination with an active anatoxin prepared from a very toxic strain against bacillary dysentery (Shiga type) has been tried with some degree of success.

Treatment of Acute Bacillary Dysentery

General measures. The first and the most important principle in treatment is to place the patient at absolute rest in bed. The ulcers in the gut will take ten days or so to heal. If the patient is not kept in bed the condition frequently becomes chronic in type, and this is especially the case with mild infections due to the bacillus of Flexner, where the patient only has a mucoid diarrhoea for a few days and neglects proper treatment of the condition.

Warmth is of importance in the treatment of bacillary dysentery, especially where there is tendency to collapse and a hot water bottle applied to the abdomen is often very helpful.

Diet is important, foods leaving coarse residue should not be given. In Shiga infection, thin gruels like barley-water and rice-water should be given and all animal proteins eliminated from the diet, as this measure will materially help in reducing toxæmia. The diet should consist solely of carbohydrates, such as arrowroot, barley-water, glucose feeds, tea or coffee with very little or no milk. These cases do not tolerate milk well as a rule, but when the temperature has come down to normal and the stools are well-formed, milk and finally pro-

teins may be gradually added to the diet. In Flexner bacillus infections, on the other hand, carbohydrates should be eliminated from the diet, and such articles as meat extracts, chicken broth, citrated milk, jellies, weak beef tea, and later eggs, should be given. During convalescence fish and meat may be gradually added to the diet, but carbohydrates should be added last of all. Many of these patients show intolerance to carbohydrates for a long time. In both groups of cases the food should be given slightly warmed, and in small quantities at a time as cold drinks are apt to increase intestinal peristalsis. A return to full diet should be very gradual during convalescence as any dietary indiscretion may lead to relapse.

Medicinal treatment. *Cathartics.* The purgative treatment still maintains its position, the idea being to lessen the absorption of toxins by washing out the bowels. There is no other line of medicinal treatment for bacillary dysentery so satisfactory and so simple as the use of magnesium sulphate and sodium sulphate in small doses repeated frequently. The loss of a day or two in starting the administration of salts will greatly prolong the convalescence of the patient by allowing time for the toxins to produce ulceration before the congestion of the large bowel is relieved. As a preliminary purge a full dose (1 oz.) of the following is given:—Sodium sulphate 2 dr. magnesium sulphate 2 dr., tincture of ginger 5 min. and peppermint water 1 oz. This is followed by 2 dr. doses of the above mixture every hour until free watery stools are passed, when the same dose may be given at six-hourly intervals till the stools are feculant and free from blood and mucus. An initial dose of castor oil with or without a little tincture of opium as indicated may be given in early phases of the disease instead of the initial saline purge.

In severe cases administration of normal saline is advised to prevent dehydration, 300 to 500 c.cm. may be injected intravenously or subcutaneously. A 10 to 25 per cent. solution of glucose intravenously in severe cases supplies nourishment and fluid and 1/100 gr. (0.6 mgm.) of atropine sulphate checks pain and tenesmus. Burkett (1921) used

Turkey rhubarb in half a teaspoonful doses every one to three hours until the drug appeared in the stool ; for children 5 gr. doses were given every 2 or 3 hours. Calomel should not be given.

Adsorbants. Kaolin and charcoal are said to adsorb toxins. Kaolin is given in suspension and as much as 300 gm. may be necessary in the course of a day, stirred up in a pint of hot tea. Charcoal in doses of 80 gm. per day may also be used, animal charcoal being preferred to the vegetable. (See also page 413.)

Bismuth is often very valuable in severe cases, associated with purging ; the carbonate is probably a better preparation to use than the subnitrate, as the latter is apt to contain impurities ; a dose of 1 or 2 dr. may be given suspended in half a tumblerful of water or soda water every 4 to 6 hours until the stools become black.

Lactose. Sugar of milk has been recommended with the idea that it inhibits the growth of dysentery bacilli and favours the growth of acid-forming bacteria. It is given in doses of two dr. 3 or 4 times a day when it acts like a saline purgative. It is particularly useful in chronic dysentery.

The routine use of opium in the treatment of dysentery is to be most strongly condemned. In many cases, however, where the patient is worn out with the constant tenesmus and pain and cannot obtain sleep, $\frac{1}{4}$ gr. of morphia may be given hypodermically at night. The resulting rest and sleep will materially help the patient in his fight against the disease. A good working rule is that if the patient has had no sleep for two nights, and the temperature is falling, $\frac{1}{4}$ gr. of morphia with $\frac{1}{100}$ gr. of atropine may be given.

Bacteriophage. It is in cases of acute bacillary dysentery particularly due to Shiga bacillus that bacteriophage therapy has given good results. In some patients treated with bacteriophage the symptoms disappear in a day or two and the patient becomes convalescent. It is important that bacteriophages possessing a high virulence for the local strains of dysentery bacilli be employed and that it be administered early in the

disease. It must be remembered that bacteriophage attacks the bacilli present in the gut, thus rendering them incapable of causing further damage, but it cannot directly repair the damage already done or neutralise the toxins already formed. It is important, therefore, that along with the administration of bacteriophage other modes of treatment which are calculated to bring about the elimination of toxins and the healing of the ulcers should be employed. For details see bacteriophage therapy, page 808.

Chronic Dysentery

The successful treatment of these cases entirely depends upon making a most careful assessment of the conditions and factors present and in securing the confidence and co-operation of the patient. Persistence and patience are necessary from the patient as well as the doctor.

Milk is a very suitable diet in the early stages, but unfortunately so many of these patients have been kept for long periods entirely on this diet that the sight of milk nauseates them. A diet consisting mainly of proteins such as soups, jellies, eggs and the juice of fresh fruits with later additions of boiled fish, minced chicken, etc. is recommended. The carbohydrates are added last of all to the diet.

A thorough overhaul of the digestive system is made. The teeth are examined for pyorrhoea or absence of molars and any defect corrected. Repeated examinations of the stools must be made until the causative organism is isolated.

In the chronic relapsing type of bacillary dysentery, little advance has been made so far as the drug treatment is concerned. Henry and Brown (1923) found *Mansonia ovata*, *Rhynchosia adenodes*, *Burcis abyssinica* and *B. sumatrana* useful. They all contain tannin. *H. antidysenterica* is also used and probably owes its action to the alkaloids it contains. In persistent extensive ulceration with secondary infection and toxic absorption which do not yield to medicinal treatment surgical treatment may be required. Rest and careful dietary measures are most important. Bowel washes are useful in cases with extensive

ulceration of the lower gut. Rogers recommends 1 to 1½ pints of olbargin solution in strength of 1 in 5,000.

Serum treatment is useless here and vaccines have been extensively tried. Some clinicians are very enthusiastic about vaccine treatment. Where possible, autogenous vaccines should be employed. See vaccine therapy, page 773.

Bacteriophage treatment acts in a most remarkable manner in some cases while it produces no effect in others. It is particularly useful where previous examination in the laboratory has shown that the causative organism is lysable by the bacteriophage. If necessary, bacteriophage can be grown on the causative organism and then administered to the patient.

Bact. pseudo-carolinus Infection

In a large number of cases of subacute and chronic dysentery in the tropics *Bact. pseudocarolinus* can be isolated from the stool. This has been suggested as a phage-mutant form of *Bact. flexner*. Although definite proof of the pathogenicity of this bacillus is lacking, it is probable that its presence in the gut gives rise to a train of symptoms which are not met with in other intestinal infections commonly encountered in Calcutta. The association of the bacillus with chronic infection with *E. histolytica*, hookworm, etc., has been observed. The common symptoms complained of are alternate constipation with diarrhoea with occasional passage of mucus in the stool. Whether the bacillus is responsible for the production of these symptoms, is difficult to say at present. When the stools contain blood and mucus salines improve the condition; any associated conditions should also be treated. Later on a course of 6 injections of autogenous vaccines should be given beginning with 10 million organisms and increasing up to 40 millions or more according to reaction; calcium and parathyroid should be given by the month.

CHRONIC ULCERATIVE COLITIS

Ulcerative colitis was described as early as 1875 though it was at that time indistinguishable from bacillary dysentery. It has now come to be recognised as a distinct clinical entity. It begins as an acute inflammation of the mucous membrane of the colon, leading to patches of localised necrosis, followed by separation of sloughs and superficial ulceration. If the ulcers heal, ragged polypoidal masses of mucous membrane remain which may sometimes lead to fibrosis and stricture.

Many workers consider that ulcerative colitis develops as a result of infection with one of the dysentery group of organisms. Dudgeon (1923) isolated Flexner's bacillus from material obtained from the surface of an ulcer in two cases of ulcerative colitis. Hadfield (1927) isolated it from a swab from such an ulcer. Tholaksen and Cadman (1928) cultivated the bacillus from the material obtained by scraping the base of an ulcer. The claim that the disease is due to the dysentery organisms is, however, discounted by many investigators.

Bargen (1928) isolated a diplococcus from the ulcers which he regarded as the cause of the disease. Although intravenous injections of rabbits with Bargen's diplococcus cause diarrhoea with blood and mucus, the experimental disease does not resemble human ulcerative colitis.

Entamoeba histolytica has also been regarded as a causative agent though this has not been confirmed by laboratory and other evidence.

Patients suffering from ulcerative colitis are often met with in the tropics. In India quite a number of cases occur in which neither *E. histolytica* nor any of the dysentery group of bacilli can be isolated, and the symptoms are very similar to those occurring in this condition.

Treatment. In treatment, certain general principles should be followed. Rest in bed, warmth and a generous mixed diet are essential. Too much restriction in the dietary is injudicious. The main principle in this direction is avoidance of cellulose-bearing fruits and vegetables and the omission from the food of such articles as may give rise to flatulence. In acute cases, liquids of high caloric value are preferable, and the diet is increased with the progress of the case towards recovery. In chronic cases, a high calorie, high vitamin and relatively low residue diet is recommended.

A great variety of drugs has been given by the mouth, main reliance being placed on bismuth salts, tannic acid compounds, kaolin and the opium derivatives. All these medications have a distinct place so far as the relief of symptoms is concerned without having any specific effect on the disease. Large doses of bismuth (a teaspoonful every 2 hours) or kaolin or 'bolus alba,' cause an amelioration of diarrhoea, with relief from the constant distressing urge to go to stool. As a sedative to intestinal hyper-peristalsis, opium is a useful drug (in the form of tincture of opium in small doses); it undoubtedly gives relief when there is excessive fermentation in the intestine. Injections of morphine to relieve this so-called 'gas' pain should

be avoided. Charcoal by absorbing gases from the intestine may relieve the patient of discomfort.

Hurst (1931) strongly advocated the use of antidysenteric serum. Recovery has been seen only in early cases, and in a very large number of cases no definite improvement is noticed and relapses after antidysenteric serum treatment are quite frequent. Bergen (1928) advocated the immunisation of the patient against the causative organism which he considered to be a diplococcus. In chronic cases repeated graduated doses of diplococcus vaccine have been administered subcutaneously. Such treatment is usually given for over a month. Though the treatment may be beneficial in certain cases, success has not been uniform. Many workers have failed to isolate Bergen's diplococcus in a large proportion of cases. Repeated serial bacteriological examination of the stool should be carried out and an autogenous vaccine prepared from any pathogenic organism found.

In a condition that is essentially a local ulcerative lesion of the colon, colonic irrigations with antiseptics and astringents are useful. But in the acute or in the early stages of the disease medicated enemas should be forbidden. Irrigation of the colon when done carefully, promotes drainage, removes products of infection, prevents absorption of toxic material and makes the patient comfortable. For this purpose, innumerable substances in the form of aqueous solution have been used. Silver salts, potassium permanganate, zinc sulphate and iodine, have all been tried. Neutral acriflavine in strength of 1 in 4,000 aqueous or saline solution has given satisfactory results. To begin with, 750 c.cm. of the solution is given twice a day and retained each time from ten to twenty minutes. Later, it may be administered on alternate days using a weak solution of sodium bicarbonate (0.5 per cent.) on the intervening days. The treatment is continued until the temperature is normal, diarrhoea has ceased, and the sigmoidoscopic and proctoscopic examination reveal the disappearance of all ulcerative lesions. Tannic acid (1 to 2 gr. in an ounce) is also a useful drug; after a preliminary lavage with normal saline solution. Tidy (1931) recommends

the following procedure for rectal medications: (1) starch and opium enema, (2) colonic washes, and (3) in later stages medicated enemas. He uses a starch and opium enema (3 oz. of mucilage of starch with 20 to 30 min. of tincture of opium) at the outset; this should be given not more than five times a week and never more than on three consecutive days. The course is continued till there are not more than five stools a day. The colonic wash consists in giving two pints of normal saline every other day and continued until the stools are less than five a day. The medicated enema is used only when the stools number less than five a day; about 20 gr. of albargin in 25 oz. of water is administered. This should not be used for more than three times a week and at least there must be a week's interval between the courses.

The after treatment of the disease requires some consideration. There is always a tendency to relapse and the treatment has often to be continued for long periods. Such associated conditions as oral and pharyngeal infections and anal complications must be treated, as relapse may follow an acute sore throat or development of an anal abscess. Diarrhoea or constipation may give trouble. Looseness of the bowels may continue for some time and may respond to starch and opium enema and colonic washes. Constipation is relieved by liquid paraffin. Surgical treatment has been advised and appendicostomy is said to be useful in some cases but opinions differ as regards its efficacy and its superiority over medical treatment.

The use of diathermy has been advocated, the active cathode being placed in the rectum, the inactive being applied round the waist. The greatest concentration of the current occurs in the rectal and sigmoid regions and the treatment is usually given for twenty minutes at a time. The result of diathermic current is to cause internal heating and improved lymph and blood circulation of the colon. Ionization treatment has also been applied in cases of ulcerative colitis. Treatment is generally given for fifteen minutes and repeated once or twice a week.

COLIFORM INFECTION

At a very early stage *Bacterium coli* appears in the intestine of the infant and throughout life man carries these germs in his colon. In health *Bact. coli* is confined to the large intestine or at any rate does not extend far beyond the ileocaecal valve into the small intestine.

Normally, barriers exist against the escape of organisms into the lymphatics or blood stream and these are:—(1) The intact intestinal epithelium, (2) mucus secretion and (3) the lymphoid tissue found in the intestinal wall and the lymphatic glands which lie in relation to the ileocolic vessels. But conditions which disturb the above protective mechanism and facilitate the escape of bacteria may be set up (1) by disease of the bowel of which chronic intestinal stasis is the most common, or by abdominal operation, and (2) by treatment, of which the most frequent is violent purgation.

Of the intestinal affections, those showing signs of irritation of the mucous membrane, *e.g.*, colitis, chronic diarrhoea, diverticulitis seem more prone to give rise to urinary infection than atonic states of the colon with simple constipation. Intestinal infection, when it is complicated is specially liable to extend to two organs, *i.e.*, the gall bladder setting up infective cholecystitis, and the urinary tract, giving rise to pyelitis and cystitis. Urinary stasis secondary to urinary calculus, strictures, enlarged prostate, gravid uterus, etc., may also be contributory factors. The coliform organisms reach the pelvis of the kidney and the bladder by the urethra as well as by the blood stream. Dudgeon, Wordley and Bawtree (1921) discuss the question of mode of infection with *Bact. coli* in the light of their own findings and those of others, and are inclined to believe that in the male infected with a hæmolytic *Bact. coli* the route of infection is from the intestine into the blood-stream either direct or by the lymphatics. In the female probably the infection is more commonly along the urethra. Of later work on the question that of Vincent (1925) points to the hæmic route of infection. *Bact. coli* may cause a primary pyelitis and cystitis but occasionally the reverse is the case. In the pelvis of the kidney there is a catarrhal inflammation extending on to the papillæ and in some cases foci of suppuration may occur in the kidney substance. The symptom of coliform infection of the urinary tract are pain and frequency of micturition and usually a rise of temperature. Not infrequently there are rigors and the patient is acutely ill. The urine is strongly acid and contains numerous pus cells. *Bact. coli* is easily isolated on culture. In cystitis if a blood culture is made during a rigor *Bact. coli* may be isolated. Cabot and Crabtree (1916) obtained positive blood cultures in 40 per cent. of their 32 cases under these circumstances. Whether such bacilli gained

access to the blood from the intestine or from the bladder lesion is undecided.

Another diseased condition associated with *Bact. coli* is cholecystitis. In such cases *Bact. coli* cannot be cultivated from the blood unless abscesses are present in the internal organs. Possett (1927) from a review of the literature of the action of *Bact. coli* in cholangitis and cholecystitis concluded that infection passes to the liver directly from the intestine and not by the blood-stream. Moynihan (1927) believed that the peritoneal coat of the gall bladder is first infected presumably from *Bact. coli* that have passed from the intestine into the peritoneal cavity. The infection of *Bact. coli* into the healthy bladder or gall bladder does not cause an infection in animals but such a condition ensues if the bile duct or urethra is obstructed. Hurst showed that the colon bacillus can grow in the duodenum and stomach if no hydrochloric acid is secreted and at the same time the movement of the stomach is inhibited. Such a condition always favours retrograde infection. It therefore seems probable that any abnormality which interfered with drainage from the gall bladder and any extraneous focus of infection, e.g., appendix, assist in the production of cholecystitis.

Septicæmia due to *Bact. coli* is very rare, but it may be found when there is a focus of suppuration, e.g., abscess in the liver, or during rigor in cystitis, or in acute infective processes. In new-born children a fatal condition known as Winckl's disease is a hæmorrhagic septicæmia produced by *Bact. coli* (Feltz and Keefer, 1924).

Whether *Bact. coli* or its products can on ingestion cause diarrhoea is still uncertain. In young infants it is very probable that gastro-enteritis may be caused by changes produced in cow's milk by many bacteria, including *Bact. coli*. The intestine of an individual and the strains of *Bact. coli* in it appear to become adapted to each other and, if there is want of such harmony, symptoms are at once produced. It is possible that foreign strains of *Bact. coli* when swallowed may cause gastro-intestinal disturbance. The problem of the causation of diarrhoea in infants and as to how far *Bact. coli* is to be incriminated is far from being settled.

Bact. coli probably does not pass through the healthy bowel into the peritoneal cavity, but when the bowel is damaged by trauma or strangulation such passage occurs giving rise to peritonitis. It is sometimes found as the sole infecting agent in abscesses found in the region of the anus and urethra.

Treatment of urinary infection with coliform organisms. In the acute stage the patient must be kept in bed so as to ensure rest and warmth. Even in the chronic stage it is important to avoid cold and fatigue. As the bowel is the source of nearly all the infections, it must be carefully attended to.

A good initial purgative should be given and then the bowel should be kept open daily with cascara; some advise liquid paraffin and agar along with high colon lavage. Suitable diet is of great importance. Too much milk must not be given, but the patient should take plenty of fluid (6 to 8 pints daily). Diet should be low in total protein content; meat, eggs, and raw milk are excluded entirely, junket, whey, butter-milk and cream being allowed. Rice, bread, honey, butter, porridge, vegetables, fish and chicken are gradually allowed when the acute symptoms have subsided.

Intestinal antiseptics have been recommended but it is doubtful whether they are of any value. A cachet containing salol 10 gr., grey powder $\frac{1}{2}$ gr., with water between meals two or three times daily is said to be useful.

In acute cases with pyrexia, full doses of alkalis are very helpful and should be continued until the urine has been rendered alkaline for 3 or 4 days. A mixture of sodium bicarbonate 30 gr., sodium citrate 30 gr., potassium acetate 30 gr., syrup of orange $\frac{1}{2}$ dr. and water 1 oz., is given four-hourly. As soon as the urine is alkaline the temperature usually falls and the mixture can later be given six-hourly and then three times a day or as required. Hexamine in 10 gr. doses in a glass of water should now be given three times a day before food. After the food a mixture containing acid sodium phosphate 30 gr., tincture of hyoscyamus $\frac{1}{2}$ dr., and chloroform water up to 1 oz. is given. The alkaline and acid treatment should be alternated every 3 days. It is well to change the hexamine for one or other of its derivatives, *e.g.*, cystopurin, helmitol, etc., every now and then. Urotropine may be given intravenously in doses of 2 to 5 c.cm. of a 40 per cent. solution. Acriflavine and mercurochrome have also been used intravenously with beneficial results. Neoarsphenamine in doses of 0.15 to 0.30 gm. intravenously every five or six days has been used with success. Hexyl-resorcinol is another drug that is often used in urinary infections. To obtain satisfactory results, the dose should not be less than 0.45 to 0.6 gm. three times a day, *i.e.* from 3 to 4 capsules after each meal; fluids should be restricted and sodium bicarbonate should not be given

at the same time. This treatment has to be continued for 2 to 3 months. Other drugs, *e.g.*, colloidal silver preparations, methylene blue, pyridium and methenamine, have been tried. Gutzeit (1931) recommended uricedan in doses of one or two teaspoonfuls well diluted two or three times a day. Irrigation of the bladder with antiseptic lotions, *e.g.*, acriflavine, mercurochrome, Condy's lotion, etc. is used in suitable cases.

Lepoutre (1930) reported excellent results with a serum prepared by injecting horses with *Bact. coli* of urinary origin. Non-specific therapy has been tried without effect. Benefit has followed the use of bacteriophage of which a strain must be employed which has a high lytic power towards the invading organism; 2 to 3 c.cm. are injected subcutaneously every other day till 4 doses are given. At the same time 10 to 20 c.cm. are given by mouth, and a like amount injected into the bladder to be retained as long as possible. While this treatment is being given, the urine should be kept alkaline and no antiseptics should be given. Autogenous vaccines are given after the acute symptoms have subsided and the results are on the whole very satisfactory. At the same time the stools should be examined and any pathogenic organism isolated included in the vaccine. Infection of the intestines by protozoa or helminths should receive appropriate treatment.

Many cases of chronic coliform infections of the urine prove very resistant to any form of drug treatment. The introduction of ketogenic diet treatment constitutes an advance. It is based on the observations that the urine of patients suffering from diabetes with ketoneuria and of patients treated with ketogenic diet for epilepsy does not putrefy on standing for several days in a warm room. Presumably the urine contains some substance which prevents the multiplication of micro-organisms. Shohl and Janney (1917) showed that when the reaction becomes acid, with a pH of 5 to 4.6, the growth of *Bact. coli* is inhibited.

The ketogenic diet in the treatment of pyelitis was first introduced by Helmholtz and Clark in 1931. Though they showed that the diet produced some change in the urine which makes it inhibit the growth of bacteria, the precise manner of

its action was not determined. All workers now agree that the change in reaction of the urine is not the only factor causing inhibition of the growth. Ketonic urine inhibits the growth of *Bact. coli* to a much greater extent than normal urine rendered acid to the same degree by the use of acidifying salts. Clark (1932) expressed the opinion that the growth-inhibiting effect is due to the presence of some bactericidal substance excreted. Dick (1932) showed that a ketogenic urine inhibits bacterial growth even when the reaction of urine has a pH of 5.5 or is more alkaline. Fuller (1933) states that bacterial growth in the urine is inhibited chiefly by 1- β -oxybutyric acid, which is excreted after ketogenic diet and that the activity of this substance increases in proportion to the acidity of urine. The clinical application of ketogenic diets in *Bact. coli* infections has been worked out by various workers. The treatment consists of giving diet which will produce ketosis, and if the pH does not fall below 5, ammonium nitrate or chloride is given in doses of 0.5 gm. three times a day. The ketogenic diet contains a preponderance of fats over carbohydrates and proteins. It is usually necessary to use a diet with a ratio of 3 : 1, i.e., F=3 (C+P). If this diet does not produce ketosis then the carbohydrates may be reduced by 5 gm. every three days. Ordinarily a ketogenic diet consists of protein 60 gm., carbohydrate 20 gm., and fat 240 gm. A normal amount of fluid (2 to 3 pints) is taken in the form of water, and it is essential that no other food is taken. The urine should be tested daily for pH value and ketone bodies, and the result of treatment judged by cultures of the urine.

In some cases this diet may fail to maintain this standard of urinary ketosis. It has been suggested that ammonium chloride in daily doses of 125 gr., in addition to other measures, may bring down the pH to 5. Poulton observed that he found a more marked ketosis if more protein was given in the diet, and he advises an alternative method by giving calcium chloride in doses of 7½ gr. daily.

CHOLERA

Cholera is an acute specific gastro-intestinal affection caused by *Vibrio cholerae* discovered by Koch in 1883. The organism

primarily multiplies in the lower portion of the ileum. The symptoms are vomiting, profuse and effortless diarrhoea, muscular cramps, collapse and suppression of urine. The disease may run a course of a few hours to a few days. The clinical course of the disease is divided into a stage of evacuation in which there is great loss of fluid from the body through repeated profuse discharge of rice-water stools and copious vomiting. Following this is the collapse stage, with signs of failure of circulation, an almost imperceptible pulse, hoarse whispering voice, cold clammy skin, subnormal axillary temperature, shrivelled and cyanotic extremities and anuria. Muscular cramps, which usually commence in the first stage, get most severe during this stage. The most dreaded and frequent complication of cholera is continued suppression of urine, death with uræmic symptoms inevitably following if the condition is not relieved within two or three days. Next to suppression of urine, the most frequent and fatal complication is pneumonia which may be difficult to diagnose during life. Suppurative parotitis occurs in about 1 per cent. of cases. In severe cases in asthenic subjects sloughing of the lower half of cornea, bed-sores or gangrene of a limb may ensue. Sudden heart failure may supervene during convalescence, if the patient is allowed to be up and about too soon. Usually a condition known as the stage of reaction may supervene on the algid stage, a febrile condition of greater or less severity may develop. Hyperpyrexia is an occasional though rare occurrence in cholera, the temperature rising to 107°F. These cases are almost invariably fatal. Convalescence is comparatively rapid considering the great severity of the disease.

India is considered to be one of the chief sources of infection of cholera. It is endemic in the delta of the Ganges and the various world-wide epidemics can be traced to that source. Though it is customary to speak of Lower Bengal as the home of cholera, it is by no means certain that other Eastern localities, *viz.*, Bangkok, Canton, Shanghai, etc., have not some claim to similar distinction. Only in such countries as Siam, India, China, the Philippines, Indo-China, where large proportion of the populations still consume water from rivers, shallow wells, tanks, ponds, creeks, does the menace of cholera persist. There is some vague reference to this disease, in ancient Greek litera-

ture. *Susruta* in India, in the 7th century A. D. described a disease with symptoms and signs of typical attacks of cholera. Detailed accounts of this disease in India were published by the Portuguese, Dutch and English physicians during the 15th, 16th, 17th and 18th centuries. It was thought that cholera did not exist in China before the 19th century and its early occurrence is stoutly denied by many investigators. During the pandemic of 1817 the infection invaded China by the land route from India. In 1830 cholera visited Europe for the first time and since then there have been at least five epidemics, *i.e.*, 1848-51, 1851-55, 1865-74, 1884-86 and 1892-95. Great Britain had been involved seriously in four of these epidemics, *i.e.*, in 1832, 1848, 1854-55 and in 1886. The 1870-73 epidemic spared Great Britain, but it crossed the Atlantic and spread in the United States.

During the great pandemic of 1883 Koch at the head of a German commission took up investigation of the disease in Egypt but soon after his arrival in Alexandria the epidemic there came to an end and Koch came on to India. It was in the Medical College Hospital, Calcutta, that after a study of 42 cases of cholera and 28 autopsies Koch in the winter of 1883-84 worked out completely the aetiology of the disease, and in his report at the first conference on cholera held in Berlin in 1884 Koch gave an account of the organism which has been but little altered by the work of the last fifty years. Koch definitely established that the organism now known as *Vibrio cholerae* is the cause of cholera. At first there was considerable opposition to the acceptance of Koch's conclusion and this opposition was strengthened by the finding of vibrios in places where there was no cholera. A considerable controversy on the significance of these vibrios started in 1884 just a year after Koch's discovery of the organism and has been in existence for nearly half a century.

The typical forms of cholera vibrio present a quite characteristic aspect and appearing as Mackie puts it as short definitely curved cylindrical organisms, with round or slightly tapering ends and measuring usually 1.5 to 2 μ in length by 0.3 to 0.4 μ in breadth. Vibrios kept under more or less unsuitable conditions may show marked atypical forms. A variety of shapes may be met with, *e.g.*, straight organisms, thicker and swollen individuals, spherical forms with faintly stained centres, spindle-, club-, and pear-shaped organisms, individuals with irregular swellings, long swollen spirals measuring upto 17 μ and cells which present a completely distorted structure. Recently, a filtrable stage of the cholera vibrio has been claimed. Pasricha, de Monte and Gupta distinguish a G-type small coccal form which are filter-passers and later develop into vibrios. They admit that the aetiological importance of this form is not yet established.

The organisms grow well in alkaline media; the oldest and still the most commonly used of these is a 1 per cent. alkaline solution

of peptone water. When grown in peptone water the organism gives what is known as cholera-red reaction on addition of pure sulphuric acid. Interesting as this reaction is, its practical importance is limited. This reaction is not specific and certain cholera-like vibrios and other micro-organisms also give rise to this reaction. Serological reactions occur and they are important for the identification of vibrios.

The cholera vibrio can also be identified by an agglutination test with a specific anti-cholera serum. Greig (1919) showed that in the early part of the season the vibrios nearly all agglutinated in high dilutions of the serum, but towards the end a few non-agglutinating vibrios were met with. These latter organisms are regarded by some as *para-cholera* vibrios. Tomb and Maitra (1925) have revived the old theory that non-agglutinating vibrios may become pathogenic and produce outbreaks of cholera. Pasricha and his co-workers (1931) in a study of the changes induced in the serological reaction of cholera-like vibrios under the influence of bacteriophage, concluded that there is some bacteriophagic and serological relationship between the true cholera vibrio and the cholera-like vibrios. Although there are many vibrios that have no relationship with the true cholera vibrio, a large percentage of vibrios that are isolated in nature in places where cholera exists, are mutation forms of the true cholera vibrio and undoubtedly play a great part in the aetiology of the disease.

It has not as yet been definitely established whether an exo- or endo-toxin elaborated by the living vibrio is of exclusive importance in the production of the symptom. Kolle and Prigge, however, made a strong case for the endo-toxin theory. Suckling rabbits up to nine days can be infected orally (Metchnikoff) but Sanarelli has shown that there is enough acid in their gastric juice to prevent the passage of vibrios into the intestines.

Apparently healthy persons, usually after contact with cholera cases, may pass vibrios in their stool and thus be a source of infection to others. Dunbar was the first to demonstrate the presence of cholera vibrios in the faeces of apparently healthy persons. Experimentally, Greig has shown that intravenous injection of cholera vibrios may produce infection of the gall bladder in guinea-pigs. In man the vibrios have not been recovered from the blood, but they have been found frequently in the gall bladder which is sometimes inflamed in fatal cases of cholera. Such persons may become cholera carriers but only a small percentage of cases pass vibrios for more than 3 to 4 weeks.

Formerly it was held that the method of transmission was exclusively by water and food supply with a certain consideration of dangers from fomites especially to that connected with clothing soiled by the cholera discharge. Dissemination by human beings is the most important factor in cholera epidemiology. Cholera follows the great routes of human intercourse. In India during the religious gatherings, people are collected together in large numbers and under highly

insanitary conditions; cholera breaks out among them and when they separate and proceed homewards they carry the disease along with them, infecting the people of the places they pass through. Cholera never travels faster than man; but in modern times owing to increased speed of locomotion epidemics advance more rapidly and follow a more erratic course than they did years ago. It always follows the lines of communication by river, road, rail or ship. Although it travels along the trade routes, it never advances far unless along its path there are places where sanitary conditions are such as will help the disease to take root and start afresh.

All the facts in connection with the spread of cholera by land or water can be best explained by cholera carriers. The individual who is excreting vibrios while in apparent health, is far more dangerous than the one who is a well-recognised case of the disease. There are three categories of carriers—the incubatory, convalescent and the healthy, of which the first one is certainly dangerous. The last two do not represent permanent reservoirs of infection as is the case in other infectious diseases. Water supplies or food contaminated by dejecta from cholera patients or carriers are also dangerous. Milk is a splendid culture medium for the cholera vibrio, and many widespread epidemics have been traced to milk infection. The common house-fly and other insects play an important part in the spread mechanically, by settling on articles of food after having been in contact with infected materials.

Laboratory diagnosis. The organisms can be found in the faeces and the vomit early in the disease, and begins to disappear from the fourth to the fourteenth day. In examining a specimen a dried film is prepared and stained by Gram's method, the vibrios can be identified as Gram-negative comma-shaped organisms. The faeces should be cultivated on $\frac{1}{2}$ per cent. bile salt agar medium and the colonies identified by fermentation and agglutination reactions. *V. cholerae* produces acid but no gas from glucose, saccharose, mannite and maltose; many strains are late lactose fermenters. When grown in peptone water the organism gives the cholera-red reaction. The test is done by adding pure sulphuric acid to a peptone water culture. Agglutination of the organisms occurs up to a titre of 1 in 1,000 or more with the specific serum, after the tenth day of the disease. It should be noted in this connection that as a rule satisfactory results may not be expected until 5 to 6 days after the onset of the illness, and that positive results have been recorded with sera from carriers or vaccinated persons.

There are many diseases which may be mistaken for cholera and an attempt should always be made to differentiate them. Severe gastro-intestinal disturbance, occurring commonly in summer, may simulate cholera. In infants summer diarrhoea may cause symptoms resembling those of cholera. Acute

bacillary dysentery, algid malaria, arsenic poisoning, meningitis in children and many other conditions in an endemic area have to be distinguished from cholera. The history often helps, a differential blood count and blood examination should also be done, but the final criterion is the detection of *V. cholerae* in the stools.

Prognosis. The mortality rate varies in different epidemics from 30 to 80 per cent., being the highest at the onset. In certain parts of India, the incidence and mortality of cholera exhibit a marked seasonal variation. It is higher in the first and last quarters of the year, and lower in the second and third quarters. Young children, pregnant women, aged and debilitated people, alcoholics and chronic nephritics do badly. A severe and prolonged collapse stage, uræmic symptoms and hyperpyrexia are unfavourable signs, but with modern treatment these can often be avoided.

Unfavourable signs are great cyanosis and restlessness with complete failure of the pulse at the wrist and especially in the brachial artery. The severity of a case can be estimated from the degree of concentration of the blood; the specific gravity of 1066 and over is of grave prognostic significance.

Prophylaxis. Of all the quarantinable diseases cholera is the one in which prophylactic measures are of great influence in prevention of infection. Theoretically, quarantine should be an efficient protection against the introduction of cholera into a community, but unless they are stringent and thoroughly carried out, quarantine regulations are of little use. Quarantine, inadvertently carried out, may sometimes actually increase the risk of an epidemic, by fostering a false sense of security and thus lead to neglect in the observance of domestic, municipal and personal cleanliness and an uncontaminated water and food supply. Moreover, in consequence of the intimate association of a number of individuals in a quarantine station, the number of carriers is likely to be increased. Cholera in the main is a water-borne disease and attempts should be made to ensure a pure water supply. All drinking water and all water in which dishes and other articles used in the preparation and

serving of food are washed, should be boiled. Water can be also made safe by treating it with potassium permanganate or bleaching powder. Disinfection of wells, ponds, etc., should form a part of every public health programme. Pure water should be cheap and within the reach of the poorest classes. Flies play an important part in the spread of the disease. All food should be protected and measures should be adopted to destroy their breeding place.

Experience in the cholera epidemics has shown that great care should be taken to preserve the general health. Fatigue, chill, excess in alcohol or in dietary should be avoided. It must be remembered that the use of purgatives, especially the saline purgatives, may precipitate an attack of cholera in a carrier or those who are liable to attacks of indigestion.

Tomb used extensively a mixture of essential oils which is made up as follows:—Oil of cloves 5 min., oil of cajuput 5 min., oil of juniper 5 min., aromatic sulphuric acid 15 min. and spirit of ether 30 min. Half to one dr. of this mixture is given in 1 oz. of water as a prophylactic measure. Once the disease has developed this mixture is of little or no value and there is some evidence to show that in excessive doses it causes damage to the kidneys and suppression of urine.

Anticholera inoculation. Vaccines are obtained by suspension in normal saline of the growth of 24-hour old agar cultures and killing the vibrios by heat at 56°C. to which 0.5 per cent. phenol is added as a preservative. In order to ensure full immunisation, a sufficient dose should be given. The usual method is to give two injections, consisting altogether of 12,000 million organisms. It is advantageous to use vaccine which is made from local freshly-isolated smooth strains. For a single injection 8,000 million vibrios is the usual dose employed, but the best recommendation that one can make is to employ the strongest dose that can be tolerated without producing an excessive reaction. While vaccination by single injection is of some value, vaccination by two injections should be the method of choice. Statistics show that the total

mortality is twenty-five times as high in the non-vaccinated as in the vaccinated. Vaccination by the mouth has also been practised according to the principle enunciated by Besredka (1927). The vaccine is made from a thick suspension of organisms killed by heat, carbolic acid or alcohol ; each dose consisting of 10-100 thousand millions of vibrios contained in a pill is given every day on an empty stomach and usually 3 to 5 doses are employed. Russell (1927) made comparative tests of anticholera vaccine and the oral bilivaccine, and he showed that the effects of anticholera inoculation is superior to the three doses of bilivaccine. The immunity only lasts for about six months.

Bacteriophage. The value of cholera bacteriophage as a prophylactic against cholera has been investigated by different workers in India and a more thorough trial should be given before its value can be definitely ascertained. d'Herelle and Malone claim that oral administration of bacteriophage is of value in treatment and that its addition to well water helps to cut short epidemics of cholera. Asheshov introduced a mixture of three types A, B and C and he is of opinion that all three must be present to be effective against cholera vibrios. Mixtures of all three have been tried as a prophylactic measure by adding to the water of wells in amounts of 50 c.cm. in the villages and towns in one district in Bihar, with the result that there was a marked drop in the incidence of cholera. Russell however holds a different view. The supporters of bacteriophage explain failure in immunising people against cholera by phage, by bringing forward the theory of lack or absence of a sufficient number of active types of bacteriophage.

Treatment. The disease being a sudden one the patient is usually seen when he is in a distressed or even in a collapsed condition. It is important to realise that as soon as symptoms suggestive of cholera appear, the patient should lose no time in going to a hospital. Medicines given by mouth at this stage are absolutely useless. The patient should be kept in a horizontal position in a warm bed and the foot of the bed raised. Nursing is important ; a careful recording of the temperature including

rectal temperature, pulse, reporting the number and character of the stools, seeing that the patient avoids chills and gets adequate attention, are essential to the proper conduct of a cholera case. On no account should the patient be allowed to get up to pass his stools but be made to use the bed-pan. In very severe and fulminant cases, the incessant use of the bed-pan exhausts the patient's strength and a better plan is to put a waterproof sheet which can be changed every few hours under the patient and to pack the buttocks with tow or cotton wool. It must always be remembered by the attendant that the stools are highly infectious and rubber gloves should be worn when washing the patient or changing bedding. Sips of water, soda water or *dab* (cocoanut) water are given frequently to allay thirst. Cramps may be relieved by friction and massage of the limbs, or if very severe by a small injection of morphia or even by repeated small inhalations of chloroform. Blankets and hot water bottles help to maintain the body temperature. All food should be withheld during the acute stage of the disease, but the intake of fluids encouraged. The course of the disease is so rapid that the successful treatment of patients suffering from cholera entirely depends upon the careful assessment of the varying phases of the disease and the application of rational methods of treatment. In no other disease is a closer collaboration between the nurse and the doctor necessary to bring about a cure. In cholera two main lines of attack are essential to counteract the effect of the powerful toxins of cholera on the body, to eliminate the toxins formed and to destroy the cholera vibrio and prevent the occurrence of uræmia. It is essential that treatment should be begun as soon as possible, the symptoms be watched carefully and the treatment be modified as the case develops so that the collapse stage and other deadly complications may be avoided. The best palliative method as yet devised for the treatment of cholera is that introduced by Sir Leonard Rogers in Calcutta between the years 1906 and 1915 which most rapidly and satisfactorily replaces the fluids, salts and alkalies lost from the body tissues. The only specific treatment of cholera, which aims at the destruction of the

cholera vibrio is the administration of bacteriophage, which by parasitization of the cholera vibrios destroys them or renders them innocuous. It must be definitely understood that bacteriophage can only attack vibrios, it cannot heal the lesions already developed nor counteract the toxins already formed, so that the use of bacteriophage alone without other measures is not rational. The treatment should therefore be directed along the following lines.

Restoration of fluid and prevention of acidosis. The great loss of fluid from the body is the essential factor to be combated and the specific gravity of the blood is the key to estimating that loss and hence the amount of fluid to be replaced. The profound fall in blood pressure, cyanosis, loss of elasticity of the skin and restlessness are largely due to dehydration. Restoration of fluid in itself revives the patient in a marvellous manner. The amount to be injected varies from three to six pints in an adult male, in accordance with the degree of concentration of the blood, as shown by the specific gravity and its effect on the pulse, which should be quite full and of good tension at the end of the infusion. In children of about six, one pint can usually be injected with safety.

Salines. Rogers found that in mild cases of cholera the loss of fluid was on an average 35 per cent. of the total body fluid ; in severe cases requiring saline injections but recovering, it was 52 per cent. ; and in cases ending fatally in spite of saline injections it was no less than 64 per cent., or nearly two-thirds of the total. The loss of fluid can be rapidly estimated by taking the specific gravity of the blood by means of a series of small bottles containing glycerine and water of every second degree from 1050 to 1070. The normal specific gravity of blood is about 1056 to 1058 and a rise to 1063 indicates the loss of three pints of fluid, 1064 of four pints, and 1065 of five pints. This furnishes a simple guide for the amount of saline to be injected. Isotonic salines were first used in the treatment of cholera as early as 1831-32, but the improvement was of short duration, the death rate being about 84 per cent. Later, clinicians tried it with similar results. The

reason of this is that in severe cases of the disease chlorides may be lost from the blood even in greater proportions than the fluid. This leads to a vicious circle and the fluid injected into the vein runs out through the intestinal mucous membrane denuded of its epithelial lining. This led Rogers to introduce the use of stronger or hypertonic salt solution to replace the great loss of salts and to help the retention of the fluid in the blood vessels. It is held that the chlorides combine with the cholera toxin and are excreted through the kidneys. Injection of gum solutions was recommended by Bayliss in cholera, but a colloid solution such as this helps to retain the toxins in the blood and has therefore been given up.

In cholera there is a marked reduction of the alkalinity of the blood which leads to the development of acute nephritis and uræmia. It was shown by Sallard (1910) that no amount of alkali given by the oral route rendered the blood of uræmic cholera patients alkaline but addition of sodium bicarbonate to saline solution reduced the death rate considerably in cases of post-choleraic uræmia. It was shown by Megaw (1911) that once uræmic symptoms had ensued, it was too late to save the patients by alkaline injections. An estimation of the alkalinity of the blood in cases of cholera showed that in no less than 79 per cent. it was reduced from N/45 to N/100, or even less. In severe cases, dying of post-choleraic uræmia, the alkalinity was reduced to N/100 or less, and once that point was reached it was too late to save the patient by intravenous injection of alkaline solutions. Cases presenting a lower degree of reduction may recover under alkaline treatment. These observations, as regards reduction of salts and alkalinity, and the need for hypertonic and alkaline solutions were confirmed by other workers independently.

The *hypertonic saline* consists of sodium chloride 120 gr., calcium chloride 4 gr. and water 1 pint. The *alkaline solution* contains sodium bicarbonate 160 gr., sodium chloride 90 gr., water 1 pint. The bicarbonate may be sterilised in an autoclave and added to the boiled saline solution.

The following are the chief indications for the use of saline in cholera:—(1) Specific gravity of blood over 1058 ; (2) blood pressure below 70 mm. Hg. ; (3) coldness of the extremities with a feeble pulse at the wrist ; (4) cyanosis, restlessness and cramp.

The intravenous injections of saline should always be controlled by the specific gravity of the blood ; as a guide for the quantity of saline to be injected in each case it may be stated that a specific gravity of 1064 or over requires 3 to 3½ pints of saline ; 1062 to 1064 requires 2 to 3 pints ; 1060 to 1062 requires 1½ to 2 pints ; 1058 to 1060 requires 1 to 1½ pints.

In all cases of collapse, 1 pint of alkaline saline is given intravenously at each injection, together with 2, 3 or more pints of the hypertonic saline in accordance with the concentration of the blood. The early and persistent use of alkalies has practically eliminated death from uræmia in cholera. The temperature of the fluid to be given intravenously should not exceed 80°F. except in very rare cases where the rectal temperature is several degrees below normal when the saline may have to be given at blood heat. In cholera the temperature may be suppressed in the collapse stage but it usually rises above normal during the reactionary stage following collapse and even in cases untreated by saline and may pass into fatal hyperpyrexia, which has to be carefully guarded against after intravenous injection of salines. This may be done by taking the rectal temperature in all cholera cases, and if it is over 100°F. (it may be as high as 108°F. in the collapse stage with cold limbs), the salines should be run in at room temperature in the tropics, with a mean temperature of about 80°F. Antipyretic measures, in the form of hydrotherapy, have to be taken if the temperature rises to 104°F. or over, after intravenous injections of salines. Hyperpyrexia is a grave complication in cases of cholera treated with salines.

The rate of infusion should be carefully controlled and should be about 4 oz. per minute as long as the pulse is not fully restored ; in this way 4 pints can be given in 20 minutes. The cannula should be tied preferably in the median

basilic vein. If the flow is greatly reduced or stopped by strong vasomotor contractions 1 c.cm. of pituitrin can be given. The infusions should be repeated if the specific gravity rises to 1063 or over, and the blood pressure is 80 mm. or less ; cramps, restlessness and cyanosis are clear indications for repeating the intravenous injections of hypertonic salines. If the pulse pressure, as represented by the difference between the systolic and diastolic readings is under 20 mm. the use of further saline is indicated, but an increase of 4 mm. in the pulse pressure is an indication for stopping the infusion. During 1915-19 cases treated in Calcutta with saline, the mortality was 20.8 per cent.

In addition to intravenous saline, Rogers combined hypodermic injections of 1/120 gr. of atropine morning and evening in acute cases of cholera. Rogers' method of treatment has been favourably reported on by all those who have tried it.

Strophanthin 1/250 gr. or pituitrin $\frac{1}{2}$ to 1 c.cm., may be given along with saline and are valuable in sustaining the heart and raising the blood pressure. Adrenalin chloride may be used either alone or along with the saline, but the effect is transitory.

Along with intravenous salines, $\frac{1}{2}$ to 1 pint of the alkaline isotonic saline with glucose should be given per rectum every four hours until 2 pints of urine are passed in 24 hours, and they will often be retained and absorbed with much benefit, especially in milder cases not requiring injection.

Relief of toxæmia. Antiserums. Although on *a priori* reasoning antiserum treatment would be the ideal method of treatment in a condition where there is such marked toxæmia the experiments carried out so far have been inconclusive. No satisfactory antiserum has yet been prepared.

Drugs. Kaolin or aluminium silicate, was first used in the treatment of cholera by Stumpf in 1906. Walker (1921) advised giving half and half suspension of finely pulverised kaolin in water to drink *ad libitum* with the idea that it will absorb the toxins and so lessen their absorption into the circulation. Colic and the tendency to vomit is at once arrested. During the War, dysentery and cholera in the German armies, were treated successfully with kaolin. Kaolin is sometimes combined with charcoal.

The rate of mortality in cholera during an epidemic varies greatly, thus in certain endemic areas in Bengal the mortality varies between 45 and 75 per cent in different seasons of the year. Thus in order to prove the efficacy of any drug it should be given throughout the whole year with alternate cases of control. In this way treatment with opium and morphine combined with mineral acids which was at one time quite prevalent, has been shown by Rogers to be not only useless but positively harmful, the mortality due to uræmia being very high. Opium eaters and smokers do badly when they are attacked with cholera. Rogers suggested treatment with potassium permanganate in form of pills with kaolin powder and vaseline and coated with sandarach varnish or salol with the idea of oxidising toxins. Two-grain pills are given every quarter of an hour for the first few hours, and then every hour till the stools become green and less copious, indicating the presence of oxidised bile. One hundred or more grains have been given without any harm. Rogers also obtained good results by giving permanganates by mouth along with hypertonic salines.

Calomel and camphor in $\frac{1}{2}$ gr. doses with 2 gr. of Bicarbonate of soda can be administered every half an hour till the colour of the evacuation changes to green after which the interval is prolonged with almost the same results.

Many other intestinal antiseptics have been used but with little success, but are still recommended. When given early the disease is said to have been aborted. Tomb (1924) found that the essential oils mixture reduced mortality and was also of prophylactic value. The mixture was given in doses of 1 dr. in $\frac{1}{2}$ oz. of water every half hour until sickness and purging ceased: usually five or six doses were necessary. With this treatment the mortality was reduced to 20.5 per cent., but in collapsed cases the death rate was 72 per cent. against 20 per cent. with hypertonic saline, and 16.6 per cent. with 2 gr. potassium permanganate pills every fifteen minutes (according to Rogers' plan). Essential oils mixture has been found to be irritant to the stomach and produces sudden suppression of urine.

Bacteriophage. See bacteriophage therapy, page 808.

Summary. The position regarding treatment of cholera is that in serious cases the hypertonic and alkaline infusions, combined with permanganate pills and kaolin, or both, orally, has reduced the mortality rate in dangerous forms of cholera to one-third of the former rate. Unfortunately these methods can only be tried in well-equipped hospitals or in the homes of well-to-do people. In villages and other places where only permanganate and kaolin are available, these are the only remedies that can be used; volatile oils may be tried in mild cases. Whenever possible bacteriophage should be given a trial. In preventing infection among the contacts bacteriophage is useful.

Wu Lien-Teh et al (1934) summed up a standard of treatment of cholera in the following lines:—

“(1) *Premonitory diarrhoea.* For this stage bismuth and soda or Tomb's essential oil mixture, or kaolin and calcium permanganate pills may be given. Atropine may be injected. In India, ol. ricini $\frac{1}{4}$ oz. is often prescribed. Opium is not recommended, but 15 min. of it are added to the ol. ricini if the case is not cholera, to be followed by 10 min. of acid hydrochloric dil. in 1 oz. of water every $\frac{1}{4}$ hour for 4 hours.

(2) *Stage of copious evacuation and collapse.* It is at this stage that the patient seeks medical aid, and is therefore most often seen by the doctor.

(a) On admission atropine gr. 1/100 is injected hypodermically.

(b) Take the specific gravity, blood pressure and rectal temperature.

(c) If the blood pressure is not over 70 mm., or the specific gravity is 1063 or more inject intravenously 3 to 6 pints of fluid, according as the specific gravity is 1063-4-5-6. That is to say, if the specific gravity is 1063 inject 3 pints, if 1064 inject 4 pints and so on. In the case of a child or woman the volume of injection is reduced accordingly. The first pint is the alkaline solution, consisting of 90 gr. sodium chloride and 100 gr. sodium bicarb. and the remainder is hypertonic saline solution.

The speed with which the fluid is injected may be fast or slow, namely 4 oz. per minute, i.e., 1 pint in 5 minutes or $\frac{1}{4}$ -1 oz. per minute, i.e., 1 pint in 20 minutes.

If the rectal temperature is normal the temperature of the fluid should be the same. If the former is 100°F. then the latter ought to be 94°F., and if 96°F. then 102°F. In this way the danger of developing hyperpyrexia is avoided.

The infusion must be repeated if the blood pressure falls again to 70 mm. or under, or if the specific gravity of the blood rises to 1063 or

over. Other indications are restlessness, cyanosis, cramps, failing pulse, etc.

The repetition of injection depends on the condition of the patient; some require one pint in 24 hours while others as many as 50 pints. Each time 1 pint of alkaline solution must be injected before the hypertonic.

Calcium permanganate water, 1 to 6 gr. to 1 pint, may be sipped or 2 gr. pills every 15 minutes for the first two hours and every half hour for the rest of the day may be ordered. Kaolin 7 oz. (200 gm.) in 14 oz. (400 c.cm.) may be given in bowlfuls every half hour.

After rallying, the blood pressure will go up to 80 or 100 mm. Normal saline to which glucose is added may be injected *per rectum* at the rate of $\frac{1}{2}$ -1 pint every 2 hours and later every 4 hours until urine is passed freely. For the circulation, 10 min. adrenalin may be injected intravenously together with the saline solution upto 120 min. in 24 hours.

If the urine remains suppressed after 12 to 16 hours and the blood pressure is low, 1 to 3 pints alkaline saline solution may be injected intravenously plus 1 c.cm. pituitrin hypodermically. Fifteen gm. of urea may be given orally with benefit."

FOOD-POISONING

In former years the term food-poisoning was used to include a variety of clinical conditions of diverse ætiology. As a result of the work of Savage and others the term is now restricted to certain acute conditions characterised by gastro-enteritis usually of sudden onset and short duration and attacking a number of persons within a short period of time. Excluding cases in which poison is added to food accidentally or with criminal intent, the vitamin deficiency diseases and the peculiar idiosyncracies of individuals to certain food-stuffs (food sensitization or allergy), three classes of food-poisoning may be distinguished:—(1) That due to poisonous foods, (2) that due to certain chemical poisons, and (3) that due to bacterial infections or toxic bacterial products.

Poisonous foods. In this class may be grouped those substances which are consumed through mistake for wholesome food. Poisonous fungi may be mistaken for edible mushrooms. The tap root of aconite has been substituted for horse radish; children may eat the attractive berries of deadly night shade. Rhubarb leaves are poisonous by reason of their high oxalate content and even nutmeg may produce toxic symptoms. Certain tropical fish give rise to symptoms of acute food

poisoning and apparently sound mussels not infrequently cause illness which has been attributed to a poison, mytilotoxin, apparently generated under unknown conditions. Sprouting potatoes may cause toxic symptoms due probably to the elaboration by the action of micro-organisms of a poison called 'solanin.' The grains of cereals may be attacked by ergot fungus (*Claviceps purpurea*) and cause gangrene of the extremities or nervous lesions. Lathyrism which is caused by a poisonous amine has been described elsewhere.

Chemical poisons. Chemical poisons sometimes find their way into foods accidentally. Epidemics of peripheral neuritis have been caused by the presence of arsenic in beer and also in fruits and vegetables; chronic lead poisoning may arise from the use of soft water. Copper, lead and chromium compounds have been used as agents for colouring food-stuffs. Antimony oxide is used as a cheap substitute for tin oxide in enamelling hardware and outbreaks of poisoning have been caused by partaking of lemonades prepared in jugs of this kind, due to the tartaric acid or citric acid dissolving a considerable amount of antimony. Tinned food may be contaminated by the metal derived from the container, but tin seems to be innocuous; the same probably holds good for aluminium. Various preservatives are added to food-stuffs but they should be either prohibited or their use controlled. Such substances are boric acid, formalin, benzoic and salicylic acids, sulphurous acid and sulphites.

Bacterial Food-poisoning.

The conception of food poisoning has undergone considerable change in recent years. It was formerly believed that food poisoning was due to a series of toxic amines called ptomaines, which appear during the later stage of protein putrefaction, but this theory is now discredited. Ptomaine bodies are relatively non-toxic to laboratory animals except in doses much larger than are likely to be consumed under ordinary conditions. Moreover it has been observed that outbreaks of food-poisoning arise from the consumption of food which is quite normal in naked-eye appearance, while protein putrefaction causes such marked decomposition of the food-stuffs that it is impossible to eat them.

Bacterial food-poisoning is now recognised as a distinct clinical entity with symptoms of acute gastro-enteritis arising as a result of consumption of food infected, in a large number of cases, with an organism of the salmonella group or food containing preformed toxic bacterial products. Our knowledge however is still imperfect and other organisms belonging to different groups as well, or other causes may also be responsible. In infections with these organisms the symptoms appear in from 6 to 24 hours after consumption of the food-stuff but may be delayed for 4 days. The patient becomes ill with severe headache followed by nausea, vomiting, diarrhoea and abdominal pains; some degree of

pyrexia may be present, but as a rule, it is slight and recovery generally follows.

Food-poisoning bacteria. *Salmonella group*. It is not possible at present to demonstrate the cause of every outbreak of food-poisoning, but the organisms of the salmonella group are those most frequently encountered. Morphologically and in general characters these organisms resemble the paratyphoid bacilli. In fact it has been observed that *Bact. paratyphosum* B (not A) may produce symptoms of acute food-poisoning, but this is very rare. They are small non-sporing bacilli, multi-flagellate and actively motile; all of them ferment glucose usually with gas production, but they do not ferment lactose and saccharose, and in this respect are allied to the bacilli of the typhoid and dysentery group. Some twenty or more types have been found which can be differentiated from one another by serological tests. The commonest member of the group responsible for food-poisoning outbreaks is *Bact. enteritidis ærtrycke*; *Bact. enteritidis Gaertner* is considered to be a less common cause of bacterial food-poisoning. Morphologically and culturally the latter resembles *paratyphoid B* and *Bact. ærtrycke*, but can be differentiated by agglutination reactions.

Although the salmonella group of organisms is regarded as an important factor in the causation of food-poisoning, many outbreaks have occurred where no organism belonging to this group could be isolated. Savage (1920) reported that out of 112 outbreaks in the British Isles, bacilli of the salmonella group were isolated in 39 outbreaks, and in subsequent observations the same worker could not find these organisms in the majority of cases. Many reasons have been advanced to explain this failure. It has been stated that certain outbreaks are due not to infections with the living organisms but to ingestion of toxins elaborated by the bacilli in the meat. These toxins are thermostabile and therefore withstand heating. Savage and White (1925) gave agar plate cultures of *Bact. ærtrycke* either alive or killed by heat at 60°C., to young rabbits orally which produced congestion of the stomach with petechial hæmorrhages; similar results were produced by *Bact. enteritidis*. Several workers have found that culture of the organisms of the paratyphoid enteritidis group are toxic to laboratory animals after some day's growth especially after parenteral injection.

The available evidence at present indicates that outbreak of poisoning following consumption of contaminated food is an infection and not an intoxication, because of the fact that poisoning follows consumption of made-up dishes where cooking has been inadequate; moreover the amount of toxin that would be necessary to cause fatal symptoms is considerable when given by the oral route. Jordon (quoted by Topley) is of opinion that in human outbreaks toxins are of little importance, because (1) well-cooked food is less liable to cause poisoning than raw or imperfectly cooked food; (2) outbreaks are generally due to sausages, meat pies, puddings and jellies which are not, as a

rule, sufficiently cooked to destroy all the bacteria; (3) ordinary roasting or boiling often fails to sterilize meat; (4) persons eating properly cooked meat often escape, while those partaking of raw or partially cooked meat are often attacked; (5) the blood serum of the patient often contains agglutinins some days after the attack, which are not likely to be formed against toxic substances alone. The reason why the bacilli cannot be recovered on bacteriological examination in many cases is due to the fact that the original food causing the outbreak is more often not examined for the causative organism. Moreover it may be mentioned that many outbreaks of food poisoning are not of this nature, but are of entirely different ætiology.

Other organisms. Various other micro-organisms besides the bacilli of the salmonella group have also been held responsible for food-poisoning outbreak. *Bact. morgani* has been found in a large number of cases of summer diarrhoea. Dysentery bacilli are occasionally the cause of acute food-poisoning outbreaks, which may sometimes be indistinguishable from outbreaks caused by the salmonella group. Dysentery bacilli of the Sonne type have been incriminated. Evidence at present suggests that it is conveyed by some carrier of the bacilli, and the symptoms begin with vomiting, passage of blood and mucus in the stools. Streptococci have been incriminated, *Bact. cloacæ*, a coliform organism, met with in sewage has caused outbreaks in some places; similarly *Proteus vulgaris*, *Ps. pyocyaneus*, the commonly distributed putrefactive organisms, are said to have been responsible for food-poisoning.

Toxic bacterial products. It has already been stated that the consensus of opinion regarding food-poisoning is that the primary cause is a bacterial infection and not an intoxication. Excluding botulism which forms a distinct clinical entity and is caused by the preformed toxins of *Cl. botulinus*, certain cases of food-poisoning have been attributed to the formation of toxic products in the food by the activity of the micro-organism. In contra-distinction to infection with the organisms of the salmonella group, the symptoms of poisoning arise within a few hours of the ingestion of the food, especially canned foods. In support of the intoxication theory Arnold (1929) stated that puppies kept in a hot room and fed on meat culture in which *Bact. enteritidis* had been growing for 24 hours, and which had subsequently been boiled for one hour, suffered from vomiting and diarrhoea. He is inclined to believe that the toxicity of meat culture is increased by heating as a result of the hydrolysis of the metabolic products in the meat. Though this still lacks confirmation it may serve at present to explain the causation of toxic symptoms after feeding with infected meat which has been cooked before consumption and in which no organism has been found subsequently.

Considerable attention has lately been directed towards a form of food-poisoning caused by the toxins of staphylococcus. A number of outbreaks due to this has been recorded, the symptoms appear in two

to three hours and consist of nausea, salivation, abdominal pain, vomiting, extreme prostration and profuse diarrhoea. *Staphylococcus* forming yellow pigments have been identified in these cases; poisoning symptoms are said to be caused by entero-toxin produced by this organism. Filtrate of *staphylococcus* culture has been found to contain several toxic substances, such as hæmolysin leukocidin; dermatoxin, lethal toxin, and entero-toxin producing food-poisoning symptoms. Ordinary laboratory animals are not affected by the *staphylococcus* toxin; in man also certain conditions are necessary for the production by the *staphylococci* of toxins in sufficient amount to prove harmful. In addition all strains of *staphylococci* do not produce entero-toxin of food poisoning, and that is why *staphylococcus* food-poisoning is not so frequent.

Mode of infection. Meat is perhaps the most common article through which food-poisoning occurs. This is contaminated either in the process of cooking or during storage. In this respect veal, pork and beef are the chief offenders, mutton being less liable to be contaminated. Tinned meat and tinned fish are frequent causes of food-poisoning. They may be contaminated before tinning by improper preservation or insufficient cooking, even if wholesome at the time the tins are opened, they are liable to bacterial contamination later on. Fresh meat is also responsible in some cases; but it is generally found that it has been previously stuffed, recooked or otherwise treated. In some cases the food has been allowed to stand for a time before consumption. Numerous epidemics of food-poisoning have also been due to eating shell fish such as mussels, oysters, lobsters, crabs, etc. Vegetables and fruits may likewise be contaminated, and milk which is a common article of diet, has on several occasions been the cause of an outbreak. It is important to remember that the food generally appears to be quite normal in appearance. The bacilli in the food-stuffs may also be unevenly distributed so that different preparations from the same meat may vary in infectivity. This is a frequent observation with regard to canned foods, and is due to the fact that the original contamination may be localised, or through defective process of sterilisation some cases may fail to be raised to the requisite temperature to kill the bacilli.

The manner in which these food-stuffs are contaminated is not definitely known. An infected animal may be the source or it may be due to the flesh of a healthy animal being contaminated during the process of preparation. It is not known how frequently animals harbour *salmonella* bacilli. *Bact. ærtrycke*, *Bact. enteritidis* and *paratyphoid bacilli* have been recovered from many sick animals. Mayer (1918) found that in 48 food-poisoning outbreaks due to *Bact. enteritidis*, meat was derived in 23 instances from animals known to be ill before slaughter. In 77 outbreaks caused by organisms of the *salmonella* group, 10 were due to food derived from sick animals. On the other

hand, sources of contamination during the course of preparation are many. *Salmonella* bacilli are occasionally present in the intestines of pigs and cattle and the meat may be soiled during slaughter. The possibility of existence of a human carrier should not be lost sight of; Fletcher was able to isolate *Bact. ærtrycke* from the fæces of patients convalescing from dysentery or enteric fever. Rats and mice suffer from infections with *salmonella* bacilli and fly infection has also been suggested. Large gaps at present exist in our knowledge of the mode of infection.

Laboratory diagnosis. The diagnosis of food-poisoning is made primarily from the clinical symptoms. To confirm it a bacteriological examination of the following materials should be done, (in the case of negative bacteriological findings, tests for detection of chemical poisons should be carried out)—(1) actual food consumed, (2) vomit, fæces of patients and blood for agglutination, (3) fæces and blood of suspected carriers, (4) blood, spleen, liver intestine in fatal cases.

Examination of fæces and vomit frequently gives positive results in *salmonella* infection. The contaminated food should be examined for the presence of the bacilli of the *salmonella* group by cultural methods, or it may be suspended in saline and injected into mice; the results are not always reliable. Canned foods are examined on similar lines.

Micro-organisms are not found in the blood stream except in fatal cases. At the earliest possible moment agglutination tests should be done with the patients' sera, and repeated at least twice at intervals of 7 to 10 days in order to detect any rise in titre.

Prophylaxis. The hygienic precautions to prevent food-poisoning primarily concern Public Health workers. A thorough systematic inspection of meat in all slaughter houses is essential. It may be stated briefly that cleanliness in the production and handling of food-stuffs is an efficient safeguard against many of the infections carried by food, particularly the bacterial ones. The diminution of human contact and handling in the preparation of preserved foods, greatly reduce the occurrence of food-poisoning as the pathogenic organisms occasionally gain access to the food through the agency of human beings harbouring the bacilli. In respect of certain diseases conveyed by food such as tuberculosis and helminthic infections from meat, naked eye examination may sometimes be helpful to detect the unhealthy stuff. This is not however useful in cases of bacterial infections of the *salmonella* group where the food-stuffs apparently look normal in appearance unless of course

the food is decomposed. Methods adopted in the prevention of infection may be roughly stated as follows:—

Cooking. Cooking of meat and all other food-stuffs is a considerable safeguard against infection and if adequate, would destroy all infections. It must, however, be remembered that in some cases the temperature in the interior of the meat during the process of cooking may not rise sufficiently high to completely sterilise the food. This is especially true of canned foods which may contain living organisms even after heating to above the boiling point for an hour or more, and several workers have shown that 70 per cent. of canned foods are not sterile.

Pasteurisation. Adequate pasteurisation seems to be a complete protection against infections present in milk. For effective pasteurisation much depends on the adequacy of the process. The temperature preferred is about 143°F. maintained for half an hour, if the temperature falls below that, the process will not be efficient. After pasteurisation or boiling, milk should be rapidly cooled as it has been shown that enormous increase of bacteria occurs during the process of slow cooling in the preparation of ice-cream after preliminary heating.

Refrigeration. The function of the refrigerator is to retard the growth of bacteria and moulds which find their way on to the surface of meat, fish and other food-stuffs. Cold storage undoubtedly tends to diminish the occurrence of food-poisoning, and this is especially the case with such foods as sausages and potted meats. It should, however, be understood that if meat has already been heavily infected refrigeration cannot prevent its rapid decay.

Preserved foods. Canned foods are very often not completely sterilised, in some cases bacterial contamination may occur after the tin is opened and hence it is always advisable to consume the entire content the day it is opened. The formation of toxic products in canned foods depends in some measure on the length of time that has elapsed between preparation and consumption. 'Blown' tins should always be rejected.

Treatment. For curative treatment, measures should be directed towards complete evacuation of the bowel. Rest in

bed is essential. In the early stages, whenever possible, the stomach should be emptied with some emetic or washed out with normal saline solution. A dose of half to an ounce of castor oil to evacuate the bowels is very helpful. No food is generally necessary for the first 24 hours except small quantities of boiled water; later peptonised or citrated milk diluted with an equal quantity of water may be given. The diet should be gradually increased as the symptoms improve. If there is persistent diarrhoea bismuth salicylate with some astringent may be prescribed. Abdominal pain and distension should be treated with turpentine stupes; tincture of opium may be given in form of a mixture. Colonic irrigations with normal saline have also been advocated in cases of persistent diarrhoea. In cases of choleric symptoms and marked collapse, subcutaneous or intravenous injections of normal or hypertonic saline should be given; rectal injection of 1 oz. of glucose in $\frac{1}{2}$ to 1 pint of saline is also of value. Stimulants are frequently indicated in the collapsed stage.

BOTULISM

Botulism is a comparatively rare form of food-poisoning which is due to the toxins elaborated by an anaerobic spore-bearing organism the *Clostridium botulinum*. It is therefore an intoxication and not an infection. The disease was first described by Justinus Kerner in 1820 and the causative organism was isolated and described by Van Ermengen in 1896 from cases which occurred in a certain village in Belgium and where it was confined to those who had partaken of a certain piece of raw ham. During the last few years epidemics of botulism have been reported from America, particularly from California; in Great Britain at the Loch Maree outbreak almost every case proved fatal.

The causative organism *Cl. botulinum* multiplies in the food and produces a toxin before it is consumed, which on ingestion, is absorbed by the gastric mucosa and upper part of the intestine. The fatal dose of the toxin for man has been calculated to be as small as 1/100 mgm. or even less. There are two types of this organism, type A and B; type A produces the most virulent toxin, which affects the nervous system. Three different strains of the organism are known, the Boise (type A),

the Nevin (type B) and the Memphis (type A). Most strains are killed by heat, but the Boise strain can withstand boiling for one hour and hence it is necessary to sterilize food products under super-heated steam. Meyer isolated seventeen different strains from the outbreak of food-poisoning in America. The spores of the organisms of different strains had various resisting power to boiling, some withstanding a temperature of 100°C. for 4 hours while others were killed after boiling for ten minutes or so. A temperature of slightly less than 80°C. destroys the toxin of most of the strains, some toxin however may be so virulent that 0.0001 c.cm. of the filtrate of a culture grown at 35°C. is lethal to a guinea-pig weighing 350 gm. The Boise strains grow most luxuriantly at about the body temperature.

Mode of infection. Nearly all the reported outbreaks were caused by food that had been smoked, pickled or canned and allowed to stand for some time before consumption; it does not follow consumption of fresh food. Investigation into the problem of mode of infection shows that the organism is a normal inhabitant of the surface layer of the soil from where it may gain access to vegetables, fruits, hay, silage and other cultivated products. Occasionally the faeces of animals such as pigs, cattle, horses may contain the bacilli but a healthy human carrier has rarely been encountered.

For botulism to occur the organism must multiply and form toxin in the food before consumption. Though the organism may be present in abundance in soil its occurrence in food-stuffs is uncommon. There are a large number of factors concerned in the survival, germination, and production of toxin by *Cl. botulinum*. The important factors are (1) the presence of spores in large numbers, (2) insufficient heating, (3) anaerobic conditions, (4) too slow cooking, (5) use of food without final cooking. Hence botulism is practically unknown in India.

Botulism differs from the ordinary forms of food-poisoning in that the gastro-intestinal symptoms are absent or insignificant, there is no pain, temperature, pulse and respiration are not affected until near the end. As the symptoms are produced by the toxins, the patient is taken ill within 24 to 72 hours after eating some contaminated food. Onset of dizziness and headache with diplopia are often the first signs of involvement of the nervous system. Later, other nerves are involved with great weakness of the extremities, obstinate constipation, thirst and pharyngeal paralysis.

Diagnosis. The symptoms of botulism are so characteristic that a diagnosis can be made on clinical grounds. The organisms can be isolated from the suspected food or the patients' faeces and vomit. The filtrate of the culture of the organism produces death in mice on intraperitoneal injection.

Treatment. The prognosis is always grave in the disease, and treatment proves effective only in mild cases. The patient

should be in bed and the stomach washed out. Antitoxin has been prepared by injection of rabbits, horses and goats with each type of toxin. Experimentally it has been found that 30,000 neutralizing doses given 24 hours after injection of toxin protects a guinea-pig. In man however the result of antitoxin treatment is not satisfactory. It may be effective only in mild cases. A polyvalent botulinus antitoxin should be given in doses of 50 to 100 c.cm. intramuscularly or in severe cases 50 c.cm. intravenously; 10 c.cm. should be given prophylactically to all those who have partaken of the food. High enema of soap and olive oil has been advocated with the idea that it neutralizes the toxin. Iodine and potassium permanganate have also been used for the same purpose. Certain other substances have been advocated which are said to delay the action of toxin. Morphine is such a drug, and similarly ether anæsthesia has been advocated with the idea that it will delay fixation of toxins by the tissues.

Diseases Conveyed by Food

Besides food-poisoning arising principally from a bacterial infection several diseases are conveyed by food contaminated by bacteria, worms and protozoa. Asiatic cholera though conveyed principally by infected water may also be transmitted by milk, butter and raw vegetables. Enteric fevers are generally conveyed by contamination of water supply, but may also be contracted through the consumption of certain kinds of fish such as oysters, milk, ice cream, butter, cheese, bread and other food-stuffs. Scarlet fever is another disease which may arise from consumption of infected milk and occasionally diphtheria may be contracted in the same manner.

Many other diseases are contracted from an animal source. Tuberculosis of the bovine type in children is generally conveyed by milk and occasionally from tuberculous meat. Undulant fever arises exclusively from goat's milk. Sometimes outbreaks of dysentery and sore throat have been traced to the consumption of contaminated milk. Anthrax is not an uncommon disease among men who handle carcasses of infected animals. Infected meat and foods prepared from meat are common sources of food-poisoning due to salmonella infections, which have been already discussed.

Certain protozoal diseases are said to be transmitted through the agency of food-stuffs; amoebic dysentery may be transmitted by raw vegetables and balantidial dysentery and giardia infections may also arise in the like manner. On the other hand, diseases caused by

worms are transmitted by food alone. Thus *Tænia solium* is derived from eating pork, *Tænia saginata* from eating beef. *Dibothriocephalus latus* may arise from the consumption of certain fresh water fish and the hydatid disease in man is caused by food or water containing the eggs of *Tænia echinococcus*.

A question of great importance in this connection is the source of infection of the food-stuff. It is generally admitted that man alone suffers from cholera, enteric fevers, bacillary dysentery and in these cases infection arises from faecal contamination of the food-stuffs. The infection may either be direct or indirect through contamination of the water supply by an acute or healthy carrier. In tuberculosis, undulant fevers, sore throat, the contamination of milk or meat arises from an animal source. In scarlet fever and diphtheria infection almost always arises from a human carrier.

SPRUE

Sprue also known as diarrhoea alba is a condition frequently met with in the tropics. It occurs in the European and Anglo-Indian residents of India but rarely among the Indians. The disease occurs in Indo-China and in the Southern United States. It occurs chiefly in the debilitated individuals who have resided for long periods in humid tropical climates.

In India it often follows attacks of hill diarrhoea in which watery stools are passed in the early morning. Hill diarrhoea occurs in many hill stations in the Himalayas during the rainy season and resembles sprue in many respects. In both of these conditions physiological derangement of the digestive functions occurs.

A knowledge about the views held regarding the nature of the disease will be useful from the point of view of the rationale of treatment of sprue. In spite of the considerable amount of work which has been done there is no agreement regarding the causation of this disease. There are two schools of thought regarding the causation of the disease.

Certain workers attribute the disease to some diet deficiencies including calcium metabolism. The total and diffusable calcium in the blood has been shown to be considerably lower in sprue than in healthy individuals. Scott formulated the hypothesis that sprue is due to deficiency of calcium metabolism. He noted the resemblance between some of the symptoms of sprue and those diseases in which calcium deficiency is a prominent feature. Vine is of opinion that calcium occurs in the blood in two states, the combined and the ionic form and it is the latter which accounts for the characteristic symptoms of sprue. As a support of this hypothesis it has been shown that the amount of free calcium rises from 6 to 10 mgm. per 100 c.cm. of serum after administration of calcium lactate over a long period. Some believe that sprue

is a deficiency disease caused by the absence of certain vitamins in the diet. MacCarrison was able to produce a sprue-like condition in monkeys fed upon a vitamin free diet. Elder (1925) thought that deficiency in the aminoacids of meat, in addition to fat soluble vitamin A and also vitamin B occurring as result of unbalanced diet in the tropics was the main factor.

Others think that the disease is of an infective nature, and is produced by yeast fungi, streptococci and some other unknown organisms. *Monilla psilosis* a specific yeast has been incriminated. Ashford (1924) produced a rapidly fatal septicæmia in guinea-pigs and white rats by intraperitoneal injections of this organism. Rogers (1918) believe streptococci to be an important factor in the pathogenicity of sprue. They could always be grown from ulcers in the tongue and vaccines from them produce reactions. Manson-Bahr is inclined to believe that there is considerable amount of evidence to show that sprue and amoebic dysentery are closely associated. In some cases the two diseases may exist together or sprue may develop secondarily in a case of amoebic dysentery the former being merely a syndrome of a primary amoebic ulceration of the intestine.

The modern conception of the disease is that sprue is essentially a disorder of the gastrointestinal tract characterised by deficient gastric secretion, of both hydrochloric acid and bone-marrow-stimulating substance, as well as mal-absorption of fats, glucose and calcium. The cause of the gastrointestinal derangement is still unknown, though it has been suggested that it may be due, either to some defective internal secretion or some as yet unknown infective agency.

Treatment. In the treatment of sprue utmost care lies in procuring bodily rest and selecting a very careful dietary for the patient. It is to be understood that sprue is a disease in which the gastro-intestinal tract bears the greatest brunt of attack. Hence if the treatment of the case is begun early in the disease by careful regulation of the diet, very successful results are obtained, while if it is undertaken too late in the period when the absorbing surface of the intestine is damaged the results are discouraging. The treatment must be thorough and persistent. In the advent of the slightest sign of relapse absolute care should be taken, extra food must be discontinued immediately and the patient should be placed on absolute rest and strict milk diet. It should be remembered that most of the patients recover under prolonged and careful dieting and rest in bed. Some cases may run a variable course and prove rapidly fatal. In the chronic cases the treatment has to be

prolonged for several years, there being temporary improvement after relapses.

Dietetic treatment. Rest in bed combined with a purely milk diet gradually increased from three to six pints daily is the backbone of successful treatment in many cases. Some authorities give bananas with the milk but exclude starches and sugars. Others prefer skimmed milk or butter-milk. Fruits such as lemons, oranges, pomegranates, bananas, pineapple, mangoes, etc., are gradually allowed after a week or two. The milk diet should be continued for several weeks till the stools are solid and the patient gains steadily in weight, after some loss for the first week or two. Then eggs, and rusks are given, carbohydrates being increased very gradually. Later, fish and chicken may be given. If the patient is averse to taking pure milk add Benger's food to it. Some clinicians give meat diet alone. For this purpose meat free from fat is minced and gradually increased till one pound is taken daily. Abundant drinks of warm water should be given in between the meals.

It is now being widely recognised that sprue is a disease of the gastro-intestinal tract. Rest to the alimentary canal is therefore the primary idea of dietetic treatment of the disease. As this is the ideal to be aimed at, minimal amounts of food should be given so that the intestine can deal with it. Fat is therefore restricted in the diet, if this is not done additional strain falls on the already overtaxed alimentary canal. Dietetic indiscretion especially an excess of carbohydrates may cause acute enteritis, because the starchy foodstuff undergoes abnormal fermentation with the production of organic acids and gas and consequent abdominal distension. Under these circumstances rational therapy lies in giving proteins as the principal constituent of diet, beginning with one of low caloric value and gradually increasing the quantity. Fairley (1930) thought that this can be attained by giving high protein diet with low fat and carbohydrates. In place of high meat protein, he advises high protein milk powder with a ratio of protein 1.0, fat 0.3 and carbohydrate 1.3. Later (1932) he advocated the use of a dried high protein milk powder (Sprulac) with ratios

of protein: fat: carbohydrate=1: 0.3: 1.3. The scheme of dietary is to give this powder in gradually increasing doses along with full doses of liver (*i.e.* equivalent to $1\frac{1}{2}$ lb. of fresh liver daily) whenever anæmia is present and suitable dietetic modifications. The first diet consists of 1 oz. of sprulac made up to 8 oz. with water every $2\frac{1}{2}$ hours for six feeds; the second one of $1\frac{1}{2}$ oz. made up to 12 oz. every $2\frac{1}{2}$ hours for six feeds; the third, fourth and fifth one of 2 oz. of sprulac made up to 16 oz. with water every two hours for six feeds.

Liver therapy. In addition to the usual dietary treatment, the routine use of liver extract has been much advocated. Various workers have used the whole liver in cases of sprue and have published accounts of clinical cures with the treatment. It has also been suggested that sprue is a disease, due, in some instances to a deficiency of some fraction of the water-soluble vitamin complex, and this is supplied by liver therapy. Though the exact part played by liver in the cure of sprue is not yet settled, its effectiveness is however well known. In order to get the maximum effect liver should be given in as large amounts as required, and by such a route as to ensure maximum utilization. Massive doses of liver preparation when given intramuscularly or intravenously give the best results. Cases that are resistant to oral therapy sometimes show dramatic and complete remissions after parenteral administration. It thus appears that a well-defined threshold requirement for liver preparations exists in certain cases, and to obtain the maximum effect this threshold requirement must be increased. Various preparations have been used, but it is advisable to use a simple unconcentrated product, because certain loss of activity results from too great refinement and concentration which explains the failures met with in these cases.

Liver soup. Liver soup made from fresh calf's liver has earned a considerable reputation. Manson-Bahr advocates its use along with dietetic measures. It may be prepared by adding half a pound of fresh liver in a pint of boiling water and then straining, 10 to 15 oz. may be given in 24 hours and this is regarded as being more easily tolerated than any other form of dietary.

Liver extract. Other liver preparations have also been used, a powdered extract is given in doses of two tubes daily, each tube being equivalent to $\frac{1}{4}$ lb. of fresh liver. Where speed is essential or where liver by the mouth is not desirable hepatex may be tried. It is given in doses of 5 c. cm. per day injected intramuscularly or intravenously for about two weeks or according to the condition of the patient; a total of 30 to 50 c. cm. brings about improvement.

The usefulness of liver therapy is more apparent because of the existence of anaemia. Minot and Murphy (1927) showed that liver was useful in pernicious anaemia as well as in sprue. In the chronic cases the blood picture in sprue resembles that occurring in pernicious anaemia with high haemoglobin index, anisocytosis and the presence of normoblasts and megaloblasts. Castle and his associates showed that in pernicious anaemia some derangement of function occurs which points to deficiency of the haemopoietic function of bone marrow. In the later stages of sprue such changes have been observed; the bone marrow may show hyperplasia or actual aplasia indicating deficient blood production. Though the definite relation between sprue and pernicious anaemia has not been established, the effect of liver therapy in both cases gives some clue to the aetiological factors of the disease.

In addition to the dietary measures 5 to 10 gr. of pancreatic extract or large doses of pancreatin and calcium carbonate or lactate three times a day sometimes produces rapid improvement. Pancreatin in 10 gr. doses after each meal with fifteen min. of 0.2 per cent. of hydrochloric acid before food is the method adopted in some places.

Drug treatment. Drugs should be given with great caution as they are liable to do more harm than good. Bismuth salicylate in 20 gr. doses about two hours after meals checks intestinal fermentation and looseness of the bowels. When diarrhoea occurs 10 gr. of Dover's powder is useful. Parathyroid $1/10$ gr. and calcium lactate 15 gr. thrice daily were recommended by Scott (1932). These are continued for 5 to 6 weeks, the patient is kept on milk diet for three weeks and later given pudding, eggs, fish, carrots and bananas. The calcium and parathyroid treatment if it is to be successful should be started in the acute stage of the disease and persisted in for several months during convalescence. It was at one time considered to have a distinct influence on the course and symptoms of the illness but it is doubtful whether the effects are at all lasting.

Treatment with Batavia powder earned a reputation at one time. This is chemically a carbonate of lime, believed to be powdered cuttle-fish bone or crab's eyes. It has been found to be of great value in elderly people when the diarrhoea persists in spite of all rigid dieting; doses recommended are 15 gr. in cachets, three times daily. For treatment of anaemia, besides intensive liver therapy injections of iron and arsenic may also be found useful.

Vaccines. There are many authorities who are inclined to believe that the disease is of an infective nature and is produced by yeast fungi, streptococci and some other unknown organisms. *Monilia psilosis*, a specific organism has been thought to be the cause of the infection, as it was found in the tongue and in the mucous lining of the intestine. On the results of these findings cases of sprue have been treated with vaccines made from this organism. The injections are given at weekly intervals and five or six such injections are necessary. Rogers believed streptococci to be the important factor in the pathogenicity of sprue and he obtained good results with streptococcal vaccines and his results were confirmed by Nicholls. Small doses such as 0.5 to 1 c.cm. containing 25 to 50 million organisms should be commenced and given once or twice a week.

HILL DIARRHOEA

Hill diarrhoea is a form of flatulent dyspepsia with passage of frothy stools. This condition, as has already been stated, is in many respects indistinguishable from sprue. Hill diarrhoea occurs very frequently in India, especially among the European population frequenting the hills.

With regard to the exact nature of the disease little is known. It seems probable that hill diarrhoea is more than an intestinal catarrh. It was at one time supposed that the food and water supply was responsible for the occurrence of the disease, but the theory of mica contaminated water as the causative agent can no longer be substantiated. It has been definitely proved that in an epidemic area no trace of mica or other solid particles can be found on centrifuging the water collected during the rainy season when the incidence of the disease is at its height.

Many authorities do not consider it to be a separate disease from sprue; hill diarrhoea being only an earlier manifestation of the latter condition. It has been found that the stools of the patients in nearly all cases contain excess of fatty acids, soap and undigested food particles. They are pale, frothy and devoid of biliary colouring matter. Occasionally cases are met with where the symptoms persist and develop ultimately the clinical picture of sprue.

The influence of climate in precipitating an attack of diarrhoea in the hills in an epidemic form, has been recognised. In India it has been shown that a sudden change of temperature is very liable to bring on an attack of this nature in the hills. It has therefore been held that the disease is due to sudden changes in the physical environment encountered before the individual has time to become acclimatised to the conditions prevailing. In the Philippines it was observed that a sudden drop in temperature within a short time after the heat of summer for about 2 months, brought on the condition in an epidemic form. There is no doubt about the fact that in such peculiar and trying condition physiological derangement of the digestive function occurs. This view receives strong support from the fact that immediate cessation of symptoms occurs if the patient is removed to the plains from the hills. Certain predisposing factors, such as, a constitutional weakness of the digestive function, lowered resistance due to long residence in the tropics, rapid changes in temperature in a moist atmosphere with low barometric pressure also play some part in precipitating an attack.

In addition to the prevalent views regarding the ætiology, the question of infection by a specific organism should not be lost sight of. Acton (unpublished) while carrying on investigations on sprue, treated many cases of hill diarrhoea. On bacteriological examination of the stool he could isolate organisms of the dysentery group in many cases. Vaccine therapy with regulation of diet apparently improved their condition. Recently, the subject has been studied in the School of Tropical Medicine, Calcutta. In the majority of cases dysentery organisms, mostly of the Flexner type, were found on examination of stools; a few cases were due to infection with *E. histolytica*. Though these infections may be present in the plains, the peculiar habits of the people in the hills together with other local conditions, are responsible for the development of the condition.

Treatment. The general line of treatment of hill diarrhoea follows that of sprue. Rest in bed with strict milk diet should be the main principle of treatment. Among the drugs recommended are drachm doses of solution of mercuric chloride in water, fifteen minutes after food. Pepsin and pancreatin may also be given after food to help digestion. Many cases have improved from a course of vaccine; prepared from the organisms isolated

from the stool. The cases which are resistant to treatment should return to the plains.

CHAPTER IV

OTHER BACTERIAL DISEASES

CEREBROSPINAL FEVER

This is an acute specific fever, of world-wide distribution, caused by *Neisseria meningitidis*, occurring both in epidemic and sporadic forms and is characterised by a low morbidity and high case mortality. Infection is spread by 'droplets' from man to man, manifesting itself by septicæmia and an acute form of meningitis involving almost the whole of the cerebro-spinal axis. The disease is most commonly met with in young children up to the fifteenth year and is uncommon over thirty-five years of age. The highest incidence and mortality have been recorded among infants under one year of age. Certain factors favour the spread of the disease and these are climatic influences (particularly winter and spring), fatigue, dirty habits and occupations, over-crowding, bad ventilation and other factors which lower the body resistance. All these predisposing factors are prevalent among the people inhabiting tropical climates.

The causative organism. The Gram-negative intracellular diplococci now known as *N. meningitidis* were isolated by Weichselbaum in 1887 from the cerebrospinal fluid of patients suffering from cerebrospinal fever. This organism is an extremely delicate one and requires special media and special care to keep it alive outside the body. It produces a powerful endotoxin. Formerly the meningococci were divided into four types but some of the recent workers recognise two main groups with subsidiary sub-groups. The exact determination of the type of meningococci prevalent in an epidemic has a most important bearing on the therapeutic use of anti-meningococcal serum. It has been shown that a serum prepared against one group of meningococci is valueless against infection with meningococci belonging to another group. Evidence on this point has accumulated during recent years. Thus a serum prepared with strains prevalent in one country has failed entirely in the treatment of the disease in another country. This is an important factor in the production of an effective therapeutic serum and it is highly desirable that serum prepared from local strains should be employed. The one great practical difficulty in the latter procedure is that it takes a

relatively long period extending to nearly a year to produce a potent antiserum and all that is possible in the face of an epidemic is to use a serum prepared from the known prevalent strains of meningococci.

Mode of infection. The meningococcus gains access to the nasopharynx when it may occasionally set up a rhinopharyngitis. From here it spreads to the meninges. There are two main theories as to the route by which the meningococcus reaches the meninges ; the first is the hæmatogenous route, and the second by a process of direct transmission from the nose to the meninges. Without entering into discussion of the evidence in favour of the two routes, we may summarise the modern and generally accepted view as to the route of infection. The meningococci reach the upper nasal passages through air infection and set up a rhinopharyngitis which in the majority of cases lasts for a few hours or a few days and clears up completely. In a few instances the meningococci may reach the meninges. Recent evidence favours the hæmatogenous route of infection because of the fact that in some cases lesions in other parts such as, endocarditis, renal abscesses, lesions in the joints, etc., occur, but usually late in the disease. These are generally held to be secondary to meningitis though they rank with it as metastasis. It seems probable that transmission of the infection may occur directly or via the blood stream. In support of the latter route of infection it may be stated that in some 25 per cent. of cases the organism can be recovered from the blood in early stages of the disease.

Prophylaxis. The disease is endemic in most of the large cities ; few sporadic cases of post-basic meningitis occur at intervals. The normal carrier rate of meningococcus has been estimated to be as high as 2 to 4 per cent. of the population of some of the large European towns. The carrier rate of meningococci has not been determined for the cities in India, but such investigation is urgently required and will prove of great interest and value. In urban areas there are usually no carriers and the disease is not endemic. For reasons that are not at present definitely established the disease breaks out periodically in epidemic form. The evidence that has been recorded so far shows that a remarkable change occurs in the carrier rate of the general population in the event of an epidemic. From the normal rate of about 2 per cent. the number of carriers increases reaching a figure of about 20 per cent. at the onset of the epidemic and 80 to 90 per cent. during the height of an epidemic. From these figures one is led irresistably to the conclusion that the majority of those developing the disease have not acquired the infection from previous cases but from contact with so-

called healthy carriers. The carrier is in fact the commonest cause of the spread of the disease. The term 'carrier' includes persons with an infected nasopharynx, either one who has not developed meningitis or one who having recovered from the disease itself harbours the organism in his nasopharynx; the former is sometimes called the primary carrier and the latter referred to as the secondary carrier. The great majority of carriers remain infective for about two months, some 15 per cent. of them may continue to harbour the organism for about six months and a small proportion of 2 to 4 per cent. may carry the organisms for as long as a year. Every carrier is potentially infectious and a source of danger.

In the prophylaxis of infection with meningococcus when the main source of contagion is by 'droplet infection' sprayed from a carrier, the essential step in preventing an outbreak or limiting its extension is to reduce overcrowding to ensure adequate ventilation and to encourage the people to lead an open air life. In outbreaks limited to institutions such as schools, etc., a search for the carriers should be made and they should be isolated; but the detection and isolation of carriers in a large community is neither practicable nor possible.

Various methods of local treatment consisting of local application of antimeningococcus serum, antiseptic gargles and nasal douches have been advised from time to time, but when tested with bacteriological control all have proved valueless. They however have a great value both in the education of the public and the removal of gross lesions. For routine use the following is recommended.

Iodine increases the flow of saliva which is inhibitory to the growth of the organisms and acts as an antiseptic and disinfectant drug before and after absorption into the system. This is taken advantage of in the prophylactic treatment. Equal parts of tincture of iodine and honey are mixed and 2 or 3 drops of this mixture are put on the tongue of the isolated carriers several times a day.

Treatment. General management. The patient should be isolated in a well ventilated room until recovery and until the swab from the nasopharynx shows no meningococci. The skin

is sponged with tepid water twice a day. The bowels are kept open by an initial purgative and then by enemata. The bladder should always be watched to see if there is retention of urine and if so a catheter should be used. The position of the patient is frequently changed to avoid hypostatic congestion of the lungs.

Diet. A diet consisting of milk, peptonised or citrated if necessary (2 gr. of sodium citrate in 1 oz. of milk), cocoa, etc., should be given in the early stages; later bread and milk, and as the patient approaches recovery, a liberal diet consisting of fish, chicken, etc., may be allowed. Administration of fluids in all forms—as plain water, glucose or alkaline water (consisting of glucose 2 oz., sodium bicarbonate 4 dr., water one pint), should be freely encouraged from the very onset of the disease, to combat toxæmia. If the patient is unconscious, nasal feeding with citrated milk, small feeds but at frequent intervals (3 oz. every two hours), should be given. If vomiting is present, lime whey, albumin water or peptonised milk may be given and these are often retained by the patient.

Local treatment. Along with general and systemic treatment, local treatment of the nasopharynx should be carried out as reinfection by organisms from these foci may lead to relapses. Such measures as spraying, douching and gargling with antiseptic lotions should be adopted. Spraying with permanganate solution (1 in 1,000), steam spray with zinc sulphate (1 to 2 per cent. solution) or 1 per cent. chloramine solution directly applied to such regions are beneficial.

Specific therapy. The main reliance in the treatment of cerebro-spinal fever is now placed on anti-meningococcus serum together with repeated withdrawal of the cerebro-spinal fluid.

Lumbar puncture. Before the introduction of anti-meningococcus serum the practice of repeated lumbar punctures was considered to be the best method of treatment. This procedure, if performed early and regularly, relieves pressure in the subarachnoid space and thereby lessens the injurious effects on the nerve centres, particularly those in the medulla. In the initial stage the fluid may be under considerable pressure. Characteristic changes in the cerebro-spinal fluid may be noticed on withdrawing it, which are of great significance. In some

cases the fluid may be straw-coloured and coagulate into a solid mass, due to escape of blood plasma into the cerebro-spinal fluid; yellow colouration of the fluid may be the result of admixture with pus. The cellular content of the fluid gives an indication of the progress of the case towards recovery. The cell count may vary between 700 to 30,000 per c.mm. with a predominant polymorphonuclear leucocytosis. Globulin is always in excess. The chloride content, which is normally about 0.73 per cent., is not altered. Stained specimens of the centrifugalised deposit should be examined in every case. The presence of meningococci can be demonstrated in a large percentage of cases. It has been found that during the early part of an epidemic of cerebro-spinal fever, diplococci are found to be scanty and extra-cellular forms may predominate. Cerebro-spinal fluid may be withdrawn under local anaesthesia though general anaesthesia may be necessary in some cases. Ker (1929) advised performing successive lumbar punctures with the patient lying alternately on the right side and on the left side, thus facilitating drainage from the ventricle which is uppermost. This is especially important when the fluid from a patient does not show any pus.

Cisterna puncture. Cisterna puncture is of considerable importance in diagnosis and treatment. It is indicated in cases where adhesions in the spinal theca have prevented the withdrawal of fluid by lumbar puncture.

Recently, irrigation of the spinal canal with normal saline at body temperature has been advocated in order to remove the pus and the meningococci and help in the circulation of the anti-meningococcal serum inside the spinal theca. About 30 to 40 c.cm. of the cerebro-spinal fluid is withdrawn by lumbar puncture, and an equal quantity of normal saline at about 100°F. is introduced into the spinal canal. The fluid is redrawn and the process is repeated till the fluid which comes out is clear. As much as 200 c.cm. of the normal saline is used in such a procedure.

Antimeningococcal serum. Jochmann (1906) was the first to introduce antimeningococcus serum in the treatment of cerebrospinal fever and prepared it by injecting horses first with dead and then with living cultures. In the treatment of human cases he gave it in doses of 20 c.cm. subcutaneously or intrathecally. It is however to Flexner (1907) that we owe our present knowledge of serum treatment of cerebrospinal meningitis. He prepared the serum by subcutaneous injection into horses at weekly intervals, of living organisms and autolysates alternately. This serum was standardised by titrating it according to the complement fixation test, and against the autolysate.

in guinea-pigs. From the time of Flexner until now many methods have been developed in the mode of preparation of an antimeningococcal serum so as to obtain the maximum therapeutic effect. A more rapid procedure than that adopted by Flexner has yielded a polyvalent serum of high titre. Numerous strains of different types are included in the preparation. Griffith prepared a monovalent serum using strains of only one type for each horse. It is however important to remember that in the preparation of an immune serum those strains of organisms should be used which are prevalent during an epidemic. Favourable results are also reported from the use of an antimeningococcal serum in which the antibodies have been concentrated by precipitation and dialysis.

The serum is said to produce its beneficial effects by neutralizing the toxin and by directly acting on the organisms, the multiplication of which is inhibited and the organisms rendered more susceptible to phagocytosis. It should be administered by the intrathecal, intravenous and intramuscular routes. Intrathecal and intravenous routes are the usual methods adopted in the acute stage. Before introducing the serum intrathecally, it is most essential that repeated lumbar punctures and efficient saline irrigation of the spinal cord be performed to remove the pus, organisms, etc., which will prepare a field for the reception of the curative serum. The general rule regarding the quantity of the cerebro-spinal fluid to be withdrawn from the spinal canal is that the amount of serum introduced should be half the volume of the fluid withdrawn. On an average, about 40 to 60 c.cm. of the cerebro-spinal fluid is withdrawn by a lumbar puncture and the spinal canal is repeatedly irrigated with normal sterile salt solution at 37°C., till the fluid returns clear. The serum, warmed to body heat, is then injected slowly, the dosage being on an average 30 c.cm. The foot-end of the bed is kept raised for at least two hours after the administration of serum, to facilitate gravitation of the serum towards the brain.

As the disease is essentially septicæmic in nature in the acute stage, about 10 c.cm. of the serum is also given intravenously along with the intrathecal administration for the first

few days to combat toxæmia. If the cerebro-spinal fluid shows abnormal naked-eye features, and the pressure is considerably increased, a much larger quantity of serum may be given intravenously. The whole procedure is generally repeated within eight hours in acute fulminating cases, then given twice daily till the fourth or the fifth day and once daily for the next five days. The intravenous administration of the serum is repeated only during the septicæmic stage and is discontinued when symptoms abate.

The amount of serum to be given to infants should be carefully considered. In children under five years of age, it is inadvisable to give more than 10 c.cm. at a time. In very young children more than a single intravenous injection is not possible and further doses of serum should be given by the intramuscular route.

The results of serum treatment depend upon three factors, namely, (1) the mode of preparation, (2) the method of titration, and (3) the amount injected. The general agreement with regard to the efficacy of antimeningococcal serum is that with a good monovalent serum (especially type 1) the mortality is considerably reduced, the relapses are less and the complications are fewer in number. The earlier it is administered the better is the result and the combined intrathecal and intravenous methods give a lower rate of mortality than the intrathecal method alone. The great drawback of serum therapy is that it is sometimes impossible to obtain a potent antiserum, this is due to the fact that sera used for some time after the start of an epidemic have been prepared from strains which differ considerably from those actually prevalent during the epidemic. If the proper type of sera is available success is marked. Nevertheless, serum treatment is a very efficacious remedy for what is otherwise a very deadly disease, and to withhold serum in any case is inadvisable.

Vaccines. In some cases even in spite of intensive treatment with lumbar puncture and anti-meningococcal serum, the results may be disappointing. Lewkowicz (1924) mentioned the use of meningococcal vaccine in the treatment of this disease but said that the antibodies did not appear in sufficient

quantity in the ventricular fluid to be of real use. Egerton (1932) considers that vaccines are useful in the acute stage of illness. Gayid (1933) is of opinion that usefulness of vaccine is more apparent in the sub-acute and chronic cases. From an observation of more than 200 cases he considers that meningococcal vaccine should have its place in the treatment of cerebrospinal fever. It is indicated in sub-acute and chronic cases, in inflammatory complications, *e.g.*, arthritis and pleurisy, and in cases which are not influenced by the usual treatment. In the acute cases it may be tried when the disease becomes worse in spite of ordinary treatment. It should be realised that in the fulminating and hyperacute cases the vaccine has no effect in the first stage of the illness, and the best method of treating these cases is undoubtedly repeated lumbar punctures and administration of serum intrathecally and intravenously with glucose solution.

The vaccine should be injected hypodermically; the dose for adults in acute cases is 5 millions, in sub-acute cases 10 millions, and in chronic cases 20 millions. The injections are to be repeated every third day, simultaneously doubling the dose. When the amount reaches 600 millions it is advisable to repeat this amount every five to seven days until recovery rather than to increase the dose any more. Six to twelve injections generally constitute a course.

Medicinal treatment. No specific drugs are known to cure the disease and they are only used to relieve symptoms. As in other acute diseases, constipation often troubles the patient and to combat it calomel followed by a saline purge the following morning is a very useful procedure. In very obstinate cases it is necessary to give an enema. For the relief of headache an ice bag should be applied. Antipyretic drugs such as phenacetin with caffeine citrate may be given and repeated if necessary. Counter-irritants in the form of liquor iodii or liquor epispasticus, when applied over the cervical spine, often relieve headache. Hydrotherapy in the form of a tub-bath at 98° F. may also be tried. Vomiting often sets in during the acute stage and interferes with the nutrition of the patient. To allay it a combination of morphine with hydrocyanic acid may be

beneficial, but repeated lumbar puncture is the most efficient measure to prevent vomiting. Sometimes, in intractable cases it is advisable to omit all feeds and keep the patient on glucose and saline injections for 24 to 48 hours. Adequate rest is most essential in the acute stage of the disease and this can only be secured by promoting sleep. In this respect morphine (gr. $\frac{1}{4}$) has been found to be very useful, especially in cases where it is accompanied by delirium and restlessness. But in uncomplicated cases, sulphonal may be tried. Paraldehyde is not effective, as it can seldom quieten a delirious patient in the acute stage; hyoscine should be avoided. Bromides in combination with chloral hydrate have also been used with encouraging results. For cardiac failure digitalin (gr. $\frac{1}{100}$) hypodermically should be administered but not strychnine, as this may precipitate convulsions.

Besides the treatment of emergency conditions in the disease, adrenalin plays an important rôle in the treatment of cerebrospinal fever especially in the fulminating types. The secretion of the active adrenal cells is said to be interfered with in this disease and the sudden withdrawal from the circulation of this important hormone may lead to loss of tone of the muscle fibres of the blood vessels and failure of the peripheral circulation. Such a condition is best avoided by treating all cases from the beginning with injections of adrenalin along with general treatment.

Various other drugs have also been tried in the treatment of the disease. Temperature is said to have been brought down by intravenous injections of tartar emetic (1.5 c.cm. of a 2 per cent. solution) in many cases. Salvarsan, neosalvarsan, intramine, hexamine, helmitol, acriflavine or trypaflavine (1 per cent. solution) have been tried both by the intravenous and intrathecal routes but without any definite therapeutic benefit.

Complications may set in during the active stage or the convalescing period of the disease. If cardiac failure with great fall in blood pressure is apprehended, saline infusion at body temperature should be at once resorted to, with other cardiac tonics, namely, injections of digitalin (gr. $\frac{1}{100}$), camphor in ether (1 c.cm.) or cardiazol (1 c.cm.), etc. Irritation due to an

intense urticarial rash may be relieved by bathing in a warm alkaline solution or by the local application of one per cent. menthol solution.

For synovitis and the severe form of oedema, pituitrin ($\frac{1}{2}$ to 1 c.cm.) may be injected hypodermically and repeated if necessary. Pneumonia if it develops is treated on usual lines. Joint affections are treated by rest, simple immobilisation of the part, warm applications, etc. If the joint is markedly distended, preliminary aseptic aspiration and later injection of the specific serum (5 to 10 c.cm.) into the joint have been advocated.

For pyelitis and cystitis intravenous injections of hexamine (2.5 c.cm. of a 40 per cent. solution) and lavage of the bladder with two per cent. sodium bicarbonate solution or by simple sterile normal saline often prove useful. Autogenous vaccine, after culture of a catheter specimen of urine, has also been tried with encouraging results. Both flaccid and spastic paralysis have been met with in convalescing cases and these are treated by massage, passive movements and electricity.

PLAGUE

Plague is an acute, specific, infectious disease of short duration with a high mortality. It is one of the greatest scourges of the human race. The disease is caused by *Past. pestis* and is primarily epizootic among rats, ground-squirrels, marmots, etc. At the present time plague is unevenly distributed throughout the world and is endemic in countries such as India and South Africa. The maintenance of infection in these areas depends on the infection of the rodents. Periodically epidemics of plague break out among these animals and man is infected from them as a rule through the agency of the fleas. In this way small isolated groups of cases occur every year. If the endemic foci remain secluded plague is confined to that area but when communication is set up with the surrounding country, the disease assumes an epidemic character. Infection does not occur by direct

contact with the sick, it spreads from place to place thus establishing various foci of plague infected areas. In some cases the disease may be confined to particular buildings, such as warehouses, grain stores, etc. The rats and rat fleas may be carried from one place to another by means of railways, ships or other modes of communication and in this way a secondary focus of plague develops from the primary site of the disease which may serve in its turn as the centre from which infection may spread to the surrounding localities. Plague is always confined to dirty and insanitary quarters and attacks mostly the lowest class of people living under unhygienic conditions. Extreme heat and dryness of the atmosphere are unfavourable for its spread. In India it occurs when the mean temperature is between 50°F. and 85°F. with a high relative humidity.

Bubonic plague. The terms bubonic plague, septicæmic plague and primary and secondary pneumonic plague are in common use but these nomenclatures do not seem to be satisfactory. It is often found that bubonic plague is accompanied by septicæmia; inflammatory enlargements of the deep lymphatic glands may be found in septicæmic plague. This is due to the fact that plague is essentially a septicæmic disease and towards the end of an attack of every form of plague the bacilli are present in enormous numbers in the blood. Crowell recognises only a primary bubonic and a primary pneumonic plague and classifies the bubonic group into (1) uncomplicated cases, (2) bubonic plague with early septicæmia or without superficial buboes, (3) bubonic plague with secondary pneumonia, (4) bubonic plague with secondary meningitis and (5) bubonic plague with secondary cutaneous lesions. The degree of involvement of the lymphatic glands and the invasion of the blood stream are dependent on the resistance offered by the tissues of the patient to the bacilli. These morbid processes have no relation to the virulence of the infecting strain as freshly isolated human strains have been found to possess a uniformly high virulence. The usual mode of infection in bubonic plague is through the skin by the bite of the infected flea but direct infection may also occur. A local reaction at the site of infection is rarely met with. The tonsils sometimes may be the site of entry of the bacilli.

The lesion of bubonic plague consists of a primary bubo at one of the usual sites—inguinal, axillary or cervical and with it may be associated a bubo affecting the nearest proximal group of glands. Secondary buboes appear as a result of infection of other glands by the blood stream. The widespread hæmorrhages and degenerative changes in the tissues are due to absorption of toxin. Bacteraemia is

present in a large number of cases of bubonic plague; it increases until death takes place but may decrease or show fluctuations. In some cases bacilli may be found in the urine.

In rare instances the bacilli have been found to persist at the site of the primary bubo for a considerable time after an attack of plague. In this condition the patient may walk about and recover completely. These carriers when attacked by any specific infectious disease, such as measles or influenza, may show the bacilli in the blood and thus may be a source of spread of the infection by means of plague-carrying fleas or by a respiratory complication. Plague bacilli are said to be present in the blood of convalescent patients and even in persons who are in good health, but these statements need confirmation. All persons are susceptible to infection. Considerable protection is afforded by an attack of the disease though a second attack sometimes occurs.

Pneumonic plague. Pneumonic plague may be either primary or secondary. Most authors agree that primary pneumonic plague originates from a case of bubonic plague in whom a secondary plague pneumonia has developed. Numerous investigations in this connection show that the lungs are secondarily involved in a considerable percentage of cases of bubonic plague. The lung complications frequently occur when the primary bubo is situated in the axilla or neck. Other possible modes of origin of primary plague pneumonia have also been suggested. In severe septicæmic cases associated with flea-borne infection, the bacilli are present in enormous numbers in the expectoration from the lungs, and the droplets of sputum from these patients transmit the infecting agents to persons in contact with them. The Plague Research Commission found that the urine of septicæmic patient killed a guinea-pig when administered subcutaneously. They comment on the risk of contracting primary pneumonic plague from the spraying of bacilli in the air while the patient is micturating. In spite of the fact that the percentage mortality in bubonic type is high, it is remarkable that India is free from pulmonary plague. A suggestion has been put forward that plague bacilli alone cannot cause widespread epidemics of pneumonic plague, and that a symbiosis of *Past. pestis* with other micro-organism is essential. This view, however, has not received support. The sequence of events in the origin in an epidemic of pneumonic plague is that the first case of primary plague pneumonia originates from a case of secondary plague pneumonia, and the subsequent outbreak of primary pneumonic plague from this make up the epidemic. Under average conditions only a small percentage of those exposed to risk are attacked by a primary plague pneumonia. The chance of infection is determined by such factors as overcrowding, bad ventilation, social habits and customs which favour the transference of the infection.

The spread of pneumonic plague is by droplet infection. A vigorous cough may emit droplets to a distance of several yards. The time of exposure of persons to droplet infection is an important factor in deter-

mining the chances of infection. The possible role of carriers in the spread of pneumonic plague, whether pneumonia is of primary form or secondary to bubonic plague, has been much discussed. In a secondary plague pneumonia the bacilli may persist for some time after convalescence, but there is no evidence that they are the source of spread of primary pneumonic plague. The carrier in an epidemic of primary pneumonic plague is a negligible factor in its spread. Similarly, sick rooms and houses are not infective apart from the plague patient, and it is unlikely that dust plays any part in spreading the infection. Overcrowding in badly ventilated house, is perhaps the most important factor. Close contact and neglect of precautionary measures against droplet infection greatly increase the risk. In some cases infection is conveyed by kissing or it has followed a meal of vel rodents. Many authors have stressed the influence of a cold climate in the origin of pneumonic plague, though it is certain that such outbreaks can also arise in hot dry weather. In ambulatory patients or patients suffering from bubonic plague, travel or other exertion may lower the power of resistance of the individual in such a way that it may light up a septicæmia or lung complication.

The organism. The causative organism of plague is a bacillus, *Past. pestis*, discovered independently and almost simultaneously by Yersin and Kitasato in 1894. Plague bacilli appear as an oval rod with convex sides and somewhat rounded ends. The bacilli are mostly bipolar and are generally extracellular. They are easily killed by exposure to sunlight; exposure for one hour to dry heat at 100°C. kills the bacilli when dried on a slide. The bacilli are however very resistant to the action of cold. Bubonic plague can be reproduced in rodents and monkeys by experimental inoculation with cultures of the organism. Pneumonic plague has also been produced in rats and marmots through inhalation of cultures of *Past. pestis*. In rats subcutaneous injection or suspension of infected tissues causes death within seven days and intraperitoneal injections causes a rapidly fatal septicæmia; infection by the mouth and conjunctiva can also be produced. Guinea-pigs are highly susceptible, dying in 2 to 5 days after subcutaneous inoculation, and in 24 hours after intraperitoneal injection with development of purulent peritonitis and septicæmia. Mice are susceptible to the usual modes of infection.

The normal virulence of the plague bacilli when tested on animals, is of a high order, but is subject to variations both under natural and experimental conditions. Freshly isolated strains are invariably virulent. A culture which is avirulent for the rat may be pathogenic for the guinea-pig and strains that have lost a part of their virulence may regain it by passage through susceptible animals; some strains, however, may fail to respond. Many attempts have been made to reduce the virulence of the plague bacillus. Rowland found that growth of *Past. pestis* in normal rat serum depressed its virulence, and growth in fresh horse serum had the same effect, but growth in the inactivated serum raised

the virulence. There is thus evidence that the virulence of the organism varies.

Rôle of the rat and other rodents in plague. The rat plays a part in the epidemiology of plague and it has been found that most of the epidemics of human plague coincide with epizootics in these rodents. The principal species which harbour the infection are *Rattus norvegicus* and *Rattus rattus*. The Indian Plague Commission showed that epidemic first appeared among the rats belonging to the species *Rattus norvegicus*; after an interval of about 10 days an epizootic appeared in the rats of the species *Rattus rattus* and the human epidemic broke out after a further interval of about 10 days. During the off-season (June to December) in Bombay plague persisted in *Rattus norvegicus* and flared up at the onset of the cold weather. The natural mode of infection of these rodents appears to be from rat to rat by contact in the absence of the fleas. In certain rats the disease has been shown to exist in a chronic form. During the height of an epizootic of plague the lesions are those of acute plague but subsequent to this period numbers of healthy rats may show atypical lesions. These rats are said to act as chronic carriers of the disease, serving to keep alive the infection from one epizootic to the next. Though this view has not been accepted by the Indian Plague Commission, evidence has been recorded to show that in this way the disease remains endemic.

Other rodents are also known to harbour the infection and may be responsible for the introduction and spread of plague. In Mongolia and certain districts of Southern Russia, epidemics are associated with the occurrence of plague in a species of marmot called the 'tarabagan.' Possibly the disease is transmitted to man by the fleas which infest these animals, and also lice may convey the infection from one tarabagan to another. Another incriminated rodent is the spermophile or suslik, species of which have been found to harbour the plague bacillus. Nikanoroff reported that in Southern Russia, measures taken to exterminate these animals on a large scale, proved very successful, one such area formerly affected with plague remained quite free from the disease. Similarly, other rodents, such as the gerbille or gerbil and the multimammate mouse have been found to be infected with plague, by several observers in South Africa. In certain parts of California, ground squirrels have been found to be infected. Several cases of human plague were traced to contact with these animals as the fleas infesting them readily attack men.

Rôle of flea in plague. It has been demonstrated that plague is communicated to the rats by the agency of certain fleas as it is known that it is never communicable from animal to animal by simple contact. Chief among these are *Xenopsylla cheopis* and *ceratophyllus fasciatus*. Yersin in 1894 found that the dejecta of flies fed on infected organs of diseased animals showed plague bacilli. Simond was successful in infecting a mouse with plague by injection of an extract of

crushed fleas taken from a plague rat, and several other workers, later on, conveyed plague from rat to rat by the agency of fleas. The second Indian Plague Commission established the rôle of the rat flea in the transmission of plague and showed that if fleas are excluded, healthy rats will not contract the disease. The fleas that have left the body of an infected dead rat convey the bacillus and in the absence of their specific hosts both of these types of fleas bite human beings.

The bacillus multiplies in the stomach of the fleas and is then passed out in the faeces; the period during which fleas may remain infective depends on several factors. In Bombay during an epidemic the fleas remained infective for about 15 days, but during non-epidemic season for 7 days. Under laboratory conditions the fleas may remain infective for 47 days. A low temperature of about 50°F. and a nearly saturated atmosphere are most favourable for the survival of the bacilli in the flea. It has been found that as the cold weather arrives in Bombay the fleas increase in number and the epidemic among rats and man starts during this period. At the onset of hot weather the flea population decreases and plague in rats and man comes to an end. During the off-season sporadic plague cases occur in rats and also in man but the conditions are not favourable for its spread. In other parts of India the incidence of plague depends upon climatic and other factors. Where these conditions are unsuitable, plague either does not occur or runs a restricted course. Madras, on account of a high mean temperature prevalent throughout the year, is relatively free from plague. Another possible cause is that the predominant flea in the Madras Presidency is *X. astia* which is a far less effective carrier of plague than *X. cheopis* or *X. fasciatus*. The Indian Plague Commission showed that a rise of the rat epizootic and consequent outbreak of the human epidemic depends on three factors, (1) a suitable mean temperature between 50°F. and 80°F., (2) presence of rats, and (3) rat fleas. This is the reason why 75 per cent. of plague cases in India are distributed over the Punjab, the Bombay presidency and the United Provinces. In Egypt optimum temperature for an epidemic to occur has been found to vary between 68°F. and 77°F., a condition favourable for the development of fleas. Besides the rat fleas, the rôle of the human flea in the propagation of plague from man to man has been recognised and may be the cause of the outbreak of an epidemic in certain localities.

Laboratory diagnosis. For bubonic plague, the bubo is punctured with a hypodermic syringe and some juice extracted. A thin film is prepared from it and stained by Gram's method, methylene blue or thionin blue; Gram negative bacilli which have a tendency to stain more intensely at the poles, suggest *Past. pestis*. For cultural examination inoculate (at 25°C. and not at 37°C.) both blood agar plates (pH 6.8 to 7.2) and broth tubes. On blood agar the colonies of *Past. pestis* are sticky and can be pushed along the surface; in broth culture chain formation may occur. The definite test for plague is however by

inoculation of the material into animals; two white rats and two guinea-pigs should be inoculated both subcutaneously (one of each variety) and by rubbing some of the material on the dry shaved abdomen (one of each variety). In positive cases the animals die in 3 to 5 days, and on autopsy characteristic lesions will be found with the bacilli in large numbers in the spleen, lymphatic glands and blood. In the pneumonic type of plague, specimens of sputum should be examined in the same way as described for bubonic plague. Animal inoculation should be performed with the sputum, but as other virulent organisms may be present in the sputum simultaneously the best results are obtained by inoculation of the nasal mucosa and conjunctiva which allow plague bacilli to pass through. In septicæmia the organisms can be isolated from blood culture; in all cases of plague blood culture gives positive results just before death.

Prophylaxis. The prophylactic measures in plague depend upon the type of infection. In pneumonic plague it is the human patient and not the rat which is to be considered. The infection is spread by the droplets of sputum laden with the plague bacillus and persons entering the room of the patient, the nurses and the attendants are liable to contract the disease. Persons who have been in contact with pneumonic plague patients should be separated and systematic medical examination made. The quarantine period should extend for seven days after the last contact with the plague patients. Physicians and attendants attending cases of plague should be protected by bag-like masks or by several layers of gauze and cotton wool applied over the face and neck. In China special costumes are worn which prevent infection.

In the case of an outbreak of bubonic plague it is almost solely the rat and the rat flea which are responsible for the propagation of the disease. The rat contracts the disease, enters a house, and dies; then the harboured fleas leave the dead rat and feed on man. The infected flea either introduces the bacilli into the wound caused by the bite or bacilli may be rubbed into a small superficial wound on the skin by the clothing, etc. In some cases bed bugs and other insects have also been suspected as transmitting agents.

Rat destruction. Rat destruction has been considered one of the most important items in the prophylactic measures. Experience has however shown that it is an expensive and tire-

some procedure on account of rapid breeding of this rodent. In Kenya Colony it has been considered a failure, while in India Dennys thinks that this procedure is a useless waste of money as an anti-plague measure. Various other workers however report that rat destruction, vigorously conducted, quickly exterminates plague. The first measure in rat extermination is the disposal of garbage; no article of food should be left accessible to the rat. Various rat-proof houses have been prepared in endemic areas.

The methods of destroying rats with chemicals are numerous. Phosphorus paste made up with glucose can be spread on pieces of bread; strychnine and arsenic if used are placed in boxes which are large enough to allow the rats to get in. Barium carbonate is considered to be a safe rat poison. Kunardt (1920) found that 3 gr. doses of barium carbonate in flour was much more effective in killing rats than other poisonous drugs, and was not poisonous to man. Fumigation of houses and other infected places with sulphur dioxide, carbon monoxide and hydrocyanic acid, has also been practised, but the last two are very dangerous. Many workers, during plague epidemics have tried to exterminate rats by impregnating bread or their bait with bacterial cultures. The best known of these organisms are the *Danysz virus* which is closely related to *Salmonella enteritidis* and brings about fatal infection in rats, their use has now been abandoned.

In India, Tewari and Lall (1925) recommend a method which they consider better than fumigation of houses for the extermination of rats. They use a mixture of potassium chloride 2 dr., potassium nitrate $1\frac{1}{2}$ dr., sulphur 2 dr., powdered and mixed with 5 dr. of mustard oil or castor oil, to which are added 1 dr. of red pepper and a handful of crushed dried neem leaves. This is placed in rat holes over a 9 inch wick of cloth soaked in a saturated solution of potassium chlorate and ignited, the holes being closed.

Besides these, careful inspection of cases should be made in a plague infected area. Houses that have had one or more cases of plague or in which infected rats have been found should always be disinfected to kill rodents and insects. Rat-proof

houses are efficient permanent protection against these rodents. All possible precaution should be taken to prevent contamination of grains and cereals. Various measures have also been directed against fleas. Cresol emulsion, carbon tetrachloride and naphthalene are flea poisons, but they have little penetrative power. Sulphuretted hydrogen is a good pulicide and will kill fleas in 1 per cent. concentration. In plague-infected ships, such substances as sulphurous acid gas, generator gas and hydrocyanic acid gas have been used as disinfectants, the last-named being considered very effective.

Vaccines. The use of vaccine for prophylaxis during epidemics has given encouraging results, Haffkine's vaccine being chiefly used. The protective value of this vaccine is difficult to assess. According to the Indian Plague Commission inoculation diminishes the incidence of attacks, but is not an absolute protection against the disease; mortality among the inoculated is said to be markedly decreased. The protection afforded by inoculation lasts for several weeks, possibly for months. (See vaccine therapy).

Treatment. In the treatment of plague, all attempts should be made to relieve symptoms. In the septicæmic form, treatment should be directed on the same lines as for an acute infectious fever. The asthenic tendencies of the disease should never be lost sight of and stimulants are indicated to resuscitate a sinking patient.

During the early stage, headache and pain can be relieved by proper hydrotherapeutic measures. An ice cap on the head and sponging of the body are very safe and efficient methods for lowering the temperature. Antipyretic drugs should better be avoided. Vomiting is often a troublesome symptom which can be relieved by calomel and a saline purgative; a mustard plaster over the epigastrium is also useful. Morphine is by far the best drug to produce sleep or chloral and potassium bromide may be used. In violent or very restless cases hyoscine is of service. Cardiac weakness manifests itself early in the disease. Hence cardiac stimulants may have to be frequently prescribed.

For the local treatment of buboes, hot fomentations of carbolic acid are useful. They should not be opened or

excised, as excision may often be followed by serious results. Indolent bubonic swellings are treated with iodine liniment. Injections of solution of iodine directly into the bubo have also been recommended. Another preparation that has been advocated is a mixture of iodine and a solution of camphor and thymol in equal parts; this is injected into the bubo in doses of $\frac{1}{2}$ to 1 c.cm. During convalescence tonics are indicated. Patients should be isolated for at least four weeks after the temperature is normal.

Antiplague serum. The use of this serum according to some, offers the best means, at present, of combating this disease. Others consider it of doubtful value. The Indian Plague Commission, from the results of the therapeutic uses of this serum, concluded that no appreciable benefit is conferred by its use. Favourable results have however been obtained when the serum is given early and in large doses intravenously. The problem of specific serum therapy in plague is likely to remain a subject of controversy until further research has determined the essential elements in the serum, whether antibacterial or antitoxic, and how they may be measured.

Bacteriophage. This form of treatment has been tried by d'Herelle and Naidu and his colleagues, but it has not so far proved effective.

Drug treatment. The treatment of plague with chemicals is far from satisfactory. Various chemotherapeutic agents have been tried but none has so far proved effective. Caius and Naidu (1927) in a study of the chemotherapy in bubonic plague recorded their observations on the bactericidal action of antiseptics on *Past. pestis*, and the effect of some of them on plague infected animals. Phenols, mercurated phenols, phthaleins and dye-stuffs were used and many of these had strong bactericidal action *in vitro*. But none of them were effective *in vivo*; mercurochrome, though active *in vitro*, had no influence on plague in rats, and so also resorcinol and mercurated trypan blue. Among other agents, intravenous injections of iodine have been advocated but they are not effective. Mercurochrome has been tried in the septicæmic form. Balfour (1925) suggested its use in plague, beginning with 20 c.cm. of a 1 per cent.

solution intravenously and increasing gradually in subsequent injections. Neo-salvarsan and Bayer 205 have been tried with inconclusive results. Nothing like a really curative treatment of plague is known.

UNDULANT FEVER

It is a long-continued febrile disease characterised by a series of pyrexial attacks with intervening periods of apyrexia. The fever resembles typhoid fever, and there is constipation, muscular pain, anæmia and enlarged spleen. The course of the fever is a protracted one and may last for 3 or 4 months.

Undulant fever is caused by two different but closely related groups of organisms, one the *Br. melitensis* and its serological variants the paramelitensis, the other the *Br. abortus*. *Br. melitensis* causes primarily an infection in goats and is transmitted to man through their milk. Because of its relative frequency in Malta, the fever is also known as Malta- or Mediterranean fever. *Br. abortus* was discovered by Bang in 1897 as the causative organism of epizootic abortion in cattle; it occasionally gives rise to the so-called abortus fever in man. This condition is indistinguishable from Malta fever and these fevers are referred to as undulant fever.

Brucella melitensis infection. Bruce (1887) first isolated the causative organism from the spleen of Malta fever cases. Injections of pure cultures of the organism give rise to a similar disease in the monkey. Inoculation of cultures into man has also been followed by the characteristic symptoms after an incubation period of from five to fifteen days. The present knowledge of the spread of the disease and the value of the prophylactic measures in the control of undulant fever have been greatly widened due to the work of the British Commission for the investigation of the Mediterranean fever (1905-07). All evidence now sustains the view that drinking of raw goat's milk is the paramount source of infection; the disease may also be transmitted by eating butter or cheese made from infected goat's milk.

Brucella abortus infection. Bang (1897) demonstrated that the presence of a small Gram-negative bacillus in the uterine exudate of the cow was the cause of infectious abortion in cattle. The intravaginal injection of this organism into pregnant cows gave rise to abortion and the organism could be recovered from the uterine exudate. It has been shown that a large number of cases of undulant fever are caused not by infection with *Br. melitensis* but with *Br. abortus*, infection being

conveyed by cow's milk. Clinically these cases are characterized by typical undulant fever, but more frequently by irregular fever or fever of a paroxysmal type. The mode of infection in these cases is through drinking the milk of an infected cow or by contact with a diseased animal. Some cases are reported where the persons have been in contact with aborting cows. Agglutinins may be present in patients' serum active against *Br. abortus* up to a titre varying between 1 in 80 to 1 in 5,120. The organism can also be found in the blood.

Laboratory diagnosis. The blood culture gives positive results in early cases (from the second day onward) and is successful in about 80 per cent. of cases. The technique is the same as that for typhoid fever but it is necessary to take more blood (about 10 c.cm.) into either 1 per cent. glucose broth or better into liver broth. Since it is not possible to know what type of organism may be the infecting agent, it is essential to make cultures in duplicate, one under aerobic condition (for *Br. melitensis*) and the other in reduced oxygen tension (20 per cent.) with the addition of 10 per cent. CO₂ (for *Br. abortus* which is very difficult to isolate and the growth of which is dependent on special atmospheric conditions). The organisms are often slow in growing and hence for *Br. melitensis* 7 to 10 days should be allowed before the culture is considered negative, and for *Br. abortus* several weeks (6 or more) should be allowed. A simple method of diagnosis is by the agglutination test. In the blood of normal persons agglutinins may be present for these organisms up to a titre of 1 in 50 (very rarely in 1 in 100). This increase in normal agglutinins is more marked in farmers and veterinary surgeons who come into close contact with infected animals. In patients suffering from undulant fever agglutinins appear about the tenth day of illness and the titre varies between 1 in 100 to 1 in 3,000 but about 20 per cent. of cases of undulant fever fail to show agglutinins. Diagnosis can also be assisted by doing an intradermal test with 1/10 c.cm. of the filtrate of a twenty days' broth culture. A positive reaction consists of a raised plaque 4 to 6 mm. in diameter and occurs about the 7th to the 10th day of the disease. The complement-fixation test is nearly always positive during the course of the disease and often for a long time afterwards. Although infection with *Br. melitensis* and *Br. abortus* are different in their epidemiology and pathogenicity, there is no marked distinction in laboratory diagnosis. *Br. melitensis* is aerobic and can be cultivated more easily while *Br. abortus* is anaerobic; guinea-pigs are insusceptible to moderate doses of *Br. melitensis* while monkeys are very susceptible.

Prophylaxis. *Malta fever.* In such a chronic and debilitating disease as undulant fever, prevention is the only method of controlling it, the treatment being far from satisfactory. As goat's milk is the principal source of infection to man a rigid ban on its use should be enforced. The health authorities

in Malta ordered the killing of all the infected goats in 1909. Concurrently with this the fever incidence fell from an annual average of 632 to 318 among the civil population. The recommendations of the Malta Fever Commission in this connection are (1) examination, segregation and slaughter of all infected animals, (2) examination of the milk of all infected goats for the presence of *Br. melitensis* and of agglutinins in serum or milk. It must at the same time be borne in mind that infection may occur in man in other way and that certain products of milk such as cheese, butter, etc., may also convey the bacilli. In endemic areas the milk should always be sterilised by boiling or only pasteurised milk and cream should be used. In addition to these, as a precautionary measure in endemic areas, the drinking water and food should receive special attention. The urine and fæces of the infected individual should be disinfected; laboratory workers and the nurses attending cases of undulant fever should be particularly careful.

No efficient vaccine is as yet available for the prevention of infection either in man or animal.

Br. abortus infection. The elimination of infectious abortion in cattle is a matter of difficulty. All the animals should be tested by the agglutination or complement fixation test. In a mildly infected herd those showing a positive reaction should be segregated. As the uterine discharge of the infected animals is infectious, all measures should be adopted for the isolation of the animal and disinfection of the stall. For prophylaxis of animals vaccines prepared from living organisms have been found to confer some degree of protection; heat-killed organisms have less protective power and dead bacilli are useless in this respect. It must be remembered that vaccines should never be used except in badly infected herds, otherwise the infection is spread rather than checked. Reports of the successful vaccination of man against *Br. abortus* infection have been published (Nicolle and Conseil, 1922; Burnett, 1924), but they are not very convincing. Recently, Dubois and Sollier (1930) prepared a vaccine using various strains of *melitensis* and *abortus* for prevention of infection in persons engaged in dealing with infected animals. The first injection is of 0.25 c.cm. containing

500 million organisms, the second of 0.75 c.cm. and the third of 1 c.cm. As a result of the full course of injections given to 111 persons engaged in dealing with infected animals, none developed undulant fever while two of the 36 controls developed the disease.

In spite of the fact that in an endemic area a large proportion of the milk supply is contaminated there are apparently very few cases of undulant fever recorded. This may be due to non-recognition of the disease, the cases recorded representing only a fraction of those actually occurring. In addition it is probable that immunity to infection may occur without recognisable clinical disease. Thus immunity might be acquired in infancy from drinking infected milk and maintained for a considerable time afterwards, till a lowering of the individual's resistance due to some other cause opens the door to infection. In endemic centres or in the face of an epidemic the general health should be preserved and the use of raw milk forbidden.

Treatment. The results of the use of drugs in the treatment of undulant fever have not been encouraging. It should be remembered that undulant fever is of prolonged duration and the treatment necessitates a careful management of the case during the illness.

In view of the constipation in this disease, it is well to use some mild purgative such as calomel in the beginning ; hydrotherapeutic measures have to be carried out to control hyperpyrexia ; antipyretic drugs such as quinine, phenacetine, etc., are not called for. The protracted course of the disease makes it necessary to conserve the vitality of the patient by rest and nutritious diet.

Drug treatment. Intravenous injections of various metallic compounds have been tried. Mercurochrome in doses of 0.2 gm. has been tried apparently with good results ; intravenous injection of 10 per cent. solution of collargol in doses of 2 to 4 c.cm. has also been advocated. Conterno (1930) used a 2 per cent. solution of trypanflavine in doses of 10 c.cm. injected intravenously with two days' interval for 8 to 10

injections. Of the 14 cases treated ten were followed up for several months ; six were cured straight away and three required a further course of 3 or 4 injections. Thusber (1930) treated 7 cases of undulant fever with acriflavine hydrochloride, keeping seven others as controls. The dosage employed was 0.1 gm., 0.2 gm., and 0.3 gm. at intervals of three days along with 20 c.cm. of saline intravenously. In five of the treated cases the fever was arrested within one month of the treatment while in untreated cases the fever continued for 9 months to 2 years. Rudnew and Krumberg (1931) after failing with different forms of treatment, finally utilised X-ray therapy, the region of the spleen being irradiated for fifteen minutes on five or six occasions. Neo-salvarsan, colloidal gold, compounds of silver with methylene blue have also been tried, but definite evidence as to their therapeutic value is lacking.

Vaccines. Favourable results have been reported by various injections of vaccines. The initial dose for sensitized vaccine is 250 million organisms progressively increased every two or three days and for autogenous vaccine 50 million organisms, progressively increased at three day intervals, to 200 million organisms. Though vaccines are reported to be successful in the treatment of undulant fever their value has not yet been established.

Autoserotherapy has also been tried with variable results. It was found by Partearroyo that 60 per cent. of the goats suffering from the disease gave a positive agglutination reaction. He reported favourable results with 50 to 60 c.cm. of antiserum, and this method of treatment is worthy of further trial.

OROYA FEVER AND VERRUGA PERUANA

Oroya fever is an acute infectious disease caused by *Bartonella bacilliformis*. Verruga peruana is characterised by the development of nodular eruptions on the skin and mucous membrane resembling those of yaws. Both the diseases are now recognised as different manifestations of one and the same disease, the trend of opinion being that Oroya fever is the first stage of the illness, eruption occurring in the later stage if the patient survives an attack. Strong and his colleagues

(1915) however failed to produce typical Oroya fever in man after inoculation of the material from verruga lesions and they considered the two diseases as distinct entities. The work of Noguchi (1926) fully established the fact that the two diseases are but different manifestations of one and the same infection. He was successful in cultivating *B. bacilliformis* from the blood of a patient suffering from Oroya fever. Intravenous injection produced remittent fever in monkeys, and verruga-like lesions appeared after inoculation with the cultures; the character of the infection depended upon the virulence of the infection and susceptibility of the host.

Lowoff and Vauzel (1931) on the other hand have shown that there are two organisms concerned in these infections, the one, *Bartonella bacilliformis* is responsible for verruga lesions and the other *Eperythrozoon noguchi*, is the cause of Oroya fever. They believe that the reason why cultures from the blood of cases of verruga or Oroya fever produce verruga only in monkeys is due to the fact that *Bartonella* can be cultivated whereas the eperythrozoon cannot be cultivated. Other workers, however, support the view that verruga and Oroya fever are different manifestations of the same disease. *Bartonella* can be observed in the red cells in cases of verruga and also in cases of Oroya fever and the eperythrozoon has not been observed in the blood of man.

The disease is considered to spread by a kind of phlebotomus especially *P. verrucarum* and also *P. noguchi*, and *P. peruensis*, though it was earlier thought to be conveyed by a tick.

Prophylaxis and treatment. It has been suggested that a species of phlebotomus is the transmitting agent. Prophylactic measures, therefore, rest on destruction of these sandflies. There has so far been no satisfactory method of treatment. With regard to the nodules of verruga peruana it may be said that they should be kept scrupulously clean so as to prevent secondary infection. The curative influence of X-rays on the various skin lesions in man suggested its application in this disease. Muller and Tyler (1930) showed that early verruga nodules when exposed to a single properly graduated dose of X-rays are inhibited in their growth. This justifies a trial of X-rays in suitably graduated doses in treatment of verruga nodules in man. Oroya fever should be treated on the same lines as for infectious fever. Intravenous injections of salvarsan are said to give beneficial results.

CHAPTER V

REMEDIES USED AGAINST LEPROSY

Leprosy is a disease exceedingly difficult to treat, but it should nevertheless be emphasised that it is a remediable disease. There is no specific remedy for the disease yet available. The methods of treatment at our disposal, however, if properly carried out, can cure quite a good proportion of the cases and there is no reason why lepers should be considered incurable and be shunned.

This dreaded disease is prevalent in many of the tropical and sub-tropical countries. The number of lepers in the world is estimated to be about three millions, but, according to Muir, when the incipient cases are taken into account, the number is very much larger. Rogers states that there is a remarkable relationship between high leprosy incidence and high rainfall, especially in not tropical climates. The only tropical areas with little or no leprosy are those with the extremely low rainfall of under 10 inches. It is suggested that abundance of biting insects in humid regions may cause punctures of the skin of man favouring the entrance of lepra bacilli derived from contact with cases of the disease. Further, damp heat is likely to favour the temporary survival of the bacilli outside the human body and in this way infection is favoured. According to others sparse populations connected with low rainfall are responsible for the low incidence and not the climatic factor.

Recent work on rat leprosy has thrown valuable light on this subject. Although the bacillus of rat leprosy is difficult or impossible to cultivate, one rat can be easily infected by fresh material obtained from another suffering from the disease. The infective material can be kept active outside the body for months. The extraordinary number of lepra bacilli in the nodular lesions of the skin and nasal mucous membrane is accompanied by little effect on the general health for long periods. This shows the low toxicity of the organism in its intact and acid-fast coating. In some phases of the disease local inflammatory and general constitutional reactions (e.g., fever) may occur. In the nerve type the bacilli may be very few in number; they are found either in the fibrous tissue of the nerve trunk or round its terminations in the skin. In this type the resisting power of the tissues is greater and the disease may die out.

Leprosy is not a hereditary disease. The disease is contracted chiefly by intimate contact, e.g., staying in the same house with a

leper. Healthy persons, as a rule, do not get it; leprosy cannot be considered to be a highly contagious disease. The first two decades of life are the periods when one is most liable to infection, adolescence and the commencement of sexual life are said to lower the resistance to the disease. Children are more susceptible than adults. The incubation period may vary from a few weeks to many years. It may be stated, however, that it is very difficult to form any accurate estimation regarding the incubation period of this disease, as the latter may exist for years without attracting any attention. The incubation period depends on the degree of reaction of the tissues to the infective organism and on the general health of the individual. A delay of six months in the segregation of children born to lepers renders them liable to get the disease. The children in the first 2 or 3 years of their life are more susceptible to the disease. The nodular cases with numerous bacilli are more infective than the nerve leprosy with very few organisms.

The disease is seen in two main types which may co-exist. These are the neural type and the cutaneous (or nodular) type. In both types there are seen various phases, described by Muir as (1) the quiescent stage, during which the bacilli may multiply and the lesions extend locally but there is no toxæmia; (2) the reactionary or inflammatory stage, during which the lesions become inflamed and general toxæmic symptoms appear; and (3) the phase of resolution, following upon the subsidence of reaction.

The primary lesions are most frequently seen on extensor surfaces of the limbs and on the more exposed parts of the body such as the cheeks, outer surfaces of the shoulders and arms, the buttocks and outer surfaces of the thighs. The parts less commonly affected are the flexor surfaces, the neck, middle of the body and soft unsupported part of the abdomen. All these point to contact infection. There is little evidence that the organisms are inoculated by insects. Recent evidence is against the primary nasal infections. Investigation of the primary lesion has shown that in 14.6 per cent. of cases are of the depigmented anæsthetic type,—maculæ; in 11.9 per cent., of erythematous red type; in 9.5 per cent., of non-anæsthetic type; in 5 per cent., there is paralysis; in 3.5 per cent., there are ulcers and erythematous anæsthesia.

Diagnosis is easy in a well-developed case. Bacteriological examination of the skin shows many acid-fast bacilli, but in nerve leprosy, bacilli may be very few or undetectable, and diagnosis has to be made on clinical grounds alone. If the acid-fast bacilli cannot be found in the nodules of the skin, the nasal mucosa should be examined. In early cases thickening of nerves such as the ulnar, peroneal, great auricular and other superficial nerves may be looked for. Erythematous patches, papular eruptions, and blisters appearing now and then on different parts of the body, depigmented patches, porokeratosis, hyper-

æsthesia, thermal anæsthesia, repeated febrile attacks are some of the symptoms.

Attempts have been made to diagnose leprosy by means of a specific allergic reaction by using a suspension of the leproma. This test is known as the 'leprolin test.' Muir adopts the following technique in preparing leproma suspension for the leprolin test. After sterilising the skin, a portion of the tissue of the thickened pendulous ear lobe is removed with a sharp knife and placed in a petri dish. Several pieces of tissue are removed in a similar manner from other patients. These are boiled in water for 45 minutes and then cut up into small pieces, which are dried for a few hours under a fan and thereafter in a vacuum dessicator over pure sulphuric acid. The dried material is ground up to a fine powder in a glass mortar and stored in a dessicator. In preparing the suspension, 0.4 gm. of the dry powder is ground up with about 10 c. cm. of saline; the fluid suspension is pipetted off; the solid residue in the mortar is again ground up with saline, and the fluid suspension pipetted off and added to the rest of the suspension, this process being repeated three or four times. The whole suspension is then shaken up in a large test tube and allowed to sediment for 10 minutes, after which the fluid is again pipetted off, the sediment being discarded. Saline is added to make 100 c.cm. along with 0.5 per cent. carbolic acid. The suspension is then standardised and made up in 1 c. cm. ampoules which are sealed and heated at 120°C for half an hour. This forms Hansen's (H) leprolin.

A control leprolin is prepared by the same method. The spleen and liver of a rat which had been inoculated intra-abdominally with rat leprosy 5 or 6 months previously, are used in place of the lepromatous skin. This forms the Stefansky (S) leprolin.

The usual dose used for inoculation is 0.2 c. cm. of this suspension intradermally.

A positive reaction is indicated by the appearance, several days later, of a red flush with a raised area round the point of inoculation. In severe reaction there is desquamation, vesication and pustulation. In cases of nerve leprosy with few bacilli, especially in those of the macular type, the reaction to Hansen's leprolin is increased, but that to Stefansky's leprolin remains the same. In cases of cutaneous leprosy with numerous bacilli the reaction to Hansen's leprolin is diminished or absent, but that to Stefansky's leprolin is apparently not diminished. A strongly positive leprolin may be taken as an indication for a favourable prognosis, as it indicates resistance to the infecting organism.

Syphilis, presence of intestinal parasites, malaria, debilitating diseases, improper diet, long residence in hot, moist and enervating climates are potent predisposing causes. Leprosy uncomplicated with syphilis does not give a positive Wassermann test.

Chaulmoogra oil. The oil is obtained from the seeds of various species of the natural order *Bixineæ*. *Taraktogenos kurzii* is a tall, evergreen tree, 40 to 50 feet in height with lanceolate or oblong lanceolate leaves. It grows plentifully in Eastern Bengal and the upper part of Burma and is distributed along the eastern and southern slopes of the Pegu, Yoma, Martaban, in the forests of Sylhet and Chittagong. The fruits, which grow upon the stems and main branches of the tree are of the size of oranges and have numerous seeds embedded in the pulp. The oil is expressed from these seeds.

Chaulmoogra has been used in the treatment of leprosy in Hindu medicine for many centuries and during recent years it has been generally recognised as the most valuable remedy in the treatment of this disease. In the Buddhist literature of ten or more centuries ago, mention is made of the great improvement in the condition of lepers after eating raw chaulmoogra seeds. There are records to show that the oil extracted from the seeds has been used in the treatment of leprosy and as a household remedy for many skin diseases since 1595. In the 'Makhzan-el-Adwiya', one of the oldest books on Mahomedan materia medica, mention is made of the use of the seeds under the name of 'chaulmoogra.' A description of the seeds and their uses is also found in ancient Chinese literature.

In indigenous medicine the oil was administered orally, mixed with clarified butter. Western practitioners quickly appreciated the beneficial effects produced by this drug and began to use it from the very early days of British rule. In 1854, Mouat reported improvement in a case of leprosy as a result of oral administration and local application of chaulmoogra. In 1868, the curative effects of chaulmoogra were so well known that it was made official in the Pharmacopœia of India, the chief preparation being an ointment which was to be made from the pounded kernels mixed with 'unguentum simplex.' It was not till 1904, when Power and his collaborators published in detail the chemistry of chaulmoogra oils, that the attention of the scientific world was drawn to this valuable drug.

Besides *Taraktogenos kurzii*, certain other trees belonging to the natural order *Bixineæ* also yield oils having a composition closely akin to that of true chaulmoogra oil. *Hydnocarpus wightiana* is one of the most important members of this group. It grows abundantly in the western parts of the Peninsula from South Konkan along the coastal range. *Hydnocarpus anthelmintica* is another member of the same family. This tree is indigenous to Siam, Northern Cochin and Gamboja. *Hydnocarpus wightiana* seeds have recently been planted in different parts of Africa, Malaya, the West Indies, South America and

elsewhere, and the oil is gradually becoming available as the trees develop. There are several other species which have also been recognised as important sources of the oil. In the following table, the names of the most important members with their habitat are given :

Description.	Habitat.
<i>Hydnocarpus venenata</i>	... Ceylon, Deccan and Burma.
„ <i>castanea</i>	... Burma.
„ <i>anthelmintica</i>	... Siam, French Indo-China.
„ <i>curtisii</i>	... Penang.
„ <i>hutchinsonii</i>	... Philippine Islands.
„ <i>subfalcata</i>	... Philippine Islands.
„ <i>woodii</i>	... India.
„ <i>alpina</i>	... India.
<i>Asterlostigma macrocarpa</i>	... Travancore.
<i>Onchoba echinata</i>	Sierra Leone.
<i>Carpotroche brasilliensis</i>	... South America.

In the older literature, it was believed that chaulmoogra oil was derived from the seeds of *Gynocardia odorata* which is a native of Sikkim, Assam and Chittagong. The fruits as well as the seeds are very similar in appearance to those of *Taraktogenos kurzii* and that is probably the reason for the confusion that existed for such a long time, until in 1901, Prain showed that it was a mistake.

The chief sources of oil in India are *Hydnocarpus wightiana* and *Taraktogenos kurzii*. *Hydnocarpus wightiana* grows in gardens and accessible places all over South India, so that seeds can be obtained quite fresh. *Taraktogenos kurzii*, on the other hand, grows in out-of-the-way places where its seeds cannot be gathered easily during the rainy season when the fruits fall. It is therefore not easy to get fresh seeds for extraction of the oil. The oil derived from *Hydnocarpus wightiana* is, therefore, preferred to the other. It is further considered to be superior on account of its higher rotation value (5.5 degrees higher than *Taraktogenous* oil).

Chemical composition. The oil is obtained from the chaulmoogra or *hydnocarpus* seeds by hot or cold extraction. The seeds yield 30 to 40 per cent. of the oil according to the method used. By hydraulic pressure about 30.9 per cent. of the oil is obtained, while by ether extraction the yield is much more and amounts to 38.1 per cent. The oil is of a pale yellow or a reddish brown colour. The oils sold in the market are usually rancid, dark brown and devoid of therapeutic action. The fatty oil has got the following properties :

Expressed oil. Oil extracted by ether.

Melting point	...	22—30°C.	22—30°C.
Sp. gravity	...	0.952 at 25°C.	0.951 at 25°C.
Acid value	...	23.9	29.5
Saponification value	...	213.0	208.0
Iodine value	...	103.2	104.4.

On hydrolysis, the fatty oil yields the following fractions:—

1. Total fatty acids, m.p. 44-45°C.
2. Glycerol.
3. Non-saponifiable portion.

The fatty acids are mixtures of several constituents and these can be separated by further analysis, yielding:

- (a) Chaulmoogric acid. (b) Hydnocarpic acid.
- (c) Probably some lower homologues of chaulmoogric acid (not definitely isolated).
- (d) Palmitic, linolic acid, etc.

Similar fatty acids are contained in oils from the seeds of *Hydnocarpus anthelmintica*, *H. wightiana* and *H. alpina*. The Philippine trees, *H. venenata*, *H. alcalæ* and *Pangium edulæ*, the South American tree *Carpotroche brasiliensis* and the African tree *Onchoba echinata* also yield oil of a similar nature. The Chinese tree 'Ta-Feng-Tzu' is nothing but *Hydnocarpus anthelmintica*. The following table by Perkins and Cruz gives the composition of the oil obtained from various species.

It will be seen from the table given above that all the species mentioned above contain chaulmoogric and hydnocarpic acid in different proportions. The virtue of chaulmoogra oil has been shown to reside in these two peculiar fatty acids of unsaturated type characterised by the presence of a ring of carbon atoms. Chaulmoogric acid— $C_{18}H_{32}O_2$ —has a melting point at 68.5°C. and is dextrorotatory. Its iodine number is 90.1. Hydnocarpic acid— $C_{18}H_{30}O_2$ —melts at 60°C. and is also dextrorotatory. Its iodine number is 100.2.

Gynocardia odorata has already been mentioned as inactive. A study of its chemical composition shows that the fatty acids derived from it do not contain either of the unsaturated acids which are considered responsible for the special action of chaulmoogra oil. The oil obtained from the market is of a brownish red colour and is very frequently mixed with gynocardia oil and linseed oil. Much of the divergence of results obtained by various workers in the treatment of leprosy in the early periods might be accounted for by the impurity of the oil employed. Taraktogenous oil is costly and naturally there is a great incentive on the part of retail dealers to mix cheap oils with it. The extended use of the cheaper *Hydnocarpus* oil has removed

COMPOSITION OF CHAULMOOGRA OILS
(Perking and Cruz)

Species.	Chaulmoogric acid	Hydnocarpic acid	Other constituents.	Fatty acids M.P. ° C.	Fatty acids specific to dextrorotatory power
<i>Gynocardia odorata</i> (pressed oil) ...	None	None	Gynocardin, linolic, palmitic, linolenic, oleic	..	None
<i>Hydnocarpus alcala</i> ...	Approximate 90 per cent.	None	Palmitic, oleic	59	59·65
<i>Hydnocarpus alpina</i> ...	Indicated	Indicated
<i>Hydnocarpus anthelmintica</i> (pressed oil) ...	Present	Present	Glucoside, oleic, palmitic	42-43	59·6
<i>Hydnocarpus venenata</i> (pressed oil) ...	Present	Present	Glucoside	43	60·9
<i>Hydnocarpus wightiana</i> (pressed oil) ...	Present	Present	Unknown unsaturated acid	41-44	60·4
<i>Onchoba echinata</i> (extracted oil) ...	85·5 per cent.	...	No palmitic, liquid acids 12 per cent. ...	18	3·49
<i>Pangium edule</i> ...	Indicated	Indicated	Unsap. 1·5 per cent. gynocardinpalmitic
<i>Toraktogenos Kurzii</i> (pressed oil) ...	Present	Present	Glucoside, palmitic acid ...	44-45	52·6

this tendency to adulteration to a great extent. Whenever there is any doubt as to the nature of the oil, it is always better to test its purity. Of all the tests, the specific rotation of polarised light is probably the best indication. The specific rotation of *Hydnocarpus wightiana* is 57.7 and that of *Hydnocarpus anthelmintica* 52.5.

Pharmacological action

Bactericidal action. The oil itself has no bactericidal action, perhaps because it does not penetrate the cell wall. The fatty acids present in it are said to possess a destructive action on acid-fast bacteria *in vitro*, but this work has not been confirmed. Recent experiments have shown that even 5 per cent. solution of the fatty acids have little or no effect on the bacillus of rat leprosy or the tubercle bacillus.

Local action. Chaulmoogra oil is irritant to the skin and mucous membranes. Nausea and vomiting are induced even with small doses, such as 3 to 4 drops. Though it is possible to develop slowly a gastric tolerance to larger doses (15 drops), there is no denying the fact that it is liable to set up anorexia and vomiting very frequently. This applies chiefly to impure oil extracted from bazar seeds. Not only the oil but the sodium salts of the fatty acids as well as the esters have pronounced irritant properties though much less marked than the original oil. The hypodermic injection of plain oil in daily doses of 5 c.cm. was found by some workers to produce intense local inflammation and induration. Corbett found that intramuscular injections produced extensive abscesses. According to Muir, if properly prepared oil from fresh seeds is used, such accidents never occur.

The esters have an irritant action. The oil does not appear to be quite so irritant on intravenous injection in man. Harper of Fiji dissolved the oil in ether and used it by the intravenous route in the treatment of his leprosy cases. Plain oil given intravenously produces embolism of the lungs. Intraperitoneal injections produce less local reaction, but after repeated injections a deposit, apparently fibrin, is found over the spleen and liver. Care must be taken in the use of the sodium salt, as it is extremely alkaline.

Systemic Effects. It has been said that chaulmoogra oil does not possess any systemic effect at all. The researches of Rogers, Read and others, however, tend to show that it does possess some systemic effects. Thomas and Muller in 1911 observed narcosis in a few of the animals to which they administered hydnocarpus oil by the mouth. Cats given doses of oil up to 3 gm. per kilo, vomited, and apparently not much of the drug was absorbed. Such a dose is exceedingly nauseating, but the animals developed deep narcosis.

Valenti obtained a preliminary stimulation of the central nervous system followed by paralysis, with the ethyl esters of chaulmoogra oil;

death may result from paralysis of the respiratory centre. Ohara observed a strong central paralytic effect and a lowering of the systemic blood pressure following the administration of the ethyl esters and the sodium salts of chaulmoogra.

Apart from certain gastro-intestinal effects the oil from fresh seeds, when properly extracted and stored, produces very little other systemic action. Irritant and toxic products are formed in the seeds when improperly collected.

Lung embolism. Costel after administering to man the oil hypodermically in daily doses of 5 c.cm. reported fatty embolism of the lung in 2 cases. Walker, McArthur and Sweeney in their chemotherapeutic studies of the action of the ethyl esters of chaulmoogra upon rabbits, reported pulmonary embolism in a large number of animals. Hypertrophy of the lungs, pneumonia and broncho-pneumonia have also been frequently observed by other workers. It is difficult to understand why the lung tissue should bear the brunt of the irritative action of the chaulmoogra derivatives. According to Muir this should never occur in man if the injections are properly given.

Hæmolysis. Hæmolysis is undoubtedly produced by intravenous injections of the sodium salts of chaulmoogric and hydnocarpic acids. With proper dilution of the salts used, this hæmolysis can be reduced to a minimum so as not to entail any special risk to the patient.

Calcium metabolism. According to Read, chaulmoogra oil given orally in small doses produced a marked increase in the urinary calcium and also an increase of faecal calcium. Continued administration, however, reverses the effect and favours calcium retention. Prolonged hypodermic administration of ethyl hydnocarpate in therapeutic doses to dogs decreases the urinary calcium and greatly increases faecal calcium so that there is a hyper-excretion of calcium. In experimental dogs, there is generally found an increase in the blood calcium after the administration of the hydnocarpatates in ordinary therapeutic doses. In toxic doses, on the other hand, a rapid depletion of the calcium-reserve is observed.

Nitrogen metabolism. A definite increase in the amount of nitrogen excreted in the urine after the oral administration of chaulmoogra oil has been observed by Read. This indicates a considerable degree of tissue breakdown. Continued administration of small doses of ethyl hydnocarpate shows progressive decrease in urinary nitrogen and a large increase in the ammonia excretion. This is an evidence of a marked degree of acidosis in the tissues.

Sulphur metabolism. Large doses of the chaulmoogrates given to rabbits, produced a temporary increase in the excretion of all forms of sulphur. The ethereal sulphates show the greatest percentage of

rise and the neutral sulphur is also increased. Repeated doses do not produce the increase seen after the initial dose; in fact, there is a slight decrease.

Therapeutic Uses

Oral administration of seeds. The administration of chaulmoogra by the oral route has been practised since very early days. This method is favoured by some institutions even to this day. At the Rangoon Leper Asylum, the regular treatment was with pills made of *Hydnocarpus* seeds, rhubarb and salt. Travers (1926) used orally the fresh nut of *Hydnocarpus anthelmintica* mixed with *Cannabis indica* and *Tribulus terrestris* and reported 11 per cent. cures. Recently, Cochrane has given a fair trial to this method with slight modifications. Fresh seeds were administered to the patients, taken after meals. The results obtained were not promising and he concluded that the oral administration of the seeds should be confined to cases refusing injections, or to young children who cannot stand injections and to those who live far away that distance prevents them from coming regularly for treatment.

Oral administration of oil. The oil was used by a number of workers. Lebœuf (1900) gave the oil in emulsion in milk, in capsules and salads. Unna (1900) used the oil and to avoid gastric disturbance administered it in the form of keratin-coated pills and also in the form of enemas. Azua used the oil and managed to give gradually as high as 300 drops per day. Denney (1929) has also given the oil in large doses orally in enteric capsules without nausea. Engel-Bey, who had a large experience with leprosy in Egypt, recommends oral administration in dosage of 30 drops of the purified oil solution under the trade name 'Anti-leprol' for a period of 3 to 4 years. Small doses have also been successfully given in pill form.

The greatest disadvantage of oral administration of chaulmoogra, however, is that it sets up gastric irritation and nausea in doses required to obtain therapeutic results. If the patients are able to tolerate large doses by the mouth, the

disease will usually improve. Others argue that if a patient can stand large doses by the mouth, his general health must be good and he is bound to improve in any case. Unfortunately in actual practice one cannot give large quantities to produce permanent results. The method of administration is to commence with 1 to 2 min. in milk or other suitable vehicle, or the drug can be placed in gelatin capsules and given directly after meals. The dose is first given once a day, then increased to 3 times a day. Every other day, the dose is increased by 2 min. until about 100 min. 3 times a day is reached. Seldom, however, can such a large dose be tolerated, firstly because of the vomiting that the drug produces and secondly because in large doses there is a tendency for toxic symptoms to appear, *e.g.*, langour, emaciation, etc. If the dose is persisted on when signs of intolerance appear, fatty degeneration of the organs may set in.

The best results recorded, within recent years, from the oral use of chaulmoogra oil are those of Ralph Hopkins (1925) of the Louisiana Leper Institution. He reported as the result of fifteen years' patient trial, a cure or improvement in 45 per cent. of 82 incipient cases and improvement in 21 per cent. of 38 advanced cases.

The oral administration of chaulmoogra is gradually getting out of the field of therapeutics. The dosage can seldom be increased to equal that of subcutaneous injection of the oil or its esters and cannot therefore be more than a palliative in this obstinate disease. Moreover, according to McDonald and Dean, oral administration with all its disadvantages is unnecessary as the results obtained by this method are decidedly inferior to those obtained by the subcutaneous or intramuscular injections of the oil or its derivatives.

Subcutaneous and intramuscular injection. The use of oil by injection appears to have been proposed first by Tourtoulis of Cairo, who in August 1899, presented the method before the Academy of Medicine and the Dermatological Society of Paris. Costel as a result of his own experience did not regard the method as one for routine employment, reserving it for excep-

tional cases. The method did not find favour for a long time on account of the pain and irritation caused at the site of the injection. An unquestionable advance was the mixture used at San Lazaro Hospital by Mercado and Heiser (1914) which consisted of chaulmoogra oil 60 c.cm., camphorated olive oil (10 per cent.) 60 c.cm., resorcin 4 gm., and ether 2.5 gm. This is mixed and dissolved over a water bath and filtered. The initial dose is 1 c.cm., increased according to tolerance. Good results have been obtained with this mixture by Mercado, Heiser and other workers. Unfortunately as it was for years prepared with crude chaulmoogra oil which is likely to contain larger quantities of fatty acids owing to decomposition, the mixture was very irritating and often caused extensive local swelling, fever and temporary disability. Naturally this militated against its intensive and long-continued use by most patients. As now prepared with refined oil of neutral reaction it is much less irritating and when used intensively seems to be giving results that are not inferior to those obtained with the ethyl ester (to be described later).

Muir has for some years used large doses of *Hydnocarpus wightiana* oil from ripe seeds with 4 per cent. creosote added as an antiseptic, both intramuscularly and subcutaneously under the skin lesion. The cheapness of the drug makes it the remedy of choice for routine use. The advantage of this product is that it is the least likely of all the drugs used to cause severe reactions.

Wilson of Korea has adopted the *H. wightiana* oil injections in preference to the esters, the Korean patients greatly preferring them on account of the absence of pain after the injections and he reports very favourable results from a trial in 300 cases. The cheapness of the whole oil is an additional advantage when a large number of poor patients have to be dealt with.

The only disadvantages of this treatment are firstly the viscosity of the oil and therefore difficulty in injection; warming the oil makes it thinner and facilitates injection. Secondly the quantity to be administered makes the export difficult.

Intravenous injection. In order to obviate the difficulty of marked irritation to the tissues resulting from intramuscular injections of chaulmoogra oil, efforts were made to introduce the drug directly into the vein. Vahram first succeeded in preparing a 'pseudo-colloidal' emulsion of chaulmoogra oil with gum arabic suitable for intravenous injection. The author recommends the first injection to be $1/4$ c.cm. progressively increased by $1/10$ c.cm. until 2 c.cm. have been given. After 20 injections given intravenously, others may be given subcutaneously. Both intravenous and subcutaneous injections may be administered every second day. Harper in Fiji (1921) began to use the crude chaulmoogra oil intravenously in doses of 15 min. daily for 6 days weekly, for months on end without ill effects. Of 40 cases so treated, all except 2 improved. The formula used for intravenous injection consisted of iodine 1, ether 250 and chaulmoogra oil 750.

According to Harper, the dosage may start with 10 min. of the above mixtures for adults and may be increased gradually to 20 min. without ill-effects. This dose is given daily for 6 days a week and may be continued for at least 5 months. Improvement in the majority of cases was recorded.

Sodium salt of fatty acids of chaulmoogra and hydnocarpus oils. Rogers (1916) working in Calcutta was able to obtain different fractions of the fatty acids and tried each one of them orally to find out the true active ingredient amongst them. Trials with gynocardic acid (gynocardic acid was originally mistaken for hydnocarpic acid, the lower-melting point fatty acid of chaulmoogra oil) showed that fractionate oil was better borne than the others and appeared to be more effective than the whole oil which contains a large quantity of almost useless palmitic acid. Gynocardic acid, however, was found to be unsuitable for injection on account of its insolubility. An attempt was made to prepare a soluble compound and in 1915 sodium gynocardate was prepared and several patients were treated with injections of watery solutions of this substance either subcutaneously or intramuscularly.

Sodium hydnocarpate. The results obtained with this salt were promising, but the injections, though much less pain-

ful than intramuscular injection of Heiser's mixture, were still painful. A 3 per cent. watery solution of the sodium salt of the fatty acids was found to be most suitable for injection purposes. Injections were given under the skin lesions on the extremities or body twice weekly in doses beginning with 0.5 c.cm. and increased by the same amount at each dose up to 5 c.cm. or more. The physician should be guided by the reaction produced in the patient as a result of the injection, *e.g.*, fever, general or local reactions in the form of swelling and softening of the skin lesions. When these reactions are manifest, the injections should be stopped for a week and the next dose reduced by 0.5 c.cm. and only increased again when no reaction ensues.

In 1916, Rogers found, by a series of animal experiments, that the same 3 per cent. solution, which was being used for subcutaneous and intramuscular injections, could as well be used intravenously. This finding opened up a new field and it was thought at the time that the great bugbear in the chaulmoogra oil treatment, namely, the question of irritation to the tissues, had at last been solved. A series of successful cases were recorded by him in 1921 by following this method of intravenous administration of sodium hydnocarpate in 3 per cent. solution. The most striking phenomenon with such injections was the occurrence of definite reaction in the diseased tissues, sometimes accompanied by fever. Later on, it was found that a weaker solution of 1 to 2 per cent. was more convenient to use and produced these untoward effects to a lesser extent. The phlebitis and blocking of the vein might be counteracted by adding a 2 per cent. solution of sodium citrate to the injection but even this was not always preventive.* Another way to avoid blocking of the vein is to mix the solution with an equal quantity of blood before injection (Muir 1927). The intravenous method, however, did not gain much popularity in view of the fact that though there was no pain, fibrous adhesions and endo-phlebitis at the site of the injection followed frequently.

Alepol. As it was observed that salts of the higher melting point fatty acids are irritant and painful, Rogers (1927)

used the sodium salts of the low-melting point fatty acids of *H. wightiana* in order to do away with this drawback. In consequence a sodium salt of the low-melting point acids has been prepared under the trade name of 'Alepol' (B. W. & Co.). Dikshit (1932) studied the pharmacological action of this drug. Its toxicity is fairly low. A 3 per cent. solution introduced into the femoral vein of cats or dogs is lethal in doses of about 0.3 gm. per kilo. of body weight. It has a selective action on acid-fast bacteria and inhibits the growth of tubercle bacilli in concentrations as low as 1 in 200,000. It also exerts a toxic action on some helminths like the micro-filaria of crows and tapeworms of cats. It has got a slight depressant action on the cardio-vascular system. Respiration is stimulated by small doses administered intravenously and the bronchioles are slightly dilated. The most important action is however on the erythrocytes. The soap has got marked hæmolytic properties, but this action can be considerably lessened by dissolving the drug in Locke's solution or by using Muir's method for giving intravenous injections of the hydnocarpates. The latter consists in withdrawing blood in the syringe containing the dose, mixing and then injecting the whole quantity intravenously. This reduces the local action on the vessel endothelium and also diminishes the hæmolytic action of the soap on the red blood cells.

This product has the great advantage of being sent out in powder form and after dissolving the amount in distilled water and sterilising, it is ready for use. Because of the ease of export and simplicity in injecting a watery solution and in addition the comparative cheapness of alepol, it is the drug of choice in countries which have to import anti-leprosy drugs. The chief drawback to the use of alepol is the pain and reaction that sometimes occur. This is due to the precipitation of the fatty acids which is likely to occur if alepol is kept for a long time or is brought into contact with concentrated acids like carbolic acid. If alepol solution is carefully prepared and if the spirit used in the sterilisation of the needles of the syringe is completely dried out, this precipitation factor and consequently the pain may be minimised to a great extent.

Ethyl esters of chaulmoogra oil. The ethyl esters of the fatty acids are liquid preparations made more fluid than the original oil and are suitable for intra-muscular injections.

Two methods are usually followed—the hot process or the rapid method, and the cold process or the slow method.

Hot process. The original method required the help of a chemist and a chemical laboratory, as it necessitated the distillation of the esters at much reduced pressure. A simpler method is as follows: 425 gm. of crude cold-drawn hydnocarpus oil, 552 c.cm. of 96 per cent. ethyl alcohol and 31.87 c.cm. of sulphuric acid (sp. gr. 1.845) are placed in a 2½ litre flask fitted with a reflux condenser; the alcohol and oil are mixed before the acid is added. The contents are allowed to boil on a water-bath for 24 hours without intermission. The reaction product is then transferred to a separating funnel and washed with water and then with 1.0 per cent. caustic soda solution; crystals of sodium chloride are then added gradually when the emulsion breaks up and esters rise to the surface. Distillation is not considered necessary now-a-days. According to Muir if the mixture is used without distillation it is less painful.

The cold process. This is a lengthy process but can be carried out in any leper institution with the most simple apparatus. The simple cold process of Muir is as follows. The oil, alcohol and acid are mixed in the proportion of 425 gm. of crude cold drawn hydnocarpus oil, 552 c.cm. of 96 per cent. ethyl alcohol and 31.87 c.cm. of sulphuric acid (sp. gr. 1.845), in a 4 lb. bottle with a tightly fitting glass stopper and left until the process of esterisation is completed, the bottle being shaken once or twice a day to mix the layers and kept in a warm place, as in the sun, to hasten the process. As it proceeds the esters rise to the top, after which occurrence half the time taken for them to rise should be allowed to elapse, when the lower layer is drawn off, and the remaining upper layer of esters washed twice with an equal volume of water and then with a 1.0 per cent. solution of caustic soda. The esters may be put up in glass-stoppered bottles or in ampoules and sterilised at 120°C for half an hour or on a water-bath at 100°C on three successive days. Antiseptics may also be added, Muir preferring 4 per cent. creosote which in Culsion treatment-tests were found to increase the value of the preparation. In the Philippines 0.5 per cent. of iodine is added by a special method which lessens the irritant properties.

These were first used on a large scale in Hawaii by Dean and McDonald (1919). In India, Ghosh (1920) independently of Dean, prepared the ethyl esters and suggested their use to Rogers. The injection of the esters of the pure acid, however,

proved somewhat irritating to the tissues of the body and Rogers discontinued its use after some time. Later, McDonald used the ethyl esters with 2 per cent. iodine by weight, with good results. Rodriguez (1925) stated that the iodized ethyl esters proved to be very efficacious and 77.3 per cent. of cases improved. This treatment soon became very popular in leper institutions. It has been used very extensively at Cullion by Lara (1930) and in Calcutta by Muir and in nearly every other active centre of leprosy treatment.

The dosage recommended in the Philippines is 2 to 5 c.cm. once a week intramuscularly. Muir mixed an equal quantity of the esters and olive oil to lessen the pain. His formula was known as the E. C. C. O. mixture and was used extensively throughout India and in the Malay peninsula at one time. It consisted of ethyl ester of fatty acids of *H. Wightiana* 1 c.cm., camphor 1 gm., creosote 1 c.cm., olive oil 2.5 c.cm. Muir used 1 c.cm. of this mixture to start with, increasing by 0.5 c.cm. at each dose twice a week up to a maximum of 10 c.cm. He injected any dose up to 4 c.cm. subcutaneously beneath the skin lesions ('plancha method'—to be described later) and any excess into the gluteal muscle. He also tried it intravenously but gave it up as less effective and less safe.

The standard preparation originally used by McDonald and Dean contained 2 per cent. iodine, but Muir showed that iodine in the mixture yields no advantage whatsoever. The addition of creosote was shown by Samson to be useful and the clinical trials are stated to yield more favourable results. The preparation known as 'Heiser's mixture' contained camphorated oil, resorcin and ether. The camphor was not reported on favourably by some but still is being used. It has been used to a considerable extent in China by Fowler (1922), Wilson (1924), Read and Feng (1925) and in many other active centres of leprosy treatment. A number of preparations of ethyl esters is available in the market, the best known of these being 'moogrol' (British), 'antileprol' (German), 'antilebrine' (Italian).

The ethyl esters, though effective are not very well tolerated especially in skin cases where they are liable to produce

reactions which are not conducive to the well being of the patient. For this reason, this remedy is now being largely replaced by the pure oil or one of the salts of hydnocarpic acid which are less active in this direction. Moreover, as the sodium salts such as alepol are now much less irritating than they formerly were, the advantages of exporting a powder compared with a fluid are so great that the esters have been largely replaced.

The intradermal or the 'plancha' method. Until recently, chaulmoogra oil and esters were most commonly injected intramuscularly, subcutaneous infiltration under the lesions (Rogers and Muir 1925) being an alternative method. The sodium salts are given intravenously as well as intramuscularly and subcutaneously. The intradermal method, formerly used occasionally by some workers, Rogers (1917), McDonald and Dean (1920), and Muir et al (1923), was first used extensively by Lara, Nicolas, Velasco et al (1929) in the Philippines who called it the *plancha* or infiltration method. The esters are injected by them into the actual lesions in the skin by means of multiple small punctures raising a wheal not more than one centimetre in diameter. Lara and Nicholas report on five early cases and one slightly more advanced case found among the children born at Cullion. Four of them became negative bacteriologically in one to two months and one in 5 months, the quickest results they know of in the literature. Nolasco (1929) found on histological examination that the remaining pathological material in infiltrated lesions was only one-half to one-fourth of that found in uninfiltrated ones. The superiority of this method is easily proved, as shown by Muir (1931). He chose patients with marked symmetrical lesions and infiltrated those on the one side of the body, leaving those on the other side as controls. Improvement was much more marked on the infiltrated side. A modified method of giving intradermal injections is described by Muir (1932). A short guarded needle is used to prevent its penetrating too far into the tissues. The actual amount of penetration is regulated, according to the thickness of the skin, by the angle at which the needle is introduced. One-half to one drop is injected at each puncture, and up to 5 c.cm. may be

injected at a sitting. The plancha method of the Philippine workers, including the infiltration of subcutaneous leproma, undoubtedly gives better results than intramuscular and subcutaneous injections, and should be adopted as far as possible.

Relative value of chaulmoogra oil and esters. The esters of chaulmoogra oil were originally made with a view to having a preparation less irritating and more easily absorbed than the oil itself. But the manufacture of oil from ripe, fresh seeds has resulted in a product which causes very little irritation, and the adoption of the intradermal method has to a certain extent done away with the need for quick absorption. The oil when injected by this method, remains longer than the esters in the infiltrated lesions, and may thus by its local action continue to produce beneficial results for a longer period. In patients with extensive lesions it may take several months before the whole affected area of the skin can be infiltrated. By intradermal injection of the oil a mild therapeutic effect can be obtained which continues for a period of several weeks in the infiltrated areas. The *H. Wightiana* oil obtainable in India, with 4 per cent. creosote added, causes on the whole no more irritation than the creosoted esters. In the Philippines it is found necessary to iodize esters in order to reduce their irritating qualities. In Calcutta, on the other hand, the esters without iodine were found less irritating than esters iodised by the method used in the Cullion Colony. This may be due to a purer form of the oil being available in Calcutta or to the method of preparation.

One disadvantage of the oil, as compared with the esters in intradermal infiltration, is that the former, being more viscous, does not penetrate the intercellular spaces as readily as the latter. This is overcome by heating the creosoted oil on a water bath to a temperature of 55°C. before drawing it into the syringe. Not more than one drop (0.06 c.cm.) should be injected at each puncture. Thus to inject 6 c.cm., which may usually be regarded as the maximum dose at a sitting, some 80 to 100 punctures should be made.

In India, the number of patients that can be treated is governed to a great extent by the expense. Recently, the

Medical Stores Dépôt, Madras, have manufactured Hydnocarpus Esters with creosote and sell at the cost price of Re. 1-3-0, a lb., to leprosy clinics. This is cheaper than the pure oil with creosote. It is easier to ensure a uniformly low standard of irritation with the esters, especially in rural dispensaries. The quality of the esters, the manufacture of which is a highly technical process, is apt to vary with the skill and experience of the makers, and a series of painful injections may frighten away patients. Where uniformly painless oil is available this is much less likely to occur. For the injection of oil a needle of a slightly larger bore is necessary. There is a great advantage with the short, guarded needles, now widely used in India (Muir 1932) as the oil passes more easily and multiple punctures can be made much more rapidly than with long needles. The relative efficacy of intradermal injection of oil and esters has not yet been fully tested, but experience up to date has shown that both are effective, and that if either of them is better than the other the difference is not great.

OTHER OILS USED IN LEPROSY

Oils with unsaturated fatty acids. In accordance with the theory mentioned in the last section, it is the unsaturated fatty acids of chaulmoogra oil (iodine value 90.7 to 104) which form the chief therapeutic factor. Various other oils of high iodine value have been tried, chief among these are cod-liver oil (iodine value 154 to 181), linseed oil (iodine value 173 to 201), soya bean oil (iodine value 137 to 143).

Rogers (1921) mentioned that all lesions had disappeared in 5 out of 20 cases treated with sodium morrhuate (prepared from cod-liver oil), as compared with similar results in 9 out of 15 patients treated with chaulmoogra preparations. This tended to show that the value of cod-liver oil preparations though considerable is not equal to that of chaulmoogra oil.

Eucalyptol. Amaral and Paranhos (1908) injected a hundred per cent. oily solution intramuscularly thrice a week. It was apt to cause diarrhoea, but satisfactory results were obtained in 70 patients, the disease being arrested and signs of intoxication diminished.

Gurjun oil. Hansen and Looft (1895) mention the use of this oil given orally in lime water without effect.

Calophyllum bigator. Neff (1929) reports good results with the injection of esters prepared from the oil of this tree, especially in relieving the nerve pain often present in lepra reaction.

HEAVY METALS

Antimony. Cawston (1920) reported decided improvement in patients with the use of a 2 per cent. solution of tartar emetic given intravenously; especially in the healing up of ulcers and absence of recurrence. Maples (1921) reported good results with tartar emetic but declared that in doses consistent with safety it does not cure. Trueherz (1927) alternated intravenous injections of tartar emetic, 2 to 3 c.cm. of a 2 per cent. solution every 4th day, with intravenous injections of antileprol, a thin preparation* of chaulmoogra oil. Hoffmann (1927) found antimony a useful drug in combination with chaulmoogra preparations, the two attacking the disease from different sides. He used von Heyden stibenyl, antimosan and stibosan intravenously. Muir (1927, 1930) advised intravenous injection of tartar emetic in doses of 0.02 to 0.04 mg. thrice a week for reducing the lepra reaction caused by iodides and in other ways.

A perusal of the above literature appears to show that antimony compounds have the power of controlling the condition known as the 'lepra reaction.'

Copper. Sugai (1916) used copper cyanide with apparent disappearance of symptoms after 6 to 12 months' treatment. Takano (1916) used cyanocuprol, 20 to 24 mgm. once a week intravenously. He stated that, unless given slowly with the patient lying down, anaphylactic symptoms may result after the 5th or a later dose. Henderson (1928) reported trials with another preparation containing 14.3 per cent. of copper. It lessened nerve pain but had little beneficial effect on the disease.

Mercury. Hansen and Looft (1895) report internal and external use of mercury resulting in patients becoming worse.

Mercurochrome. Denny (1925) injected 5 mgm. per kilo. intravenously (34 c.cm. of a 1 per cent. solution in patients of 150 lb. in 44 cases). As severe reactions followed, this had to be reduced to half the dose. Rao and Roy (1932) giving smaller doses than the above (10 c.cm. of a 1 per cent. solution) in 12 reacting cases, obtained cessation of reaction. Muir and Chatterji (1932) beginning with 3 c.cm. of a 1 per cent. solution and increasing to 10 c.cm., injections being given intravenously once a week, found that septic conditions of the skin, gums and the gastro-intestinal tract were cleared up and consequently the lepra reaction could be controlled. They, however, emphasise the danger of continued use of mercurochrome as the necrosis and liquefaction produced in the leproma tend to continue for many months and the consequent lowering of the patient's resistance cannot be controlled. As soon as the septic condition or the lepra reaction has yielded, the use of this drug should be discontinued.

Avenyl is a mercury preparation soluble (0.25 to 0.5 per cent.) in chaulmoogra oil and esters. (For further details see page 753).

Gold. Puente and Pierini (1926) used sanocrysin in doses of 0.025 to 0.5 gm. in 5 patients with slight improvement in some cases associated with diarrhoea, rise of temperature and weakness. Hoffmann (1927) obtained resolution in eye conditions with Krysolgan. Paldrock (1927, 1928, 1929 and 1930) used solganal, in combination with CO₂ snow applied to the nodules. The number of patients treated was small, 6 or 7, but Paldrock claims that his treatment is the only one which gives specific results. He also used lopion, another gold preparation, which causes loss of weight and gastro-intestinal derangement. Feldt (1928) considered that such preparations as durocantha, gold potassium cyanate, krysolgan and solganal act by stimulating the natural defensive processes of the body through the reticulo-endothelial system and thus excite the natural healing powers. Muir (1932) tried solganal in a series of cases, but found that it produced unfavourable reactions. The question of the advisability of reaction production is still unsettled, and the superiority of gold preparations over other cheaper forms of treatment would have to be well established before it could be brought into general use. The great majority of leprosy patients are very poor, while this form of treatment is necessarily very expensive.

Lead. Sandes (1913) tried the lead salts without improvement. Lead selenide injections have been tried by the Calcutta workers without benefit.

Bismuth was used by Matta (1923) in the form of trepol. No improvement was recorded.

Arsenic. Hopkins (1916) found that Fowler's solution diminished the duration and severity of lepra fever. Brault (1907) considered atoxyl more useful in leprosy than all other forms of arsenic then available. On the whole arsenic has not been found to produce any permanent good results excepting in cases complicated with syphilis.

Summary of the action of heavy metals in leprosy. Most of the heavy metals appear to have a double action. In large doses they can produce a lepra reaction, with beneficial effects in some cases, if carefully regulated and not pressed too much. In small doses they have the property of controlling or limiting lepra reaction.

MISCELLANEOUS REMEDIES

In addition to the above remedies there are a considerable number of drugs which is difficult to enumerate. Only a few of the important ones will be mentioned here.

Carbolic acid was used by Hansen (1895) in 53 cases. It produced no effect in the disease.

Sodium salicylate was considered by Danielssen (1895) as a good tonic in leprosy; 0.25 gm., dissolved in 2 c.cm. of normal saline and

injected intravenously, relieves the bone and joint pains common in leprosy.

Creosote was given orally by Hansen and Looft (1895) without effect. Muir (1925) injected it in combination with hydnocarpus esters, adding also camphor. Later (1923) he began to use it along with hydnocarpus oil and esters in a 4 per cent. solution. It decreases the viscosity of the oil, and is antifebrile, antiseptic and tonic. Samson (1923) after a well-controlled experiment with four groups obtained the best results with the cases injected with creosote dissolved in chanlmoogra esters. He found that it stimulates the appetite and causes an increase in weight.

Fibrolysin was also tried by the same worker (1928) and also by Figueredo (1929) with negative results.

Aniline dyes such as methylene blue, trypan blue, carbol fuchsin, etc., have recently been used in the treatment of leprosy by various workers. Some workers claim promising results, but it is still too soon to make any definite pronouncement.

External or local treatment. Leprosy is a systemic disease and any form of local treatment is not expected to help the condition. Local treatment, however, sometimes becomes necessary to remove the unsightly leprous nodules and speed up the absorption of the leproma. Caustics and local counter-irritants in the form of carbon dioxide snow and repeated freezing with ethyl chloride have been used from time to time. Trichloroacetic acid applications have also been employed.

Hot mineral baths have been recommended. These apparently have no useful action on the disease itself but are of benefit indirectly by improving the general nutrition of the patient.

Radio-therapy and electro-therapy. Several workers have reported beneficial results with X-rays, radium, ultra-violet rays, diathermy, etc. These methods apparently have no direct effect on the disease but are known to relieve the neuralgias and the paræsthesias so common in leprosy. With regard to the ultra-violet rays, Denney (1928) found that ultra-violet rays relieved pains and healed up perforating ulcers. Rose (1928) found ultra-violet rays combined with zinc ionization of great value in healing up perforating ulcers of many years standing. Muir (1930) found that ultra-violet rays improved the general resistance of patients to leprosy, lowered the sedimentation rate and are useful in clearing up complicating tinea and streptococcal infections which are very frequently associated with leprosy.

Irradiation of chaulmoogra oil. Hirst (1925) suggested that the effect of the chaulmoogra oil might be increased by irradiation of the oil with certain forms of sun or light rays. Labernadie (1929) irradiated *H. wightiana* oil by means of a mercury quartz lamp and added ergosterol to another sample. The number of cases treated however is too small to warrant any definite conclusions on the utility of the method.

Vaccines and serum inoculation. The discovery of the lepra bacillus and the success obtained in producing immunity in other diseases by the injection of vaccines and sera, led to various attempts at immunity production by injections of bacillary suspensions, sera, etc.

Autogenous vaccines have been used by many workers. Wooby (1907) used graded doses of lepra bacilli obtained from ground-up nodules and killed by heat. Nicholls (1908) placed a subcutaneous nodule in broth and after incubating for 14 days, dessicated the whole and powdered it in an agate mortar. A suspension was made from this and injected. Walker (1924) used a standardised suspension prepared by grinding up nodules with sand and reported promising results in the cases treated. Wayson (1921) produced bullæ by means of CO₂ snow applied over the lesions; the fluid obtained was reinjected after adding iodine. Hansen (1926) obtained bacilli in the same way from the blister fluid of lepers and injected them after incubating for 2 to 3 months. Collens (1930) prepared a bacillary suspension by triturating leprous nodules with 60 per cent. alcohol and glycerine in equal parts. This treatment was used in combination with injections of chaulmoogra esters and very good results were reported.

Vaccine treatment in leprosy is not possible if a large number of patients has to be treated for prolonged periods. Active suspensions of the leprosy bacillus can only be obtained in advanced leprosy cases with nodules all over the body and this is not always possible.

Tubercle bacilli and their products. Both the organisms of leprosy and tuberculosis are similar in that both of them have an acid-fast coating. The reputation of tuberculin as a useful agent in the treatment of tuberculosis led to the use of

this substance in leprosy. Its use however did not give satisfactory results in the hands of Danielssen (1891) ; Goldschmidt (1891) and Arnand (1896) however obtained improvement in several cases. Lie (1905) considered that the smallest doses gave the best results and that tuberculin deserved further trial. Row (1926) used suspensions of autolysed cultures of tubercle bacilli washed free from fatty substances in petrol ether. He reported favourable results by this method. The consensus of opinion at present is that tuberculins or the bacillary emulsions are not very useful.

Suspensions of acid-fast organisms. Apart from *B. tuberculosis* and its products, various acid-fast organisms and their products or extracts have been inoculated by various workers with the idea of producing a specific active immunity. Deycke and Raschid (1908) popularised a preparation (Nastin) which consisted of a killed suspension of an acid-fast organism obtained from leprous nodules. Later, they mixed this suspension with benzyl chloride, and called it 'Nastin-B'. Many workers appear to have obtained favourable results with this preparation in the earlier years. Later observations under more controlled and careful supervision showed that though some initial benefits might result, no permanent improvement was discernible.

Rost's 'leprolin' also enjoyed a temporary phase of popularity only to be cried down later.

Markianos (1930) digested rat-leprosy bacilli with pepsin and pancreatin, washed them with water and then with alcohol and then defatted. Suspensions of these organisms were injected in increasing doses into patients. Some improvements in patients thus treated were claimed by the worker.

Sera. Various attempts have been made to produce an immune sera by injection of material taken from leprous subjects or supposed cultures of lepra bacilli into horses. Results were not encouraging. Leverde (1897) inoculated sheep and goats with the juice of nodules and treated many patients with the serum without any benefit.

Autohaemotherapy. Sezaryl (1930) inoculated seven cases of leprosy subcutaneously and intravenously with their own

blood, 5 to 10 c.cm. being given at a time. Subjective symptoms and nerve pains were reported to have been diminished.

Protein shock. Muir (1923) used a suspension of Kedrow-sky's acid-fast bacillus intravenously and obtained favourable results due to the protein shock induced. Manson-Bahr (1928) gave typhoid-paratyphoid vaccine intravenously and thought that the improvement which resulted was due to the protein shock. Mixed streptococcal and staphylococcal vaccine, milk injections, etc., have also been tried. There is no doubt that the general condition of the patient is frequently very much improved by such injections. It is likely that the beneficial effects so often observed with various vaccines, sera and bacillary emulsions are due to the shock-like reaction produced by the foreign protein contained in them.

General health and leprosy. The general health of the patient has a marked influence on the course of the disease. Many leprologists have more than once emphasized the importance of the subject. Lebœuf (1914) laid stress on rest, good hygiene and good food as in tuberculosis. Muir et al (1923) considered all measures calculated to strengthen the body resistance of the patient, of supreme importance in the treatment. Wade and Rodriguez (1927) stated that exposure, improper feeding, weakening diseases and sexual over-activity were all contributory factors in lowering the resistance of the patient and in helping the rapid progress of the disease. Wilson (1929) showed the marked influence on the progress of the disease that can be produced by exercise and cheerful mental and physical occupation in his leper colony in Korea. In the Leonard Wood Memorial International Leprosy Conference held in the Philippines in 1931, experienced physicians agreed that careful and persistent efforts to eliminate intercurrent affections which tend to reduce the general resistance of the patient are essential to successful therapy. General measures, like personal hygiene, supervised or graduated physical exercise, occupational therapy, the stimulation of moral and mental welfare, are also of definite value. Diet demands the primary consideration.

Diet. Embrey (1923) carried out a large diet experiment in the Culion Leper Colony, and found that, by balancing the diet the general health of the patients improved and progress under special treatment was enhanced. The importance of diet in the causation of leprosy, and consequently in its treatment, is brought out by the extensive survey carried out by Santra (1927), which shows the bearing of famine, ill-balanced diet and badly preserved or decomposing food on the incidence of leprosy. Rodriguez (1925) states that the importance of proper diet and sufficient exercise cannot be exaggerated in the treatment of leprosy, and general tonics are of value.

The rôle of intercurrent diseases. It has already been mentioned that intercurrent diseases favour the progress of the disease by lowering the general resistance. A review of the literature however shows that in many instances complicating diseases seem to have actually benefited the condition. Thus, Denney (1922) referred to the effect of vaccination on 118 leprosy patients; there were febrile reactions in 51 out of 91 nodular cases, but they appeared to improve after the reactions passed off. Muir (1927) referred to several cases in which kala-azar complicated fairly advanced leprosy. The patients later recovered from the complicating disease under treatment and the improvement in the leprosy complicated by the kala-azar was so striking that other leprosy patients volunteered to have themselves infected with kala-azar. Pinard (1929) mentioned temporary amelioration of leprosy following an artificial infection with benign tertian malaria. Bahnia (1930) mentioned the effects of a severe attack of pneumonia; the leprosy patches cleared up so rapidly thereafter that he believed the acute febrile condition was responsible for the improvement. This beneficial effect of intercurrent diseases is therefore difficult to explain. The improvement induced in these ways is always temporary. Muir, after testing the method by inducing such diseases as malaria, kala-azar and rat-bite fever, concluded that, though the signs of leprosy may be diminished safely to a certain extent, final recovery is not possible and ultimately the disease is never improved, but always retarded, due to complicating factors.

Lepra reaction. Lepra reaction is one of the most commonly known phenomena in leprosy. In discussing the treatment of leprosy, we cannot leave aside its important relationship to the disease. The clinical signs of lepra reaction are swelling up of formerly apparent lesions, the appearance of lesions in parts where they were not formerly visible and a general febrile condition. Bacillæmia is present, at least when reaction occurs in the more advanced skin cases. In nerve leprosy, the involved nerves become swollen and painful. The lepra reaction may occur apparently spontaneously, but it is generally associated with lowering of the general health due to some accompanying disease or other causes.

Lepra reaction and leprosy treatment. Some authors are of opinion that the lepra reaction is beneficial in leprosy, while others hold that the reaction is distinctly harmful. It is very difficult to give a definite opinion on its real value as distinguished leprologists have stated entirely opposite views. Rogers (1916) writing of treatment with gynocardate of soda stated that the most striking result is the occurrence of definite local reactions in the diseased tissues, sometimes accompanied by fever. This reaction is beneficial to the patient by causing absorption of the leprous nodules. Hollmann and Dean (1919) mentioned that, with fractional esters, in all nodular cases there were local reactions at the site of leprous lesions. Denney (1922) wrote that after vaccination febrile attacks occurred, followed by improvement. McDonald (1921), on the other hand, said that reactions are manifestations of toxæmia and usually retard the progress of the disease. Rodriguez (1925) expressed an almost similar opinion, while Lara (1928) was more definite and stated that improvement was greater in cases not showing reaction and that reactions were definitely dangerous. The position therefore appears to indicate that mild reactions in healthy patients are usually attended with beneficial results but severe reactions in undernourished patients with consequent low general resistance are injurious to the disease.

For purposes of treatment lepra reaction may conveniently be divided into two types: (a) Reactions of a toxic nature which subside when the cause disappears automatically or is removed

by the treatment. (b) Reactions in which in addition to the presence of toxæmia, a sensitization factor is present. In this latter type, the reactions tend to recur at frequent intervals or may continue indefinitely. The treatment must vary according to the type. In the former type the treatment consists in removing the cause, if necessary. Thus a single dose of potassium iodide will cause a reaction which subsides in an unsensitized patient with the excretion of the drug from the body. An attack of malaria may cause a reaction which subsides after a few days of quinine administration.

In the latter type a vicious circle is formed, the depression of health caused by the reaction being sufficient to prevent its subsiding. Such a condition may continue for weeks or months, and unless effective treatment is adopted, recurs frequently, sometimes at regular fortnightly intervals. It is necessary, therefore, in addition to removing the cause, to take special means to desensitise the patient.

The fact that excessive treatment may result in the production of a lepra reaction of the second type is well-known to leprologists. The common method adopted to obviate this has been to push special drugs until signs of reaction begin to appear and then to stop treatment till the patient recovers, after which the special treatment is resumed. Ehlers (1900) and Crocker (1900) recommended intermittent courses of mercury. Heiser (1914) gave intermittent courses of chaulmoogra and resorcin. Paldrock (1928) allowed his patients a six months' interval to recover after a course of CO₂ snow and solganal before resuming the treatment.

The following references from the literature mention certain drugs which have been used for the treatment of lepra reaction.

Fowler's solution was found by Hopkins (1916) to be the best remedy for diminishing the duration and severity of lepra fever.

Alkalis have been used by many workers both orally and intravenously. Rodriguez (1925) mentions giving intravenously 20 to 25 c.cm. of a saturated solution of sodium bicarbonate daily for several days. He gave 2 to 3 gm. of sodium bicarbonate

orally 4 or 5 times a day. Roy (1931) recorded two cases of severe and intractable pain in nerve leprosy unalleviated by various other drugs, which yielded to two intravenous injections of 150 and 200 c.cm. respectively of 0.5 per cent. sodium bicarbonate in normal saline with 5 days interval. On the other hand, the patient may become worse after 20 c.cm. of the same solution.

Calcium chloride was given, as advised by Mitsuda, by Rodriguez (1925) in a 2 per cent. solution intravenously in doses of 20 to 30 c.cm. daily for a week. Hasle (1929) gave intravenous injections of 10 c.cm. of freshly prepared 2 per cent. pure calcium chloride, 15 injections in one month, and a second series after an interval of 15 days, without any ill effects; in 15 of the 20 cases treated there was healing of ulcers, softening of nodules, relief of neuralgic pains and benefit to the general health.

Adrenalin was recommended by Muir (Rogers and Muir 1925) for the relief of nerve reaction, 3 min. being given in saline solution infiltrated subcutaneously along the course of the nerve; this often gives relief within a few minutes. He also stated (1924) that two min. of 1 in 1,000 adrenalin solution mixed with 30 min. of saline and injected daily intramuscularly is often useful in stopping leprotic fever. Wheatley (1926) used this remedy in the general lepra reaction with good results. Green (1929) used adrenalin to desensitise patients. Eubanas (1931) used 1.0 to 1.5 c.cm. of a mixture containing $\frac{1}{2}$ to 1 per cent. cocaine and 5 per cent. adrenalin solution in nerve reactions. He usually obtained relief of pain after an average of 2 injections and no recurrence took place within six months.

Ephedrine sulphate was used by Muir and Chatterjee (1928) in place of adrenalin in nerve reaction. This drug has the advantage of being effective when given by the mouth in 0.02 gm. doses. Relief is often obtained within half to one hour. It may also be given in the same dose suspended in 10 c.cm. of a $\frac{1}{2}$ per cent. sodium bicarbonate solution infiltrated along the course of the painful nerve, often with almost instantaneous relief. Muir found however that in a certain proportion of cases

neither adrenalin nor ephedrine has any effect in stopping nerve reaction.

Potassium antimony tartrate is one of the most useful drugs in the control of the lepra reaction.

Mercurochrome is also valuable, especially when reaction is caused by complicating septic infection.

CHAPTER VI

TUBERCULOSIS

Tuberculosis is an infection caused by *Mycobacterium tuberculosis*. The lesions are characterised by nodular bodies, tubercles and diffuse infiltrations which either undergo caseation, necrosis and ulceration or heal with sclerosis and calcification. It is responsible for one-seventh of all deaths in the world. It has been described as the commonest, most fatal, and perhaps the saddest of those diseases which oppress mankind. It spares neither age, sex, race nor nationality. It is wide-spread amongst civilised communities. In primitive peoples living in their native countries tuberculosis either does not occur or is very uncommon. The incidence of the disease increases proportionately to the degree of crowding, as is especially common in capitals and great commercial and manufacturing towns. Tuberculosis in the human subjects takes many forms; it may be localised or more or less disseminated. In children and susceptible individuals acute generalised forms predominate, while in resistant individuals it is localised. No part of the body is immune, but such organs as the lungs in adults and bronchial glands in children have a predilection for tuberculous infection. The common conception of tuberculous infection is that it generally occurs during the early years of childhood. Pulmonary tuberculosis in the adult shows the characteristics of localisation and chronicity because it occurs in a person immunised by a mild infection in his early years. Heimbeck (1931) studied the incidence of tuberculous infection and its relation to morbidity at various ages and in various classes. He used von Pirquet's cutaneous tuberculin test and his conclusions were that in childhood only a small number is infected with tuberculosis, and the percentage increases slowly during this period of life as the children are kept at home, due to contact with cases of tuberculosis. During working life the second and great period of infection begins. It is during youth that the majority of people and all who have escaped infection

during childhood become infected. There is comparatively less morbidity during childhood and a wide-spread morbidity during the young adult period, corresponding to the time when the second period of infection occurs.

The problem of tuberculous infection in India is somewhat different from that of Europe or other countries. The infection rate in India is considerably lower than that of European countries, and this is due to the fact that the urban population in this country is 7 to 20 per cent. of the total population as compared to 80 per cent. in England and Wales, 56.2 per cent. in U.S.A. and 53.7 per cent. in Canada. India stands intermediate in position between the highly bacillized European races and the scarcely bacillized African races. The incidence of the disease varies greatly in rural and urban areas, between small and large cities, in different industrial areas, and also between various industries. Though tubercle bacilli are the essential cause of tuberculosis such factors as living conditions, nutrition, habits and customs of the people ultimately determine the susceptibility or resistance to infection. Thus in India the less immune people such as the Bhils and Gurkhas are very liable to infection when they migrate to large cities.

The following figures of the incidence of tuberculous infection in different ages among people in India as based on positive von Pirquet test will be interesting (Ukil, 1934).

Age	Incidence	Age	Incidence
0 to 5	... 11.4	21 to 25	... 50
6 to 10	... 30.1	26 to 30	... 52.7
11 to 15	... 33.3	31 to 40	... 56
16 to 20	... 38.1	41 to 50	... 59.4

Tuberculosis in human beings was previously believed to be a hereditary malady, but careful autopsies on the foetus and infection experiments with their tissues have failed to demonstrate the existence of tubercle bacilli in their organs, and it is admitted that the hereditary transmission of tuberculosis is of minor importance. The offspring of the tuberculous patients if separated immediately from their parents and guarded

against subsequent infection generally remain perfectly free from the disease. Recently, a filterable form of tubercle bacillus has been demonstrated in the placental tissue but the evidence with regard to it is not conclusive.

The organism. *Mycobacterium tuberculosis* is a minute rod-shaped organism slightly bent or curved with an average length of 3 to 4 μ . When stained it may present a beaded appearance. Aberrant forms are not uncommon, viz. long filaments or branched forms.

Tubercle bacilli may be divided by cultural and pathogenicity reactions into four types—human, bovine, avian and cold-blooded. Of these the first two only are found in natural infections of man. The frequency of the bovine and human types in different varieties of tuberculosis in patients of different ages has been worked out. It is clear that, taking all ages into consideration, the majority of infections are due to the human type. The proportion of bovine infections is highest during the first 5 years of life, and in adults, infections due to the bovine bacillus are uncommon. Pulmonary tuberculosis is almost invariably due to the human type. Primary abdominal tuberculosis is almost invariably due to the bovine type, but secondary abdominal tuberculosis which occurs most frequently as a late complication in pulmonary tuberculosis is generally due to the human type. The surgical types of tuberculosis, involving bones, joints, lymph nodes, etc., are usually caused by the bovine bacillus. It is interesting to note that pulmonary tuberculosis and surgical types are seldom found together.

Mode of infection. The majority of the cases of tuberculosis in adults and children may be attributed to infection after birth. Tubercle bacilli may enter the body through all surfaces, e.g., the skin; conjunctivæ and the lining membranes of the genito-urinary, alimentary and respiratory passages. The respiratory tract is the most frequent avenue of infection.

The picture of tuberculosis varies with the age, the susceptibility, dose and the mode of infection. It is characterised by enlargement of the lymphatic glands in children with a tendency to generalisation. Enlargement of the tracheo-bronchial lymph glands with or without involvement of the lungs is of common occurrence; most authorities believe that this is almost always secondary to a focus in the lungs. The other commonly encountered variety is that in which the mesenteric glands show tuberculous lesions which may or may not be accompanied by ulceration of the intestine. In young children tuberculous infection frequently terminates in death from generalised military tuberculosis or tuberculous meningitis. In older children who have greater powers of resistance, the lesions generally become chronic with localization in the bones, joints, skin, kidney or testes. In adults, the lungs are more frequently involved and the process extends by direct propagation with the lung and along continuous mucous surfaces.

Natural tuberculosis is a local disease in the beginning; if the person is susceptible, a tuberculous lesion develops at the site of lodgement of the bacilli. If the primary focus starts in the lungs either in a bronchiole, an infundibulum or an alveolus, a typical lesion develops with caseation and necrosis. If the focus is in a lymphoid follicle in the intestine, the nodule becomes necrotic, and caseous in the centre; it then softens and ulcerates. From the initial focus of infection the disease spreads by way of the lymphatic stream, circulation or along continuous surfaces. The lymphatic mode of spread occurs commonly in children. The bacilli lodge in the lymph glands where they form characteristic tuberculous lesions, or chains of tubercles may develop in the lymphatic vessels of the mesentery, in the lungs, in the peribronchial tissues and in other places as well. Infection passes from one set of glands to other groups or directly into the thoracic duct. When bacilli in large numbers gain entrance into the blood stream, acute miliary or chronic disseminated tuberculosis develops. The blood stream may also be invaded by an eruption into a vein or artery from a tubercle which has ulcerated into the wall of the vessel. If the number of invading bacilli is small, chronic forms of tuberculosis affecting mainly the bones, joints or kidneys result. Direct extension of tuberculous process is not infrequent. Broncho-pneumonia may result from the breaking down of a caseous gland into a bronchus; the pleura and the pericardium may be infected from a focus in the lung; tuberculosis of the kidney may lead to descending infection of the ureters and the bladder.

The mode of infection of the lungs has not been finally settled. Koch in 1884 and numerous other investigators found that the avenue of infection in pulmonary tuberculosis was the respiratory path. Calmette asserts that it is by way of the alimentary canal that the lungs are infected; he found that very much smaller doses of the bacilli are needed to produce the disease by this route than by inhalation. Most workers, however, maintain that inhalation is the principal source of pulmonary infection. Aschoff argues that in the guinea-pig, inhalation of from 5 to 20 bacilli is sufficient for the purpose, but that feeding with 20,000 bacilli may fail. According to other workers, the infection occurs chiefly through the tonsils with or without local lesions. The bacilli pass into the cervical lymph nodes, travel down this chain to the apical pleura or to glands at the root of the lung and thence into the lung substance. Though it has been shown that tubercle bacilli may pass through intact pharyngeal and intestinal mucous membrane and thus infect other organs, this mode of origin of pulmonary tuberculosis is extremely infrequent.

Clinical Varieties of Tuberculosis

(a) *Tuberculosis of the lymphatic system.* Tuberculosis of the lymph nodes is met with at all ages, but is more common in children than in adults, and may occur in old age. It may occur in the form of generalised tuberculous lymphadenitis or local tuberculous adenitis. In exceptional

instances a diffuse tuberculosis of nearly all the lymph glands of the body is met with. In infants and children there is a form of general tuberculous adenitis in which the various groups of glands are successively, more rarely simultaneously, involved and in which death is caused either by cachexia or by an acute miliary process. Glands of the neck which drain the lymph from the mouth, throat, nose, ears, and scalp are more commonly involved. Some local focus of irritation is usually present in the form of pediculi capitis, decayed teeth, chronic otorrhœa, adenoids or eczema of the face. The localised form of cervical adenitis is most common in children particularly in those whose surroundings are unhealthy and whose general conditions are deteriorated by insufficient or bad food and want of fresh air. The progress of this form of adenitis is slow and tedious; death rarely follows. The tracheo-bronchial lymph glands are almost invariably involved in cases of initial infection in tuberculosis. In children the bronchial adenitis is apt to be associated with suppuration. When the glands attain some size they give rise to various symptoms by pressing on the adjoining mediastinal structures.

In *tabes mesenterica*, the glands of the mesentery and retro-peritoneum become enlarged and caseate; more rarely they suppurate or calcify. A slight tuberculous adenitis is quite common in children and is often accidentally found (post mortem). It may be a primary lesion associated with intestinal catarrh or secondary to tuberculous disease of the intestines. In adults tuberculous disease of the mesenteric glands may occur as a primary affection or in association with pulmonary disease. It may exist with tuberculous disease in the intestines or in any other part.

(b) *Tuberculosis of the serous membranes.* These are chiefly involved, simultaneously or consecutively. It may be acute or chronic or of the form in which the tubercles are hard and fibroid, the membranes much thickened and with little or no exudate. There may be no visceral association in these cases. The pleura, pericardium and peritoneum are affected.

Pulmonary tuberculosis. Three clinical groups may be recognised (1) acute pneumonic tuberculosis; (2) chronic ulcerative tuberculosis and (3) fibroid tuberculosis.

Acute pneumonic tuberculosis. The mode of onset resembles that of lobar or lobular pneumonia, but in some cases it is not quite so sudden. In children, acute tuberculosis often follows an attack of measles or whooping cough, whereas in adults, there has usually been a pulmonary tuberculous focus for some time.

Chronic ulcerative tuberculosis. Under this heading may be grouped the great majority of cases of pulmonary tuberculosis in which the lesions proceed to ulceration and softening. The general symptoms of fever, sweating and emaciation and local signs and symptoms are characteristic.

Fibroid tuberculosis. This form may come on gradually as a sequence of chronic tuberculous broncho-pneumonia or follow a chronic tuberculous pleurisy. In other instances the process may supervene upon ordinary ulcerative tuberculosis. The disease is chronic, lasting from ten to twenty or more years during which time the patient may have fair health. Modes of death in pulmonary tuberculosis are by asthenia, asphyxia, syncope, hæmorrhage or with cerebral symptoms.

Tuberculous laryngitis. Tuberculous laryngitis is usually associated with pulmonary tuberculosis. The disease may be localised to the vocal cords, interarytenoid space, ventricular bands or epiglottis. There may be swelling, infiltration or ulceration. The posterior part of the vocal cords is most often affected.

Tuberculosis of the alimentary system.

(a) *Lips.* Tuberculosis of the lips is very rare. It occurs as a solid tuberculoma or in the form of an ulcer either alone or along with laryngeal or pulmonary disease. The ulcer is usually very sensitive and may be mistaken for a chancre or an epithelioma.

(b) *Tongue.* The disease begins by an aggregation of small granular bodies on the edge or dorsum. Ulceration proceeds, leaving an irregular sore with a distinct but uneven margin and a rough caseous base. The ulcer is very indolent and is always secondary to pulmonary or laryngeal tuberculosis.

(c) *Salivary gland.* The salivary glands seem to possess a strong immunity and very few cases have been reported.

(d) *Palate.* Tuberculosis of the hard or soft palate nearly always extends from the neighbouring parts and the lesions are usually multiple and ulcerated.

(e) *Tonsils.* There may be infection of the crypts, superficial ulceration or an infiltration with miliary tubercles.

(f) *Pharynx.* In extensive laryngeal tuberculosis, it is not very uncommon to find an eruption of miliary granules on the posterior wall of the pharynx. Adenoids of the nasopharynx may be tuberculous.

(g) *Oesophagus.* This condition is very rare, and is a pathological curiosity. Slight extension from the larynx is not infrequent.

(h) *Stomach.* Many cases are reported which are doubtful.

(i) *Intestines.* The tubercles may be primary in the mucous membrane but are more commonly secondary to disease of the lungs, and in rare cases the affection may pass from the peritoneum.

In some European countries primary intestinal tuberculosis occurs most frequently in children in whom it may be associated with enlargement and caseation of the mesenteric glands or with peritonitis but the incidence of primary intestinal tuberculosis in India is small (5.1 per cent.) because of the rarity of infection of the cows. Secondary involvement occurs in chronic pulmonary tuberculosis. The lesions are chiefly in

the ileum, cæcum and colon. The caseation and necrosis may lead to ulceration which may be very extensive. Perforation and peritonitis are not uncommon in the secondary ulceration. Extension from the peritoneum may excite tuberculous disease in the bowels. The affection may be primary in the peritoneum or extend from the tubes in women or the mesenteric glands in children.

Tuberculosis of the liver. This organ is very constantly involved in (a) miliary tuberculosis. In chronic tuberculosis miliary tubercles are not uncommon in the liver. (b) Solitary tubercle. Occasionally tuberculous masses are found, sometimes associated with perihepatitis, sometimes with tuberculous peritonitis and in children with tuberculous adenitis. (c) Tuberculosis of the bile ducts: This is the most characteristic tuberculous change in the organ and is not uncommon. (d) Tuberculous cirrhosis: In all chronic forms of tubercle in this organ there may be fibrous overgrowth. Hanot, who described several varieties, states that this condition may be primary. Practically it is very rare, except in connection with chronic tuberculous peritonitis and perihepatitis.

Tuberculosis of the brain and cord. Tuberculosis of the brain occurs as (a) an acute miliary infection causing meningitis and acute hydrocephalus; (b) as a chronic meningo-encephalitis, usually localised and containing small nodular tubercles, and (c) as the so-called solitary tubercle. In the spinal cord the same forms are found. The acute tuberculous meningitis is almost always cerebrospinal. The solitary tubercle of the cord is rare and usually secondary.

Tuberculosis of the genito-urinary system. Any part of the genito-urinary system may be invaded. The disease may be limited for a long time to the urinary or the genital tract. As a rule, only in the later stage does involvement of both systems occur.

Infection of the genito-urinary tract occurs in various ways. (a) Congenital, (b) by infection from areas of tuberculosis already existing, and (c) by infection from without. Urogenital tuberculosis is commonest between the ages of twenty and forty years. Males are affected much more frequently than females. Once the urogenital tract has been invaded, the disease is likely to spread rapidly. The lymphatics may afford a means of spreading of the disease but in the majority of cases the infection is hæmatogenous.

Kidneys. Primary tuberculosis of the kidneys is rare. In general tuberculosis the kidneys frequently present scattered miliary tubercles. In pulmonary tuberculosis it is common to find a few nodules in the substance of the organ or there may be pyelitis. In a majority of the cases the process involves the pelvis and the ureter as well, sometimes the bladder and prostate.

Ureter and bladder. This rarely occurs as a primary affection but is nearly always secondary to involvement of other parts, particularly

the kidneys. It may follow pyelonephritis or be associated with primary disease of the prostate or vesiculi seminalis.

Prostate and vesiculæ seminales. The prostate is frequently involved in tuberculosis of the urogenital system. The seminal vesicles may be involved primarily or secondarily. An extremely rare lesion is primary urethral tuberculosis. Chronic hyperplastic tuberculosis of the corpus cavernosum of the penis had also been described.

Testes and epididymes. This may be primary but more frequently is secondary to tuberculous disease elsewhere. In young children the testes proper may be involved first, but in adults the globus major of the epididymis is first affected. The lesion in the testes may heal completely or the disease may become generalised.

Fallopian tubes, ovaries and uterus. The fallopian tubes are frequently the seat of genital tuberculosis. The disease may be primary. The condition is usually bilateral. It may occur in young children. Tuberculosis of the ovary is always secondary. There may be an eruption of tubercles over the surface and an extensive involvement of the stroma with abscess formation. Tuberculosis of the uterus is very rare. It may be primary and occasionally the process extends to the vagina. Tuberculosis of the placenta is more common than has been supposed.

Tuberculosis of the mammary glands. There may be solitary or disseminated nodules, a sclerosing mastitis or caseation with abscess formation. The disease is most common between the fortieth and sixtieth years. It may be associated with tuberculous disease of the lungs, whilst a like affection may arise secondarily in the axillary glands; possibly in some cases the primary trouble lies in the glands, the breast being subsequently involved. Prognosis is not serious if total eradication of the disease is possible.

Myocardium. Miliary tubercles are sometimes met with in the acute disease. Large caseous tubercles are rare. The infection may pass from a mediastinal gland.

Endocardium. As a rule it is a secondary form, the result of a mixed infection, so common in pulmonary tuberculosis.

Arteries. Primary tuberculosis of large vessels is very rare and is usually the result of invasion from without. The disease however, may occur in larger arteries and not result from external invasion.

Chronic tuberculous endarteritis is met with in all places where tubercle is actively developing; in fact tubercles are often formed around arterioles and lead to their obliteration. The tuberculous endarteritis may however spread widely beyond the focus of mischief and in almost any portion of the pulpy granulation tissues this change can be seen.

Tuberculous disease of the bone. Bones may be affected in many ways by tubercle, the process starting either beneath the periosteum or more commonly in the cancellous tissue of the interior. The infection is secondary to disease elsewhere and the bronchial or mesenteric glands

are the commonest source of its origin. The osseous affection is often insidious in its onset and chronic in its course; it has a considerable tendency to involve the neighbouring joint and to give rise to suppuration.

Tuberculous disease of joints. This may commence either in the synovial membrane or in the articular end of the adjacent bone or it may spread to the synovial membrane from the periosteum as a result of tuberculous periostitis or from a neighbouring bursa. In children the disease commences most frequently in the epiphysis whilst in adults it may start either in the membrane or the bone with about equal frequency, but considerable variation occurs according to the particular joint affected. The disease usually commences in a most insidious manner. In the early stages with suitable treatment a complete cure may supervene with a movable joint; but later adhesions develop, with greater or lesser restriction of movement. Acute miliary tuberculosis may supervene as a complication at any time with a tuberculous affection of the lungs, brain, kidney or other viscera and may prove fatal.

Tuberculous disease of the spine. This disease most frequently occurs in children under the age of ten years; it has been shown that 60 per cent. of these cases are due to infection with the bovine type of organism in some countries of Europe; in India, bovine tuberculosis is rare. It may however occur at any age and equally in either sex. Any part of the spinal column may be involved but the lower dorsal is by far the commonest. The disease commences either as a periostitis or as osteomyelitis. Left to itself the disease usually progresses more or less steadily, the bone lesion becoming gradually more marked, and abscesses are likely to develop. If treated efficiently, repair by ankylosis may be confidently expected. As in tuberculous disease elsewhere the patient runs the risk of developing acute miliary tuberculosis. In spite of these possibilities the prognosis is good as regards life in cases free from complications and where suitable treatment is practicable.

Tuberculous disease of the skin (see skin disease).

Diagnosis. *Clinical.* In the early stage of infiltration, physical examination may fail to reveal any significant signs. Even when cavitation has occurred the signs may be absent or slight. For practical purposes more than 50 per cent. of cavities are absolutely or relatively silent, and if cavities are silent, it is obvious that areas of early infiltration may be equally so. If too much reliance is placed upon physical signs many early cases of the disease will be missed at a time when treatment might be effective.

X-ray. With great improvement in radiography the modern physician lays appropriate stress upon this as the most important method of obtaining more direct evidence. The modern skiagram shows the cardiac shadow with clearly defined margins, the compact though ragged shadows

of the glands and vessels of the lung roots, the trachea and its bifurcation, and the bronchovascular shadows spreading into the lung fields like the branches of a tree, and subdividing until as slender as silk threads they reach their terminal ramifications. The lung parenchyma between these striæ forms a delicate grey background against which any abnormality due to inflammation is easily detected. Radiology has shown that the common onset of pulmonary tuberculosis is an area of broncho-pneumonia situated below one or the other clavicle and revealed as a small area of coarse mottling in the centre of which a circular clear area may often be seen, indicating breakdown of the lung tissue with resulting cavity formation. Less commonly heavier shadows in the lower lobes reveal basal tuberculosis. Occasionally a film shows supraclavicular shadows due to apical tuberculosis, a relatively benign form tending to heal spontaneously.

Laboratory methods. Tuberculosis is one of the few diseases in which a diagnosis can often be made by microscopical examination alone. The simplest method is to stain a film of sputum, pus or other pathological product with Ziehl-Neelsen's stain. When the bacilli are present in very small numbers, attempts may be made to concentrate them by the antiformin method or by such methods as those of Faisca, Douglas and Meanwell, the last method is particularly useful for milk.

Urine should be centrifuged and films made from the deposit. With cerebro-spinal fluid it is best to allow the fluid to stand till a fibrinous clot forms; this should be removed, spread on a slide and stained in the usual manner. In both pulmonary and non-pulmonary tuberculosis the bacilli may often be found in faeces and for their detection some concentration method, such as antiformin or ligroin method should be employed. Tubercle bacilli may be found occasionally in the blood in advanced or military tuberculosis but the chances of finding them are very small indeed.

Cultivation is not often used in diagnosis but it may be useful when animal injection is impossible. The material should be obtained sterile and inoculated in Dorset's egg medium.

Animal inoculation. This is a most delicate test for the diagnosis of tuberculosis. The susceptibility of the guinea-pig to tuberculosis is extremely high, even minute amounts of infective material will cause infection in this animal. The material, sputum, pus, milk, etc., should be injected subcutaneously or intramuscularly into the thigh. In positive cases, in guinea-pigs so inoculated and killed after 3 weeks, there will be found a caseous local lesion, enlargement and caseation of the inguinal, sublumbar and portal glands and necrotic areas in the spleen and liver. It is advisable to inoculate two animals at the same time. If no signs of tuberculosis are apparent in the animal killed after 3 weeks the other should be kept 6 weeks after inoculation before being killed. In cases

of doubt, the suspected material or one of the glands mashed up in saline should be injected into a fresh animal.

Tuberculin tests. The two common methods are the single puncture method and the intradermal method of Mantoux. *The single puncture method.* Undiluted Koch's old tuberculin (O.T.) is used in this test. With ordinary aseptic precautions, a puncture about 3/16 inch deep is made on the anterior surface of the forearm with a sterile hypodermic needle, previously dipped in the concentrated old tuberculin solution. This introduces about 0.25 mgm. of tuberculin into the skin. A control puncture may be similarly made with another sterile hypodermic needle, a little away from the original one. The reaction following the puncture usually appears in two to four days. When positive, an area of erythema and œdema appears over the site where tuberculin was injected. *The intradermal tuberculin test of Mantoux.* Old tuberculin (O.T.) is also used in this test in dilutions of 1 in 10; 1 in 100; 1 in 1,000; 1 in 10,000 and 1 in 20,000. The skin of the anterior aspect of the forearm is sterilised with absolute alcohol and with a sterile 1 c.cm. tuberculin syringe, 0.1 c.cm. (0.1 mgm.) of old tuberculin (1 in 1,000) is injected intradermally. The initial dose in cases of recent hæmoptysis, cutaneous and joint tuberculosis, should not exceed 0.1 c.cm. of 1 in 10,000 (0.01 mgm.) old tuberculin. In positive reactions, an erythema extending to about 1 cm. develops in two to four days. Severe reactions result in swelling and even necrosis of the injected part. When positive reactions are obtained with higher dilutions, injections of stronger solutions of old tuberculin should be attempted to obtain similar reactions. The use of a solution stronger than 1 in 10 is not advisable.

The tuberculin reaction is a reliable test for hypersensitiveness to tubercle toxin and indicates past or present tuberculous infection. To exclude all tuberculosis, a negative reaction with a strong solution as with 0.1 c.cm. of 1 in 10 old tuberculin, is of proved value in clinical diagnosis. In children, a negative reaction excludes tuberculous adenitis, on the other hand the diagnosis of active tuberculosis with a positive reaction in a child under two years of age is suggestive. With complete calcification of tuberculous foci and destruction of the bacilli, the tuberculin reaction may be negative. King (1932) maintains that 90 per cent. of those showing a positive reaction to 0.1 c.cm. of 1 in 20,000 O.T. (0.005 mgm.) or smaller amounts have active clinical tuberculosis while those having arrested infection require large doses to show a reaction. Hart (1932) finds that patients suffering from latent bone and joint tuberculosis show reactions to minimal doses of tuberculin and that some patients with advanced disease require large doses to produce a positive tuberculin reaction. A positive Mantoux reaction, with indefinite physical signs in a child usually suggests some active focus of infection.

The determination of the *opsonic index* was introduced by Sir Almroth Wright as a method of diagnosis of tuberculosis. This is based on the estimation of the relative quantity of opsonin present in the serum of the suspected person as compared with that observed in healthy individuals. In man, in a certain proportion of early cases of pulmonary tuberculosis, the opsonic index might be low (a fact of diagnostic importance), while in other patients in this stage the index might be within normal limits. The results are variable and cannot be relied on.

The *complement fixation test* has been used with positive results in many cases of pulmonary tuberculosis, but on the whole the results do not give any indication as to the activity of the tuberculous process.

Serological tests. These methods of diagnosis are not satisfactory. The general consensus of opinion is that as methods of diagnosis they are unreliable. Many persons with tuberculosis fail to react while others who appear perfectly well do react.

The sedimentation of the red corpuscles of the blood has been studied in tuberculosis. Its rapidity is said to be increased in active pulmonary tuberculosis, and more so in the caseating and exudative types than in the fibrotic type of the disease. The sedimentation test assists in estimating the activity of or arrest of pulmonary tuberculosis, but is of doubtful value as a diagnostic test.

Prophylaxis. The preventive measures which are necessary to stamp out the disease might fall into three main categories: (i) Children with predisposition to tuberculosis need special care in their upbringing and such occupations should be chosen for them when they reach the age of puberty that they keep themselves in open air. (ii) Two great sources of tubercle bacillus are the sputa from infected cases and tuberculous milk; the latter is practically negligible so far as India is concerned. The former is a public as well as a private concern and all open cases should be isolated; this alone is an effective means of stamping out the disease. (iii) The third factor which resolves into a series of sociological questions lies in bad hygienic and economic conditions of life. Proper education and health propaganda will help the former question a good deal but unless the economical conditions of life improve very little gain can be achieved in this line.

The use of various types of antituberculosis vaccine is still in the experimental stage. Many attempts have been made to obtain satisfactory immunity by inoculation with human or bovine bacilli attenuated in various ways. Calmette advocated

a vaccine (B.C.G.) of a living culture attenuated by growth in bile, but immunization with B.C.G. vaccine cannot as yet be said to have established its claim as a preventive in man.

Treatment of pulmonary tuberculosis. The treatment is here considered mainly from the point of tuberculous affection of the lungs as this is the most commonly encountered clinical manifestation of tuberculosis. The treatment of other forms is more or less on the same principle. The tuberculous affections which need manipulative or surgical interference have not been dealt with.

General measures. Tuberculosis though a deadly disease is a curable disease if treatment is taken in hand early. Some are cured naturally without even realising that they have had tuberculosis. Sanatorium treatment in the true sense of the word and the increased use of collapse therapy and surgical treatment have increased the number of what are to all practical purposes 'cures' of tuberculosis. But people still die of tuberculosis and the demand still continues for a radical method of healing.

In the days when the early pathology of the disease was not properly studied and pulmonary tuberculosis was diagnosed only in its later stages, the treatment of consumption was based almost entirely on rest, open air, sunshine and nourishment, in which nature played the predominant part. This traditional routine is applied to all cases. Treatment is controlled by accurate temperature and pulse record; meals should be regular and ample. A total caloric value of 3,000 to 3,500 is usually required.

A liberal mixed dietary should be given, and solid food may be eaten during the febrile period. No attempts at over-feeding should be made. The Gersos-Hermandorfer diet, which has been widely used in Germany has not proved so successful in pulmonary tuberculosis as in the tuberculosis of skin and other tissues.

The essentials of this diet system are sufficient fresh vegetables, fruits and vegetable juices (uncooked), fresh milk (one pint or more daily), sour milk, eggs, especially the yolk; salt, fresh meat foods, oat meal and farinaceous foods should be

given in restricted amounts. The regime also includes two medicinal preparations ; mineralogen, a special blend of mineral salts of vegetable origin and a phosphoric acid and cod-liver oil preparation, both being administered thrice daily. Rest is the keynote, for the better the rest the better the chance of recovery. When the diurnal swing of the temperature does not exceed one degree and its acme be not above 98.6 and the pulse rate does not exceed 86, the patient is allowed up for one hour, and hour is added to hour until the patient is up for four hours when he is given some work (occupational therapy). Symptomatic treatment is given as required in a particular case.

Sanatorium treatment. This is recommended to suitable cases after the preliminary treatment but is totally unsuited for acute febrile or very active cases. The patient is kept under skilled medical supervision, his immunity being increased by food, fresh air, rest and exercise. His habits are changed under strict discipline. On arrival of a new-comer to a sanatorium he is kept in bed for a few days in order that his resting temperature may be observed and necessary examinations carried out. If there is pyrexia, rest is enforced till the temperature returns to normal. Then the system of graduated exercises is resorted to. After three months' stay it is usually possible to decide whether the patient is responding to treatment and if so, it should be prolonged for at least another three months or until the sputum is free from tubercle bacilli. During convalescence advice has to be given as to the best climate which will suit individual patients most, whether at home or abroad. One should clearly understand that it is not necessary to go abroad to be cured of tuberculosis.

Requisites of a good sanatorium. Sanatoria in India are of recent growth, the first one having been started at Almora in the year 1908. The plains in most parts of India being warm, it was thought that more elevated regions of the country would afford patients' protection from the deleterious effects of excessive heat on the tuberculous process. In a recent study made at Madanapalle Sanatorium (2,500 feet) it was found that the progress towards recovery was hampered during the summer and was favoured during the winter. During the last two decades, sufficient experience has been gathered in India as regards the benefit of a suitable climate in assisting patients towards recovery.

For achieving good results, selection of the site must be made after considering many important factors. It must be remembered that a modern sanatorium is no longer a home for rest-cure but is a hospital situated in a good climate and equipped with adequate facilities for the latest methods of diagnosis, treatment, recreation, and industrial and vocational training. Authorities with extensive experience of Indian conditions are of the opinion that the best altitude for Indian patients for applying sanatorium treatment is between 2,500 and 4,000 feet above sea level. The altitudes of some of the sanatoria in India are ; Bhowali in U. P., 6,000 ft.; Hill Crest in U. P., 5,000 ft.; Dharampur in the Punjab, 5,000 ft. ; Belair (Panchgani) in Satara, 4,500 ft. ; Madanapalle in Madras, 2,500 ft. ; Itki in Behar, 2,300 ft.

Having found a suitable altitude, the next point which should engage attention is the climate, *i.e.*, rainfall, humidity, the minimum and maximum temperature, the direction of winds and the presence of dust, mist and smoke in the atmosphere. The experience of Indian workers seems to favour a place where the patients from the plains can stay throughout the year, which is neither too wet nor too dry, and which is neither too warm nor too cold. The soil should be dry and the site sheltered with an abundance of pure, fresh air. A sanatorium should not be near a town or a factory, as dust from such places is likely to increase the tendency to useless coughing.

In 1931-32, of the patients admitted into the Madanpalle Sanatorium 95.7 per cent. of early and moderately advanced cases improved, and the disease was arrested in 84 per cent. of early cases and 30.6 per cent. of moderately advanced cases. From a study of the after-histories of over 2,000 patients discharged from this sanatorium, it has been shown that 51 per cent. of them were alive for 5 years after discharge and 46.5 per cent. were doing full work. We consider this a very satisfactory result under Indian conditions and one which compares very favourably with that in Europe.

Artificial pneumothorax. The first great advancement in the radical treatment of pulmonary tuberculosis was in the last decade of the nineteenth century when Forlanini in Italy and Murphy in America devised *collapse therapy* for the treatment of pulmonary tuberculosis. The introduction of air in the pleural cavity was practised over two thousand years ago by Hippocrates and the modern idea of introduction of air into the pleural cavity as a therapeutic measure in certain pulmonary affections was first held by Carson of Liverpool as far back as 1822. Forlanini in 1882 gave it a practical shape and the method of collapse therapy by artificial pneumothorax is now recognised all over the world as one of the best in the

treatment of certain cases (about 5 per cent.) of pulmonary tuberculosis. The therapy is of particular value in certain cases of pulmonary tuberculosis, bronchiectasis, localised abscess of lung and interlobar empyema. It has also been adopted for the relief of pain in dry pleurisy and for broncho-pneumonia in children. Its induction in pulmonary tuberculosis is advisable in cases of unilateral disease which remains pyrexial after absolute rest in bed for about a month, in hæmoptysis which cannot be checked by ordinary methods, in unilateral acute pneumonic tuberculosis and in certain carefully selected cases of bilateral disease. The principles underlying this treatment are rest, evacuation of the septic material which has collected in the cavities and bronchial tubes, and hastening the fibrotic process. The contra-indications to artificial pneumothorax are active bilateral disease, asthma, fibroid lung and visceral complications.

Technique. The apparatus commonly employed in the procedure consists of two glass bottles, one of which is graduated from 0 c.cm. to 1,100 c.cm., a glass manometer, a four-way glass connection, glass filters, glass tubes, rubber tubes and the pneumothorax needle. Riviere No. 1 needle, generally used for primary induction, consists of a blunt cannula with a thin edge for penetrating the pleura and a trocar for piercing the tissues of the chest wall. No. 2 needles are employed for refilling purposes. The whole apparatus should be sterilised before use. The glass manometer is filled with coloured water up to the mark zero. The glass bottles are filled half their volumes with coloured solution of perchloride of mercury (1 in 1,000). The patient should be lying near the edge of the bed with a pillow under the chest and shoulder to widen the intercostal spaces. About half an hour before the operation, the patient should be given an injection of morphia ($\frac{1}{4}$ gr.) to prevent pleural shock. The site of puncture should be the sixth intercostal space in the anterior axillary line. The skin of the region is made aseptic with absolute alcohol or tincture of iodine. A 2 per cent. novocaine solution is injected through the intercostal space right down to the pleura to prevent pleural shock. The patient should be warned against coughing during the operation. With the trocar in position, the No. 1 pneumothorax needle is pushed in through the anaesthetised spot for about 1 c.cm. or less if the patient is thin and emaciated. The trocar is then withdrawn and the cannula pushed through, down to the para. Oscillations in the fluid column of the manometer indicate the contact of the cannula with the parietal pleura. The cannula is then pushed into the pleural cavity, avoiding damage to the lung tissues. The fluid level in the manometer now falls below zero and the

oscillations are synchronous with respirations. The oscillations should be at least 3 to 6 cm. and are often as much as 10 cm. ; each cm. of fall of fluid in the manometer corresponds with a change of pressure in the pleural cavity of 2 cm. of water. By opening the clips attached to the rubber tubes, air is slowly admitted into the pleural cavity. Even when as much as 300 c.cm. of air has been introduced into the pleural cavity, the manometer still records a negative pressure. The needle is then withdrawn and the punctured site may be sealed with collodion and cotton wool. If cough is distressing, a large pad and a firm chest binder may be used to minimise extravasation of air into the extrapleural spaces. The amount of air in primary induction and the subsequent amount in refills depend in all cases on the personal factor of the patient. Usually the second refill is undertaken two days after the first and the third three days after the second. The interval of subsequent refills is gradually lengthened to a week, ten days, a fortnight and so on. About 400 to 500 c.cm. of air will suffice for a first refill otherwise a high intrapleural pressure might result in mediastinal displacement of viscera. Variations of the pulse, temperature and body weight should be recorded to judge the effects of collapse therapy. Radiograms are often essential to determine the degree of pulmonary collapse. Pleural shock, surgical emphysema, gas embolism in vessels, intrapleural effusions with subsequent pleural adhesions are the common complications in collapse therapy.

Oleothorax has been recently introduced with advantage. The oil used consists of liquid paraffin or olive oil containing oil of gomenol (2 per cent.) Indications of oleothorax are :—(1) pleurisy complicating pneumothorax, (2) obliterative pneumothorax or incomplete collapse of the lung, (3) as a substitute for pneumothorax and (4) pleuropulmonary perforations.

Apicolysis is a process in which localised collapse of the upper part of the lung is produced by separating the lung and the adherent pleural layers from the upper chest wall. It was much advocated in the past, particularly by German surgeons, but the results are not satisfactory.

Collapse therapy by *phrenic avulsion* has been practised during recent years with considerable success. This is the operation of removing the phrenic nerve in its entirety. The idea is to paralyse the diaphragm which then rises steadily for at least four months to a variable height. The collapse after phrenicotomy is not however as complete as in complete pneumothorax. It has the advantage however of being applicable in cases of pleural adhesion when air cannot be introduced into the pleural cavity.

Another surgical method of treatment of pulmonary tuberculosis is thoracoplasty. This may be partial or complete according to the number of ribs removed. Removal of ribs allows the softer parts of the chest wall to fall in thereby giving rest to the affected lung which

is gradually collapsed. Thoracoplasty must not be done too early nor yet too late and never as a last resort. It should be recommended in suitable cases when artificial pneumothorax is impracticable and phrenic avulsion is insufficient. Cutting the adhesions by thoracoscopy is not in vogue at the present time.

Chemotherapy. During recent years chemotherapy has been attempted in pulmonary tuberculosis. The striking efficacy of arseno-benzene preparations in the treatment of syphilis has stimulated much research work to find a preparation of heavy metal which will be equally potent in tuberculosis. There are two main difficulties in the chemotherapy of tuberculosis, (1) the devascularised character of the tuberculous foci, and (2) the resistant nature of the tubercle bacilli to penetration of the cell substance by chemicals. The power of the tubercle bacilli to resist the action of chemicals is well known. Though this is true, the fact that tuberculous lesions may undergo calcification by deposition of lime salts indicates that these foci are penetrated in some cases by substances in solution. By vital staining method the presence of such dyestuffs as trypan red or trypan blue has been demonstrated in the tubercle. Potassium iodide was found to enter freely into tubercles when injected. DeWitt working with various dyes showed that methylene blue penetrated the tuberculous focus and even stained the tubercle bacilli within it but it had no bactericidal property. Later, a series of investigations were carried out by various workers to find an actively bactericidal substance which would penetrate into the interior of the tubercles. Koch, so far back as 1890, showed that gold cyanide in high dilution would inhibit the growth of tubercle bacillus *in vitro* but was of no therapeutic value in the living animal. Chaulmoogra oil was found to inhibit the growth of the bacillus *in vitro* as gold did, but in clinical practice it had no demonstrable value. The same is true of sodium morrhuate which is often used in doses of 0.5 to 1 c.cm. of a 3 per cent. solution by injections. Cerium, manganese, cadmium, mercury and copper have been tried without success.

Gold. Koch (1890) showed that compounds of gold prevented the growth of tubercle bacilli in culture and gold-potassium-cyanide was for some time successfully used in

the treatment of lupus. Only the inorganic salts of gold were used in therapeutics till Feldt (1916) introduced a complex organic compound of gold which he named 'krysolgan' and more recently 'solganal,' an aromatic compound containing 36.5 per cent. of gold has been introduced. Mollgaard (1924) used 'sanocrysin,' an inorganic salt of gold, in the treatment of pulmonary tuberculosis with beneficial results. Simultaneously, other workers in France and Germany applied aurotherapy in the treatment of arthritis. Since then krysolgan, solganal and other salts of gold have been extensively used in the treatment of pulmonary tuberculosis, lupus erythematosus, leprosy and various streptococcal infections.

Pharmacological action. Like all other heavy metals, gold is a protoplasmic poison and the soluble salts of the metal possess bactericidal properties. The metallic salts such as the chloride, have irritating properties and cannot therefore be used on injured surfaces. Metallic gold, even in colloidal form is apparently not absorbed from the gastrointestinal tract, and when the soluble compounds are given by the mouth, only small traces are absorbed. After injection of a soluble salt, absorption is complete and rapid. Elimination is slow and occurs chiefly through the kidneys and to a lesser extent through the intestine and bronchial mucous membrane. Experimentally nephritis has been produced in rabbits by the injection of relatively large amounts of gold and in man, acute nephritis with all its symptoms has been produced by the use of gold compounds. When given by injection, gold can be recovered from the stool and there may be ulceration of the stomach and upper bowel as a result of its elimination through these organs. The part of gold that is absorbed is retained in the tissues for a long time. In experimental animals the bulk of the absorbed metal can be demonstrated in the spleen, the liver coming next in order.

Gold is much less toxic than most of the heavy metals. Neutral preparations are apparently not at all poisonous when given by the mouth. When given by injection, gold may produce erythematous, morbilliform and urticarial rashes. Solganal and especially solganal-oleosum is said to be much less toxic than other gold preparations. The general toxic effects resemble those of arsenic and both acute and chronic forms of poisoning are known.

Certain other effects of gold therapy have been observed in man. Initially there is improvement in appetite, digestion and general sense of well-being. Large doses may produce abdominal pain and distension with elevation of temperature and nervous excitement. Tendency to bronchitis, during gold therapy, has also been observed.

Therapeutic uses. The investigations of Mollgaard (1924) placed gold salts on a permanent therapeutic basis. He reported successful results following the intravenous injections of sodium-auro-thiosulphate, better known as sanocrysin. A certain amount of success in the treatment of pulmonary tuberculosis was obtained and the early cases of open infection of the lungs improved rapidly, but advanced cases did not stand the treatment well. It is claimed that gold penetrates the lipoid substance of the the bacillus, gets into its body, kills and dissolves the protoplasm, at the same time producing direct immunising effects. There is no direct evidence to show however that these compounds are able to destroy tubercle bacilli, and even in such concentration as 1 in 2,500 in human blood, the tubercle bacillus grows just as well as when none is present. It should be remembered that tubercle bacilli are intra-cellular and are therefore less accessible to the action of drugs.

The most difficult point in gold therapy is the regulation of the dosage. The doses should be gradually increased, care being taken that the reaction caused by the previous dose has subsided. The reactions to gold therapy vary considerably in different individuals and it is necessary to find the optimum dose in each individual case. In some cases gold salts produce certain secondary effects such as fever, epigastric pain, rash and albuminuria; they are therefore contraindicated in renal and intestinal tuberculosis and also in advanced cases of pulmonary tuberculosis.

The following are some of the compounds of gold which have been used in the treatment of tuberculosis.

Sanocrysin. It is an inorganic gold compound containing the negatively charged ion ' $\text{Au}(\text{S}_2\text{O}_3)_2^-$ ' to which its therapeutic properties are due. It is very soluble in water, diffuses rapidly, is stable and decomposes slowly in the body. The dosage of sanocrysin, as now employed, is to give it in gradually progressive doses, beginning with 0.01 gm. intravenously and increasing it to 0.025, 0.05, 0.1, 0.15, 0.2, 0.25, 0.3, 0.35, 0.4 and 0.5 gm. at weekly intervals. As soon as a dosage of 0.5 gm. has been reached it is inadvisable to increase it in Indian patients. In all cases the dosage should be regulated with respect to temperature, general condition and pulse of the patient, until a total of 4 to 5 gm. of sanocrysin has been given.

Toxic symptoms have been noticed after injections of sanocrysin in tuberculous patients. These consist of sudden rise of temperature with malaise and sometimes rigor. The urine on examination may reveal albumin but it is transient and soon passes off. Vomiting and diarrhoea may occur and among other signs that have been observed are skin rashes, neuritis, oedema of the face and eyelids. In order to avoid these toxic effects it is better to begin the treatment with small doses and at longer intervals. If, in any case, a reaction occurs the treatment should be suspended for the time being, and restarted with the original dose when all the symptoms have subsided.

The class of case that responds favourably to sanocrysin treatment is the exudative forms of tuberculosis with very little exudation. The exudative type and acute cases do not react at all well to treatment. The effects produced in favourable cases are complete disappearance of tubercle bacilli from the sputum, a general improvement in the clinical picture of the case with marked lowering of the temperature. Many favourable results have been published with regard to the effect of the drug in lowering the mortality in tuberculous cases. Clarke in 1929 found that after sanocrysin treatment of tuberculosis, the mortality rate was considerably reduced among the treated compared with the cases who had not received the drug. Heap (1929) also obtained encouraging results in patients of good physique with no involvement of the intestine. It seems therefore that the drug is effective in early cases and in patients of good physique, but in advanced cases and in intestinal tuberculosis it is a failure.

Solganal and *solganal B* are described as di-sodium derivative of p-sulphomethylamino-o-auromer-capto-benzene-sulphonic acid, containing 36.5 per cent. gold. Treatment is commenced with small doses; 0.01 gm. in cases where there is no fever and if there is a temperature the dose should be reduced to 0.0001 gm.; later the doses are increased gradually, two injections being given weekly. Laryngeal tuberculosis has also been successfully treated with the salt. Recently *solganal-B-oleosum*, an oily preparation of *solganal-B* has been introduced. It is said to form a deposit in the muscles and hence prolong the absorption of the gold. *Krysolgan* contains 60 per cent. gold, the indications for its use are as in the case of the gold salts generally. *Lopion*, another gold preparation, has the same action and uses.

Mode of action in tuberculosis. The way in which gold acts in tuberculosis is not known. It has been shown that dilute solutions of gold inhibit the growth of tubercle bacilli, but the addition of animal serum minimises the effect. Thus Sweany and Wasick (1925) working with sanocrysin showed that there was complete inhibition of tubercle bacilli in dilution up to 1 in 200,000, partial inhibition in 1 in 500,000 and slight inhibition in 1 in 1,000,000; but in strains of recently isolated bacilli, growth took place in dilution of 1 in 20,000. On addition of serum, the bacilli grew well in dilution of 1 in 1,000 of sanocrysin in

salt solution. Fry (1926) showed that sanocrysin in a dilution of 1 in 2,500 in normal human or ox blood, did not in any way alter the growth of tubercle bacilli *in vitro*. Similarly it has been found that tubercle bacilli grow just as well as in the plasma of patients after a dose of sanocrysin as in plasma drawn before the dose. It is, therefore, obvious that gold does not act directly on the tubercle bacilli either *in vitro* or *in vivo*, and therefore some other factors must be operating in the process. Davies (1933) states that gold may act in tuberculosis by stimulating some defensive mechanism in the patient, most probably the cells of the reticulo-endothelial system. It is well known that these cells have a great phagocytic power and gold by stimulating the reticulo-endothelial system increases the power of the body tissues to combat infection. In support of this, Feldt has shown that the action of solganal is greatly diminished by injection of substances which block the cells of the reticulo-endothelial system and by excision of the spleen.

Calcium. Calcium is largely used in the treatment of pulmonary tuberculosis either by the mouth, intramuscularly or by the intravenous route. The frequent use of calcium is based on the idea that the calcium content of the blood is low in tuberculosis and that this favours the growth and activity of tubercle bacilli. Careful experiments both in the laboratory and clinically on human beings have shown that calcium does not influence the course of tuberculosis. Even when large amounts of calcium chloride are injected intravenously the rise in blood calcium is temporary. The use of calcium has however been favourably reported upon in intestinal tuberculosis. An intravenous injection of 5 c.cm. of a 5 per cent. solution gives prompt relief in pain and discomfort when they are due to dietetic indiscretion or catarrhal condition of the bowel. When however the intestinal symptoms are due to extensive ulceration, amyloid infiltration or localized peritonitis and peritoneal adhesions, the chances of relief of symptoms are remote.

Tuberculin. Tuberculin was introduced by Koch for the treatment of tuberculous infection in man. An enormous number of different varieties of tuberculin have since been prepared; they can be divided into five main classes:—(1) Concentrated filtrate of old broth cultures, (2) suspension of the bacilli, (3) preparations containing modified tubercle bacilli, (4) living attenuated cultures of the organisms and (5) preparations containing non-human types of the bacilli.

The name tuberculin should be strictly applied to filtrates of broth cultures, and tubercle vaccine to preparations of actual bacilli. The most important constituent of the former is a toxic body or antigen distinct from the antigens of the bacillary body. If tuberculin is used the patient is desensitized to the toxic agent contained in tuberculin while with tubercle vaccine immunity is produced against the bacilli.

Old tuberculin (Koch) is made from human or bovine strains; the bacilli are grown in glycerin veal broth in large containers and then incubated at 37°C; their contents are then strained through muslin or

paper-filters and the material evaporated to one tenth of its original volume. The tuberculin may then be heated to 100°C., the unconcentrated filtrate is sometimes used and known as T. O. A. The other important type of tuberculin is the bacillary emulsion (B. E.). Koch prepared B. E. by grinding living bacilli until all were killed, and this material emulsified in saline and diluted constitutes B. F. Some constituents of the tubercle bacillus have been shown to be toxic for animals, and many attempts have been made to eliminate the toxic material by extraction with acetone and digestion of the bacilli with trypsin, or with preliminary treatment with formalin. These preparations have, however, not been found to possess any advantage over those of the whole bacilli.

The success of treatment with tuberculin lies in the proper selection of the dose and of the interval between the doses. In the early days large doses of tuberculin were administered, but this had to be abandoned owing to toxic reactions and generalization of tuberculosis following such procedure. Tuberculin is now administered in so small a dosage initially that no reaction is produced; the dose is then repeated at short intervals and increased gradually so that no reactions occur. Wright and his followers advocate a scheme of dosage dependent on the changes produced in the opsonic content of the serum following injection of tuberculin. According to this scheme the dose depends upon the condition of the patient. If the patient is seriously ill, the dose must be small and should be frequently repeated, while if the lesion is circumscribed large doses may be given. The initial dose in cases of localised affections such as adenitis and arthritis is 0.00001 mgm. of tuberculin repeated at weekly intervals. Tuberculin is only given now-a-days to cases of the productive form of tuberculosis with a minimum amount of toxæmia, *e.g.*, tuberculous affections of the lymph glands.

The following general scheme of dosage is recommended.—

1st dose	1/4000	million of a milligram
2nd "	1/2000	" " "
3rd "	1/1000	" " "
4th "	1/500	" " "
5th "	1/200	" " "
given twice weekly,				
6th dose	1/100	" " "
7th "	1/50	" " "

at weekly intervals.

Doses in individual cases should, however, be modified according to the reaction produced.

The increase of the dose depends entirely upon the individual as well as the maximum quantity of the final dose. The relation of the quantity

of the final dose to the benefit derived from the treatment has not been worked out.

No patient should be given tuberculin who cannot follow this treatment for at least five months, although shorter courses seem to be of some benefit. In the more advanced stages a longer duration is required.

Symptomatic treatment. Besides the above treatments certain complications call for special treatment. The most important are (a) *Cough*. Certain amount of effort on the part of the patient aided by a sedative linctus containing syrup of phosphate of codeine or hydrochloride of heroin is all that is mostly needed to check the ineffective dry cough. If there is much secretion expectoration can be helped by sodium chloride 3 gr., sodium bicarbonate 5 gr., spirit of chloroform 5 min., and water to 1 oz., in 1 oz. of hot water. Night sweats may be distressing; the bed clothes should be light and the windows kept well open at night. A pill containing oxide of zinc 2 gr., and dry extract of belladonna $\frac{1}{4}$ gr. at night should be tried or subcutaneous injection of accoline 0.02 gm. once or twice daily. When the sweat occurs the patient should be sponged with toilet vinegar, the night clothes changed and a warm drink given. (b) *Hæmoptysis*. In the case of hæmoptysis if it is known from which side the blood is coming, to prevent the infected blood from being aspirated into the healthy lung, the patient should be inclined slightly to that side and propped up in a semi-recumbent position. Normal horse serum 10 c.cm. intramuscularly or 10 c.cm. of 10 per cent. solution of calcium chloride intravenously should be injected to stop the bleeding. Later, calcium should be given by the mouth. If the bleeding is severe and the patient cannot be calmed, a hypodermic injection of sulphate of morphine $\frac{1}{4}$ gr. should be given immediately. The morphine may be given up to a dose of 1 gr. within 24 hours if the bleeding still persists. When the bleeding cannot otherwise be controlled endeavour should be made to collapse the affected lung by artificial pneumothorax. All food should be taken cold and an aperient of sulphate of magnesia in 2 dr. doses should be given.

(c) *Diarrhæa*. This may result from irritation of the food, from toxæmia and amyloid degeneration or from tuberculous ulceration of the intestines. The diet should be reduced and consist chiefly of milk. Vitamins should be administered in the form of cod-liver oil $\frac{1}{2}$ oz. or other standard vitamin A and D preparations and tomato juice about 9 oz. a day. Lead and opium pill 4 gr. thrice daily or starch and opium enema can also be used for the relief of the symptoms.

For increasing the weight cod-liver oil and malt 1 dr. thrice daily after food may be given and with the hope of aiding the healing process in the lungs, collosol calcium and calcium chloride are recommended.

CHAPTER VII

VIRUS DISEASES

Loeffler and Frosch (1892) discovered that when fluid from a vesicle in foot-and-mouth disease of animals is diluted and filtered through porcelain candles which hold back all visible bacteria, the filtrate retains its infective power unimpaired. Microscopic examination of the filtrate failed to reveal a micro-organism ; cultures on ordinary media also failed. This work was further supported by Iwanswsky and Beijerinck and thus was established the existence of a new class of infective agents. Many names have been given to the agent but none is entirely satisfactory. They have been designated as invisible microbes, ultramicroscopic viruses, inframicrobes, microplasms, strongyloplasms, chlamydozoa and filterable viruses. The name filterable virus has become the most commonly employed term, but since some of the genuine examples of the class are not filterable, and some other microbes, though filterable, are not viruses (*e.g.*, leptospira), it would be preferable to omit the word filterable and use the term virus as applicable only to this class of organism.

The viruses multiply illimitably in the tissues of an affected animal, but with the exception of the organisms of bovine pleuro-pneumonia the viruses have not so far been cultivated in a medium completely free from living tissue cells. The simplest theory of the nature of viruses is that they are living organisms. Stanley (1935) has succeeded in separating from the juice of Turkish tobacco plants, a crystalline protein having the properties of tobacco-mosaic virus. This substance produces typical tobacco-mosaic disease on inoculation into tobacco plants. At present there is no reliable information as to the size of the viruses.

Most of the viruses are relatively resistant to the action of 50 per cent. glycerol, differing in this respect from most of the visible microbes. Like ordinary bacteria all viruses are destroyed at high temperature. Phenol in 1 to 2 per cent. strength destroys many of them.

Some virus diseases, *e.g.*, small-pox, are extremely contagious while others like poliomyelitis are of low infectivity. They may occur in an epidemic form. The transmission of infection from the sick to the

healthy by means of insect vectors, including lice, ticks, mosquitoes, sandflies, mites and plant aphides, is illustrated by such diseases as typhus and trench fever (lice), Rocky Mountain fever (ticks), tsutsugamushi disease (larval mites), pappataci fever (sandflies), dengue (mosquitoes) and the plant mosaics (aphides). The epidemiology of certain forms of virus disease remains yet obscure. In herpes simplex, the most commonly held view is that the virus, while normally present, becomes active and produces its characteristic lesions only when the natural resistance of the body is reduced by some intercurrent infection (*e.g.*, pneumonia, common cold, etc.). A similar view has been held with regard to encephalitic sequelæ of measles, chicken-pox and vaccination against small-pox. Season plays some part in the epidemiology of virus diseases. For example, poliomyelitis is common in late summer while encephalitis prevails in the spring months.

The cell changes produced by viruses in the course of their interaction with the host tissues are variable. Within certain cells infected with some filterable viruses there occur atypical bodies or granulations, which are known as 'cell inclusions' or 'virus bodies'; such formation of inclusion bodies is characteristic in certain diseases, for example, Guarnieri bodies in small-pox and Negri bodies in rabies.

Immunity. An effective and lasting immunity has been found to develop after an attack of certain virus diseases, such as small-pox, chicken-pox, mumps, etc. The immunity in the great majority of cases appears to last throughout life, but in some diseases, *e.g.*, herpes simplex and influenza, this immunity is not well-developed. Certain essential differences are said to exist between infections with a virus and bacterial infections, but it is probable that the mechanism of virus infection does not materially differ from that in bacterial diseases. Andrewes and others (1931) noted that in experimentally infected animals the virus of foot-and-mouth disease of cattle does not appear in the blood before the commencement of the febrile reaction, and after that it persists in the blood throughout the febrile period. Yellow fever virus has been shown to appear in the blood of monkeys 1 to 2 days after infection. The virus of vaccinia has been recovered from the blood after intradermal inoculation in the rabbit; similar investigations with highly potent strains of virus show that a generalised vaccinia may occur after dermal inoculations with a widespread eruption on the lips, tongue and in the internal organs. In certain respects, however, the virus diseases differ from bacterial infections; they have a tendency to localise in certain parts and to produce characteristic inclusion bodies in certain cells which have a marked bearing on the nature of immunity development.

Immunity to virus diseases may be active or passive. A passive immunity conferred by the administration of an antiserum prepared

from an animal is usually of short duration. Attempts have been made to confer immunity in virus diseases with the use of convalescent human serum, but the results are not as yet satisfactory. An active immunity on the other hand is nearly always produced by an attack of the disease, or it may be artificially induced. The latter is produced by the injection of a sublethal dose of living virulent virus, or a virus that has changed its character during adaptation to a different host, or a fully attenuated virus followed by injection of less and less attenuated virus until virulent virus can be given. Immunity can also be successfully produced by the injection of the killed virus; an example of this nature is Semple's carbolyzed vaccine used in rabies. Similarly there are records of successful immunization against many virus diseases in animals with vaccine containing dead virus, such as phenolized vaccine against cattle plague, formolized vaccine in foot-and-mouth disease of cattle, and against herpes and psittacosis by injection of formolized virus. It has been argued that the protection afforded by inactivated virus is temporary, but evidence at hand indicates that the injection of inactivated virus confers some degree of immunity if the method of preparation of vaccine is efficient. There is general agreement that certain methods of killing, such as subjecting to high temperature, may remove the antigenic value of some of the viruses. The usual method at present adopted is to give the living virus after partially immunizing the patient either with inactivated virus or with an antiserum. For the latter an effective method is the so-called site-to-site inoculation with virus and antiserum, that is, virus into one site and serum into another. Successful vaccination is generally indicated by a generalized reaction. It may also be produced by administering the antiserum after the injection of the living virus, and this is the method adopted at the present time in the prophylaxis of measles.

The mechanism of antiviral immunity is imperfectly understood. The fate of a virus when introduced into an immune animal is not known. Experiments so far made go to show that the viruses concerned in the production of diseases have special affinity for some tissues and are found there in greatest number. Vaccinia virus is found in the highest concentration in the lymph of the pustules, the virus of foot-and-mouth disease in the fluid of the vesicles, the virus of rabies or poliomyelitis in the central nervous system. In immunized animals the injection of a pathogenic virus is not followed by characteristic signs of infection, because of the virucidal property of the blood. In experimental vaccinia in rabbits specific antibodies have been found to appear in the plasma as early as the third day after infection; in case of yellow fever simultaneous presence of virus and protective antibodies in the blood has been observed on the 4th and 5th days of the disease. Analogous observations have been made with regard to many virus

diseases which indicate that there exists a definite clearing mechanism in the blood of all immunized and partially immunized animals.

The nature of the reaction that occurs in the blood in the production of immunity is still controversial. Most of our knowledge in this connection is derived from the work that has been done with vaccinia virus. The virus-containing material from the pocks of variola or vaccinia may give specific complement fixation or visible precipitation reactions *in vitro* with the serum of an immunized rabbit. Ledingham (1931) showed that the tissues of animals infected with vaccinia contain minute granules, the Paschen bodies, which are capable of agglutination by immune serum. Other investigations on this line have been carried out. Thus specific complement fixation with herpes virus and anti-herpes serum, with foot-and-mouth virus and the corresponding antiserum, with yellow fever virus and convalescent human serum, has been demonstrated by various workers. There is no doubt that both in an attack of virus disease in man and experimentally infected animals specific antibodies are produced. These antibodies form a sort of loose combination with the filterable viruses, but attain stability after a lapse of time and appear to be confined to the globulin fractions. A specific cellular immunity has also been suggested to explain the mechanism of antiviral immunity. In addition, as the reticulo-endothelial system is intimately concerned with the pathogenesis of virus diseases, it seems probable that it also plays an important part in the immunity production.

A scientific classification of the filterable viruses is hardly possible for want of knowledge of the essential biological characters of the members of the group, their mutual affinities and relationships. Our present knowledge is indirect, being finally expressed in terms of their pathogenic effects or the reactions they produce on their hosts. Joseph Fine has given a satisfactory classification on epidemiological and pathological grounds.

A. Diseases in which the virus possesses an intermediate host. They fall under two groups:—

(1) The yellow fever group, including (a) yellow fever, (b) dengue and (c) sandfly fever.

(2) The typhus group, including (a) typhus (*Rickettsia prowazeki*), (b) Rocky Mountain spotted fever (*Dermacentroxenus rickettsiæ*), (c) tick typhus, (d) trench fever (*Rickettsia quintana*) and tsutsugamushi fever.

B. Diseases in which the viruses are transmitted directly. They fall under four groups:—

(1) The dermatropic group (affecting the skin or the mucous membrane only):—the viruses of (a) warts, (b) molluscum contagiosum and (c) trachoma.

(2) The neuro-dermotropic group (affecting the skin and capable of

affecting nervous system).:—the virus of (a) herpes zoster, (b) varicella and (c) small-pox.

(3) The neurotropic group (affecting the nervous system only):—the viruses of (a) acute anterior poliomyelitis, (b) acute disseminated encephalo-myelitis, (c) rabies, (d) encephalitis lethargica and (e) disseminated sclerosis(?).

(4) The respiratory group (affecting the respiratory tract):—the viruses of (a) measles, (b) mumps, (c) influenza, (d) common cold (?) and (e) psittacosis.

TYPHUS AND ALLIED FEVERS

Typhus fever is an acute infectious disease, and is considered to be caused by *Rickettsia prowazeki*. Many typhus-like fevers have been described. Megaw suggests classifying the typhus group of fevers in the following way according to the nature of the transmitting agents:—(1) louse-borne typhus or typhus exanthematicus; (2) tick-borne typhus or Rocky Mountain fever. In India and many other places there is a typhus-like fever closely resembling Rocky Mountain fever. (3) Mite-borne typhus or Japanese river fever, which contrary to the idea suggested by the name, occurs in many localities of the Far East.

Rickettsia. The name Rickettsia has been used generically for certain minute bodies which are found in the gut of the infected lice. Da Rocha Lima proposed the name in honour of Ricketts, who first called attention to these bodies, and Prowazek, who further studied them. The name is also used for other very similar bodies, *R. quintana*, found in lice taken from trench fever patients and the species present in ticks infected with the virus of Rocky Mountain fever. The resemblances among these three species of rickettsia are very striking. Each of them is associated with a definite disease in man and is found in enormous numbers in the arthropoid host. In each species the size of rickettsia is very small, $0.5\ \mu$ or less in diameter. They are non-motile, Gram-negative and stain feebly with aniline dyes, but can be coloured by prolonged use of weak Giemsa stain. *R. quintana* is found free in the lumen of the gut, *R. prowazeki* in the lining cells and the lumen of the midgut of pediculi and the rickettsia of the Rocky Mountain fever is present in the cells and lumen of the gut and other parts of the infected tick. The use of the name rickettsia has been extended to include minute forms found in many parasitic insects and arachnids. Many of these are, however, not pathogenic.

Da Rocha Lima (1916-19) made a careful study of the condition governing the appearance of rickettsia in lice and the association of these bodies with the virus. He maintained that rickettsia was a living microbe which was present in the blood but was unrecognizable microscopically. The presence of typhus virus in a louse can usually be detected by examining films of the midgut and its contents for *R. prowazeki*. The virus and the rickettsia are so constantly associated that it is an almost inevitable assumption that the virus is identical with the rickettsia. A louse which contains numerous *R. prowazeki* has always been found infective unless the louse has been dead some time, or both the virus and rickettsia have been killed as the result of treatment by heat, drying, or perhaps sometimes by the action of bacteria in the louse. *R. prowazeki*, like the virus, is not found in lice unless sufficient time has elapsed since they were first fed on the infected blood and kept at a suitable temperature.

TYPHUS FEVER OR TYPHUS EXANTHEMATICUS

Typhus fever is a louse-borne infection. It is a febrile affection which lasts for ten to fifteen days with a peculiar rash appearing on the body between the third to the fifth day. Though it is principally conveyed from man to man by the agency of the lice, other vectors may also play a part in its transmission. The disease is of great antiquity and is probably identical with many of the plagues described by the older writers.

A distinct advance as to the nature of the disease was made by Nicolle and Conseil (1910) who were successful in conveying the disease to monkeys by lice previously fed on typhus patients and they also successfully conveyed the disease from monkey to monkey and from rabbit to rabbit by inoculation with the blood of the infected animals. Ricketts and Wilder (1910) described rickettsia bodies as the causative organisms of the disease and later Da Rocha Lima fully worked out the nature of these organisms.

Nicolle showed that in typhus fever the blood is only infective during pyrexia and for one or two days later. Attempts to obtain active virus in filtrates have been usually unsuccessful. Feigin (1927) claims that at certain stages of its development the virus can pass through a filter.

It has been shown that after an infective meal the louse does not become infective for 7 to 10 days. The virus is much more concentrated in the louse than in the infected blood. The mode of entry of the virus from the infected louse has been the subject of controversy. Nicolle, Blanc and Conseil (1916) showed that the excreta of infected lice was highly infective, and Bacon and Arkwright (1923) concluded that the

mechanism of infection was by the contamination of a scratch with the lice excreta; they considered the bite an unlikely source of infection.

Active immunity is invariably established after an attack of the disease. The duration of immunity varies; in guinea-pigs it lasts a year or longer. Da Rocha Lima (1918), Weil and Breinl (1924) produced active immunity in animals by means of dead louse virus. Passive immunity can be conferred by convalescent serum after the febrile attack.

The agglutination test was first employed by Wilson, a modification of which is now commonly known as the *Weil-Felix test*. It is very reliable in most cases. This is carried out in the same way as the *Widal test*, but the organism which is used is *Proteus X 19*, which strangely enough has no association with the disease. A positive reaction in dilution of 1 in 100 is diagnostic. The reactions remain positive in dilutions of 1 in 50 or over for about 3 months.

TICK TYPHUS

(Rocky Mountain Spotted fever)

A few cases of typhus-like disease transmitted by the bite of ticks have been recorded by Megaw. This disease resembles Rocky mountain spotted fever, which occurs in the Bitter Root Valley of Montana and the neighbouring mountainous parts of Idaho, Wyoming and Nevada. As the tick typhus of India has not been thoroughly studied, the classical Rocky Mountain spotted fever will be described in detail.

Rocky Mountain spotted fever closely resembles typhus fever but the tendency to hæmorrhage and gangrene is greater in this disease. It is transmitted to man by the bite of the wood-tick, *Dermacentor venustus*, though contact of the skin with the contents of a crushed tick may cause infection. In the wood-tick the virus is transmitted from larvæ to nymph, from nymph to adult and from the adult through the eggs to the next generation. The natural hosts and reservoirs of the virus are certain rodents on which the immature ticks feed. The rabbit-tick *Hæmaphysalis leporis-palustris* also plays an important part in the dissemination of the virus.

The organisms commonly accepted as the cause of the disease are rickettsial bodies described by Ricketts and Wolbach. They are present in the blood of infected men, monkeys and guinea-pigs, and in the salivary glands, alimentary sacs, oviducts and eggs of ticks.

These organisms are known as *Dermacentroxenus rickettsi*. The virus does not pass through a Berkefeld filter and is destroyed at a temperature of 50°C; defibrinated blood remains infective for 12 days if kept at a temperature of 10°C. A period of some five days must elapse before a tick is capable of transmitting the disease after a feed of infected animals. Tick virus is more penetrating than mammalian virus and it can pass through unbroken skin. Guinea-pigs are easily infected by the inoculation of blood and by bites of infected ticks. White rats and monkeys are susceptible but domestic rabbits are not susceptible. Natural immunity is unknown but artificial immunity can be produced with a potent vaccine prepared from infected ticks but not from vaccine prepared from mammalian virus. Though rickettsial bodies have up till now been accepted as the cause of the disease, many workers have failed to find any correlation between the numbers of the rickettsial bodies and the concentration of the virus in the tissues. They conclude that *Dermacentroxenus rickettsi* probably represents only one of the several phases of the infecting agent.

Tick typhus of India. In India Megaw (1921) described a typhus-like fever which he believed to be due to the bite of a tick and later he described many cases presenting symptoms like typhus fever among men exposed to tick bites. The incubation period of the disease varies from one to three weeks, the temperature continues for twelve to sixteen days ending by lysis. The Weil-Felix reaction is variable and is usually of low titre. There is a striking resemblance between the Rocky Mountain fever and the tick typhus of India and the latter may be regarded as closely allied to it, if not identical. The points of dissimilarity between the tick typhus of India and Rocky Mountain fever are that in the former the spleen is rarely enlarged, albuminuria and jaundice are not seen, and that inoculation experiments fail to transmit the disease to guinea-pigs.

MITE TYPHUS

(Japanese River fever, Kedani disease or Tsutsugamushi disease)

This disease presents symptoms closely resembling those of typhus and is believed to be caused by rickettsia bodies. It has been known for a long time in Japan, being particularly prevalent during the summer and along the course of certain rivers. An identical though milder form of the disease occurs in Sumatra, Malay States and the typhus-like fever described by Ghosh in India and the *fièvre exanthématique* of the Mediterranean are probably of similar nature.

The disease is conveyed by the larvæ of certain mites, chiefly *Trombicula akamushi*; the adult mite is infected from wild rats and mice, the virus being transmitted to their larvæ which are capable of infecting human beings. The natural reservoirs are the wild rodents in which the virus persists throughout the winter though they may not show any symptom. Monkeys and rats can be experimentally infected by blood or tissues and also by the bites of mites or inoculation of their crushed bodies. In man natural infection occurs from the bite of mites; a sore develops at the site and is followed by a fever of 2 or 3 weeks' duration, enlargement of the neighbouring glands, a typhus-like rash, and leucopenia. The chief histological change is an increase of lymphocytes around the arterioles in the deeper layers of the corium. There are no specific changes in the internal organs. The virus occurs in the blood, lymphatic glands and in the mononuclear endothelial cells of the spleen, but it disappears early in convalescence. Plasma and serum do not contain the virus, and Kawamura (1923) reported that the polymorphonuclear cells remained infective even after repeated washing. It has not been shown to pass a filter. The causative organism is closely related to the Rickettsia bodies occurring in Rocky Mountain fever, and Sellards proposed the name of *R. nipponica* for it. Hayashi (1920) observed characteristic intracellular bodies at the site of the ulcer in man, and called them *Theileria tsutsugamushi*. There is no cross immunity between this disease and typhus. The Weil-Felix reaction is usually negative but is sometimes positive in low titre with non-indologenic strains. No immunity seems to have developed after an attack, though repeated attacks have been known to render the subsequent infections less severe.

As the prophylaxis and treatment of the typhus group of fevers are conducted on the same principles, they may be considered together.

Prophylaxis. The prevention of typhus fever lies in measures adopted to avoid being bitten by lice. The body lice can be destroyed by thorough cleansing with a cresol bath. The clothes and dressings of the infected person should be sterilised; this can be done by exposing them to bright sunlight, by boiling or by the use of disinfectant lotions, such as, cresols and other coal-tar compounds; soaking in 2 per cent. lysol destroys both the pediculi and their eggs. A practical method of killing lice and their eggs is to expose them to a temperature of 55° C. for half an hour. Disinfection of the clothes on a large scale may be accomplished by super-heated

steam. It is also important to get rid of lice from the hair and bodies of those infected.

Vaccine. Attempts have been made to successfully vaccinate man against typhus fever. Though the typhus vaccine is yet in the experimental stage, the results so far reported appear to be encouraging. One method of vaccination consists in giving inactivated typhus blood. The blood of a patient in the acute stage of the disease is defibrinated and then incubated for about half an hour at 58°C. This is injected in doses of 1, 2 and 5 c.cm. at intervals of four to five days and is said to afford protection. Blanc and others (1933) prepared a vaccine with a living virus. The virus utilised in their experiments was a rat-typhus virus of low virulence. Several volunteers were inoculated with this virus and a mild reaction resulted. When later inoculated with a dose of the same virus there was no reaction at all. By treating the virus with ox-bile it was still further attenuated, although still active it produced a slight febrile reaction in man; those vaccinated were later shown to be immune to injections with epidemic typhus virus. Lice fed on these protected people did not become infected either after the immunising dose or the test dose, i.e., they did not become carriers of the germ.

Weigl has prepared a vaccine which has given good results in typhus fever. It is prepared by infecting lice with the blood of a case of acute typhus or from the blood or organs of an infected guinea-pig. The lice usually succumb to the infection in 9 to 10 days. The intestine is removed in a sterile manner, ground up in normal saline and a small quantity of 0.5 per cent. carbolic acid added. The dose is approximately 150 intestines per man divided into three doses. Weigl's vaccine has been largely used in Poland, some 6,000 persons have been inoculated. Of those who had received three doses of the vaccine none developed typhus although all were exposed to infection. Missionaries in China have also been successfully protected by this vaccine.

Weigl's vaccine affords protection to those inoculated and in some cases such people develop the disease, they

have a mild attack and are no danger to others since the virus is not present in the peripheral blood. Subsequent to the preparation of Weigl's vaccine, other workers prepared a modified form of this vaccine. Chrzanowski and Mosing (1933) found that rickettsia remains in the excreta of lice for very long periods. At first they used the excreta of lice which, however, produced a severe reaction and was therefore discarded. The method now employed is to emulsify the excreta in 0.5 per cent. carbol saline. A thick emulsion is formed which is centrifuged lightly and the supernatant fluid containing the rickettsia pipetted off; this is then centrifuged again at a high speed, the rickettsia is thrown down and the supernatant fluid drawn off; the sediment is then washed several times until a suspension of pure rickettsia is obtained. This vaccine compares very favourably with Weigl's original intestinal vaccine and produces just as good immunity. The employment of this vaccine will probably effect large economies both in time and personnel.

In case of typhus-like fever caused by the bite of a tick, avoidance of the bite is the best preventive. The infected part may be cauterized. Preventive vaccination is successful only in mild types of the disease; unfortunately the protection lasts for a short period.

With regard to mite-borne infection it is known that the virus is never transmitted from man to man. Cleanliness is of primary importance; destruction of field-mice and rats which harbour the infection should be undertaken whenever there is an outbreak. The field labourers should dust their bodies with sulphur powder to keep away the mites. Disinfectant lotions may be sprayed over them. A mixture of cajuput oil and tobacco juice, smeared on the skin is a good preventive. The body and clothes should be immediately washed on leaving the infected area. Special clothing may be worn.

Treatment. *Typhus fever.* The treatment of the disease is on the same line as typhoid fever. Strict attention should be paid to general hygiene, care of the mouth, and nutritious and easily digestible food should be given. The patient should be

in a recumbent posture and care taken to prevent any bed sores developing. Cardiac stimulants such as camphor and caffeine may be indicated. There is no specific drug known which is effective. Muhlens tried novasurol and reports that intravenous injection of novasurol in doses of 1 c.cm. in 1 per cent. solution appears to shorten the period of illness. Convalescent serum has been shown to have a curative effect in typhus fever. In experimental animals, such as guinea-pigs, the action of the convalescent serum (usually 10 days after the fever had ceased) is said to be specific. Jelin (1933) found that the effect was more marked when the serum was given early and in large doses, for instance, 24 to 48 hours after the injection of the infective material into guinea-pigs. The normal human serum, however, has little or no effect, while curiously enough, normal sheep serum possesses curative properties. Following the good results obtained with convalescent serum in animals, this has been used successfully in human cases. The only difficulty lies in obtaining a sufficient quantity of serum from human beings.

Serum from convalescent patients should be given in doses of 20 to 50 c.cm. It is said to lessen the severity of symptoms without having any effect on the duration of the illness. Nicolle's serum consists of serum from horses which have been immunised against the virus by injection of emulsions of spleen and adrenals of infected animals. It has given good results when given early in the disease. This serum has been tried intrathetically.

Rocky Mountain fever. The treatment is conducted on general principles as for typhus fever. Convalescent serum may be tried. Among the drugs used mercurochrome has been injected intravenously in 1 per cent. solution.

Japanese river fever (mite typhus). The treatment is on the same line as louse-borne typhus. Arsenical preparations such as salvarsan have been tried but have been found ineffective. Serum from cattle which have recovered from an attack, may prove beneficial.

INFLUENZA

Influenza is an acute infectious disease of disputed ætiology, characterised by fever, prostration, liability to pulmonary complications and to epidemic incidence.

There are several theories with regard to the ætiology of this disease. The earliest theory proposes Pfeiffer's bacillus as the cause of the disease. Experimental evidence has been advanced to show that Pfeiffer's bacillus is the cause of influenza. Blake and Cecil (1920) sprayed the nose and throat of 12 monkeys with cultures with partially successful result; but experiments on man have been less successful. This bacillus is, however, a very widely-distributed organism, and has been found in measles, tuberculosis, broncho-pneumonia and lobar pneumonia. It has been found in the healthy throats in 30 per cent. of cases in a series of students during non-epidemic times. Though it may be said that the virulence of Pfeiffer's bacillus may undergo periodic variations, evidence in favour of Pfeiffer's bacillus as the cause of the world epidemic of influenza in 1918 is very scanty. In the early stages of the epidemic Kristenson found this bacillus in very few cases, while Ledingham could not isolate it from any of his cases in Mesopotamia. In the later stages Pfeiffer's bacillus was commonly found, but this is the time when complications are frequently met with. Opie and others found that pneumococci and hæmolytic streptococci were even more prevalent than Pfeiffer's influenza bacillus.

Other theories embrace the view that influenza is caused by a mycotic organism, which has been found in the sputum, lungs, urine, blood and faeces in different types of cases. The organism appears to pass through various stages, coccal and bacillary forms, and at times shows the formation of spores.

That the disease is due to a filterable virus was first shown by Nicolle and Lebaillly (1918), who reproduced the infection in volunteers and in monkeys by the subcutaneous and intravenous inoculation of influenzal sputum passed through a Chamberland filter. These results were later confirmed by other workers. Filtrates of blood from influenza patients were also infective. Olitsky and Gates showed that the filter-passer was of the nature of a visible cultivable organism. A minute Gram-negative coccobacillus called *Bact. pneumosintes* was grown anaerobically and recovered only in the early stages of influenza in man and from the lungs of rabbits experimentally infected by filtrates of early influenzal sputum. This organism was not obtained in the normal throat, in non-influenzal conditions or in the later stages of influenza. Other workers failed to isolate this organism and found it in the healthy throat. It has been suggested that *Bact. pneumosintes* is not very pathogenic itself, but may favour secondary invasion by

Pfeiffer's bacillus and many other organisms, *e.g.*, streptococci, etc., by lowering local resistance in the respiratory tract.

In recent years, evidence is again accumulating to implicate a filterable virus element in the causation of influenza. Dochez reproduced typical colds both in chimpanzees and human beings by means of the filtered nasopharyngeal washings from natural cases. Andrewes and Oakley (1933) had a like success in human volunteers with filtered nasal washings from patients with colds. Smith et al. (1933) produced in ferrets, fever and nasal catarrh by the intranasal instillation of filtrates of throat washings of influenza patients. Convalescent influenza serum was found to contain antibodies which prevented the disease in ferrets. This view receives strong support from the experimental work of Shope who found that a filterable virus is the essential factor in the causation of swine influenza. Though Shope's virus by itself produces a mild and transitory illness, association with *H. influenza* gives a complete picture of influenza. It seems that in epidemic influenza in man a filterable virus is closely associated. In certain cases this infection may facilitate the invasion of the body by many visible bacteria giving rise to various complications.

The disease tends to occur in pandemics about every 10 to 40 years, and in epidemics about every 9 months. The disease spreads with great rapidity and affects different strata of the population in different epidemics. In the 1889 pandemic, infants and old people were affected, whereas in 1918, young adults were chiefly the victims. The disease spreads with great rapidity.

The following clinical types should be recognised, and the treatment should, therefore, vary accordingly. The mild type is characterised by fever, pain all over the body, lassitude and sometimes epistaxis and vomiting. The severe or the respiratory type includes cases of pneumonia. The onset is like that of the mild type and pulmonary complications set in usually from the fifth day of the disease. A peculiar heliotrope cyanosis occurs in certain cases. The mortality rate is high in these cases (about 40 per cent.). The gastro-intestinal type of the disease is marked by vomiting, diarrhoea with blood in the stools; the fever when it persists is generally slight. The cerebral type of influenza is rare and is characterised by high fever, delirium generally of a low muttering type and ending in coma.

Prophylaxis. Owing to the fact that the causative agent of the disease is still unknown and its mode of transmission is not understood, complete success in prevention is not possible. It should be understood that the disease spreads rapidly by transfer of the infecting agent from one person to another. In an epidemic the virulence of the causative organism may be heightened during its passage from host to host. Isolation of

the patients should be practised wherever possible. Overcrowding increases the danger of infection as it favours transfer of the infected material and is the most potent cause in the spread of epidemic. Generally speaking the best course to adopt is to pursue a regular healthy life avoiding excesses of any kind.

The prophylactic treatment with drugs is without effect. Vaccines have been tried to prevent an attack, especially among children. In view of the fact that secondary bacterial invasions take place in the upper respiratory tract, efforts have been made to mitigate the severity and cut down the number of these infections by employing a vaccine composed of the visible pathogenic organisms. This is a simple antigenic mixture consisting of heat-killed cultures of pneumococci, *M. influenzae* and *Streptococcus hæmolyticus*. This is given at weekly intervals over a long period of time, about 8 to 10 injections being given before the winter and a similar number after it. This vaccination, though it has not been proved to be effective in preventing an attack, is claimed to have the power of reducing the severity of infection in those vaccinated. Other measures have from time to time been advocated, such as excess of vitamin A and D in the diet and irradiation with ultra-violet rays, but they do not in any way seem to diminish the chances of infection.

The Committee on the Preventive Measures of the Public Health Services, America, are of opinion that the following precautionary measures and practices of personal hygiene may be advantageous in the prevention of this communicable affection of the upper respiratory tract. (a) Crowds should always be avoided thereby lessening the chances of direct contact infection. (b) Any public assemblage or school and college need not be closed down, but they should be under strict medical inspection and any person or persons showing suspicious symptoms of the upper respiratory tract infection should be promptly isolated and no visitor should be allowed in such institutions and isolated communities. (c) Cleanly personal habits, and avoidance of all such acts as coughing, sneezing or spitting should always be strictly observed. Hands should be washed thoroughly before eating particularly by those who attend the sick. Adequate sleep and rest, avoidance of exposure to fatigue and any bodily excess, eating a moderate mixed diet and partaking freely of a sufficient amount of pure water, are measures to increase the general well-being of an individual. On these points of personal hygiene the prevention of such diseases depends.

Treatment. It is essential for the patient to take to bed early, as there seems to be a greater liability to pneumonic involvement in those who do not take early rest. The bed should be placed well away from the walls and the room should be large and well ventilated. Neglect of fresh air not only hinders recovery in the presence of pulmonary complications, but also tends to induce them. Fresh air is the most important factor in the treatment of influenza.

In the early stage the diet should consist of fluids only, later easily digestible solids are given. The patient is sponged regularly with tepid water. An initial dose of calomel followed by a saline purge should be given in all cases.

There is no specific drug for this malady. Dover's powder 10 gr. with aspirin 5 gr., at the onset, often relieves the early coryza. Quinine salicylate in 3 gr. doses, thrice daily, is helpful. A diaphoretic mixture with sodium salicylate is given for fever and pains. When the cough is troublesome local applications on the chest, throat paints and sedative mixtures are often of service. Inhalation of compound tincture of benzoin is very useful; failing this a spray containing chloretone and menthol, 2 per cent. of each, in liquid paraffin, may be used. In intractable cases relief may follow from the administration of a mixture containing syrup of chloral $\frac{1}{2}$ dr., ammonium bromide 20 gr., liquid extract of glycyrrhiza 20 min., in repeated doses.

Treatment is mainly dependent on symptoms and complications as they arise. The common complications are sinusitis, otitis media, mastoiditis, bronchitis and broncho-pneumonia. These should be treated on the usual lines. If pneumonia is due to type-I pneumococcus, anti-pneumococcal serum may be of service; convalescent serum has also been tried in these cases. The serum appears to have a specific effect in that the temperature begins to fall and there is considerable amelioration of symptoms. Many workers who used the serum, report rapid improvement in the general condition of the patient together with rapid resolution of the pneumonic condition. The usual procedure is to remove some blood by venesection and to inject

10 to 20 c.cm. of the convalescent serum intravenously ; this may have to be repeated. Cardiac stimulants should be started early if required.

Some authorities give antistreptococcus serum early in the disease in all bad cases, with favourable results. Besides these, many experimental methods of treatment were exploited during the pandemic of 1918-19, including various antiseptics intravenously but no remedy has yet been found successful.

Auto-hæmotherapy has also been recommended, 10 c.cm. of blood being injected intramuscularly and repeated twice. The occurrence of nervous complications should be recognised early. If symptoms of meningitis develop immune serum should be given. The convalescence should be carefully managed as relapses are frequent. Good food, fresh air, and tonics are indicated after recovery from illness.

DENGUE

This disease, also known as dandy fever and breakbone fever, occurs in many parts of the world. Dengue is characterised by a sudden onset, a diphasic febrile course lasting for 3 to 8 days, headache, severe pain in the body and limbs and rash. From time to time dengue fever assumes an epidemic form. It is caused by an ultramicroscopic filterable virus transmitted by the mosquito *Aedes ægypti*. It is not transmitted by *Culex fatigans*, the common culicine species.

Evidence has been produced to show that the disease is caused by an ultramicroscopic virus. Ashburn and Craig (1907) infected a volunteer with the filtered blood from a case of dengue. Other observers noted the infectivity of the serum of dengue patients. That the cause of the disease is a leptospira was suggested by Couvy (1922) and Carbonoboa (1924) who reported the presence of spirochaetes in the blood and other fluids of the body, but the claim has not been substantiated. Sellards and Siler (1928) found numerous rickettsia bodies both in the lumen and epithelial cells of the hind gut of the infected *Aedes ægypti*. In the hands of most investigators the infective blood has failed to produce the disease in animals. The virus is introduced into the human body by the bite of the infected mosquito. Siler et al. (1926) passed the virus from man to mosquito and back to man through six generations without attenuation or increase in the virulence of the virus. They confirmed the transmission of dengue by *Aedes ægypti*. The pre-infective period in

the mosquito after an infective meal is usually from 11 to 14 days; the virus is not transmitted through the eggs of the mosquito. In man the incubation period by mosquito transmission is about 7 days but may be delayed till the tenth or the eleventh day. Ashburn and Craig (1907) found it to be $2\frac{1}{2}$ to 7 days after intravenous inoculation of 20 min. of the infective blood. It has been shown that the patient is most infective to mosquitoes from the first day of the disease, and by the end of the third day he is not, as a rule, infective. Cleland et al (1918) got successful results with blood taken between 18 and 90 hours and Manoussakis (1928) found the blood infective from a few hours before the onset of symptoms until defervescence.

Prophylaxis. In tropical climates the disease is mostly endemic because of the persistence of the *stegomyia* mosquito throughout the year, though it may be quiescent for a time and then flare up again. For an epidemic to spread in a certain locality, the factors concerned are: (i) the existence of infection in human beings or mosquitoes in sufficient numbers, and (ii) the existence of susceptible persons and suitable conditions of temperature and humidity. As the mosquito may remain infective permanently, there is a great danger to new-comers to an epidemic locality of being infected, thereby allowing the disease to spread rapidly. An infected person can also transmit the disease to distant places provided there are sufficient mosquitoes to act as reservoirs of infection.

These mosquitoes are essentially domestic and they breed in places in the immediate neighbourhood of human dwellings. Hence, if prophylactic measures are to be successful, steps should be taken for the destruction of mosquitoes and prevention of mosquito bites. As the virus of dengue is present in the blood of patients for about three days the patient should be protected from mosquito bites by proper screening during the period.

Prophylactic vaccination. It has been found that following an attack of dengue an immunity is established which may last for two to several years, but it has been known to be as short as 53 days (Siler 1926). Unlike yellow fever an attack of dengue does not give rise to protective properties in the serum nor is it possible to obtain a vaccine of the virus for treatment. Hence vaccine therapy has not been successful in protecting against

infection with dengue. Blanc and Caminopetros (1929) prepared a vaccine from killed virus which was ineffective ; better results were obtained with a virus treated with bile. St. John and Holt ((1931) prepared a vaccine from the spleen and liver of infected animals following the line of Hindle's vaccine for yellow fever. Though it did not protect a person from an attack, infection if it occurred was rendered mild.

Treatment. Dengue is hardly ever fatal. Treatment is mainly aimed at relieving symptoms. Dengue runs a definite course and all energetic measures to cut the disease short are useless. In the beginning of the illness a saline diaphoretic mixture may be prescribed. Antipyretic drugs such as phenacetin may be given for the relief of headache and backache and the high temperature should be brought down by hydrotherapy. Adrenalin has been recommended in dengue with the idea that it overcomes the asthenic stage and hastens the period of convalescence. Arsenical preparations have been tried ; acetylarsen in doses of 3 c.cm. by hypodermic injection or treparsol in doses of 1.0 gm. daily is said to abort an attack. Sulpharsenol has also been recommended.

SANDFLY FEVER

It is also known as phlebotomus fever, pappataci fever and three-day fever, on account of its being transmitted by sandflies—*Phlebotomus pappatasi*, and running its course for 3 days. It is caused by a filterable virus and is characterised by sudden onset, rapid rise of temperature with fall by lysis on the third day, headache, pains in the eyeballs and muscles, injected conjunctiva, bradycardia and leucopœnia with a large mononuclear increase. Thus it simulates dengue clinically and they have been mistaken for one and the same disease but it is to be understood that an attack of sandfly fever never confers any immunity for the other disease and *vice versa*, and they have also a different geographical distribution.

The virus of sandfly fever is present in the patient's blood during the first 24 hours of illness. The blood has been found to retain its infectivity after passing through a filter (Doerr, 1908). This was later confirmed with different filters by other workers. Blood from a patient

taken within 24 hours of illness is capable of causing an infection in susceptible persons, but taken towards the end of the second day it loses its infectivity. At 55°C. the virus is destroyed in 10 minutes (Lepine 1927) but at 27°C. and in the dark it has been preserved for a week by Birt (1910). Attempts to transmit the disease to animals have failed. The usual vector is *Phlebotomus pappatasi*, but in addition, *P. perniciosus*, *P. minutus* and *P. sergenti* have been incriminated. The sandfly must bite the patient within 24 hours of the onset of the disease so as to be capable of transferring the disease to another. The incubation period in the sandfly is 7 days, but infectivity once established is permanent. Doerr thinks that the virus may be transmitted hereditarily by the insect to the egg. Wittingham and Rook confirmed the transmission from generation to generation.

Immunity is usually established after an attack of the disease, but it is rather short and a relapse or second attack may occur in 3 to 8 weeks. The serum of convalescents possesses definite protective powers. Doerr (1909) found this protective action in serum seven days after an attack and in one case, two years after an attack of fever. McCarrison (1915) was unable to infect 4 persons immunised with convalescent serum.

Prophylaxis. The prevention of sandfly fever rests on the measures against its carrier *Phlebotomus pappatasi*. Sandflies should be destroyed and their breeding places eliminated by spraying tar around habitations. Long boots should be worn after sunset, and electric fans, wherever possible, used to keep away the flies. An ointment containing oils of eucalyptus, anise and turpentine, 3 min. each, and lanolin 1 oz., applied to the wrists and ankles helps to keep away the flies. Mosquito nets are not protective as the flies can pass through their meshes.

Treatment. Treatment is carried on in the same lines as for dengue. Tincture of iodine should be applied to the bites. The patient should be kept in bed for 5 or 6 days and the pains relieved by antipyretic drugs, such as aspirin, etc.

YELLOW FEVER

Yellow fever is an acute non-contagious fever characterised by toxæmia, albuminuria, jaundice and a tendency to hæmorrhage. It is essentially a disease of the tropics especially tropical America and the west coast of Africa. Since the famous discovery in 1900 that this disease is transmitted by the domestic mosquito, *Aedes ægypti*, anti-mosquito campaigns seem to have

eradicated yellow fever from most of the endemic centres in the new world.

Noguchi (1919) described a leptospira known as *L. icteroides* as the causative organism of yellow fever. By the dark ground illumination method, a considerable number of these organisms was found in the blood, liver and kidneys of guinea-pigs inoculated with blood from certain yellow fever cases; further a pure culture of the organisms was obtained in an artificial medium and he successfully transmitted them through series of guinea-pigs. Later, the observations of other workers, including those of Noguchi himself, failed to substantiate the previous findings, as they failed to find any leptospira in a number of yellow fever cases. Kligler (1928) in Palestine found that *Aedes aegypti* which is the carrier of yellow fever could not act as a carrier of leptospira. Subsequently Stokes, Baur and Hudson (1928) in west Africa discovered that the monkeys of the species *Macacus sinicus* and *Macacus rhesus* could be easily infected with yellow fever with the production of symptoms and pathological lesions identical with human yellow fever, and they proved that the agent of yellow fever is ultramicroscopic and passes through Berkefeld filters. Convalescent sera from severe cases of yellow fever in doses of 0.1 c.cm. protected monkeys from further infection with the virus. Later, Sellards and Hindle (1928) showed that the virus maintained its virulence even when frozen, and they were able to infect a monkey with the frozen blood and liver of infected monkeys after twelve days. Hindle prepared a vaccine from the livers and spleens of infected monkeys which successfully immunised monkeys against enormous doses of the living virus.

In spite of numerous researches the causal agent of the disease is still under discussion. Recently, Kuczynski (1929) has announced the cultivation of a micro-organism from cases of yellow fever, and considers this to be the causal agent, but it has not been confirmed. In view of the results of filtration experiments, yellow fever is included in the groups of diseases caused by filterable viruses. It has been shown by several workers that the virus will pass through Chamberland filters when present in the circulating blood of man. The virus in the mosquito, on the other hand, is unable to pass through the filter. It has been suggested that the virus may have different morphology and dimension in the mosquito.

The work of the American Commission to Cuba established the fact that yellow fever is transmitted by the bite of the mosquito variously known as *Stegomyia fasciatus*, *Aedes argenteus* and *A. aegypti*. When fed on the blood of a yellow fever patient during the first three days of an attack, the mosquito becomes infected and after a period of twelve days is capable of transmitting the disease. Once infected the

mosquito remains so for the rest of life. The French Commission (1903) confirmed these findings and further found that infectious serum if heated for 5 minutes at 55°C. loses its virulence but has prophylactic and curative power. The infective serum becomes inactive in 48 hours, unless preserved under petrolatum when it remains virulent for 5 days. Cutaneous vaccination with the infective serum is without result.

Spread of yellow fever to India. The possible extension of yellow fever to new countries from the endemic foci is an important question which is attracting much attention. At the present time the complete absence of yellow fever from India is due to the absence of the virus. There is however clear evidence to show that the population of India has little or no immunity against the disease; the climatic conditions are also favourable for the development of infectivity in the insect vector, *Aedes ægypti*, which is prevalent in many places in India, especially in the principal ports. The introduction of the virus into any of the susceptible hosts, man, monkey or mosquito, might be enough to start an epidemic of the most alarming magnitude. Hitherto neither infected mosquitoes nor infected human beings have been introduced into this country, because the length of the voyage from infected countries has been an effective barrier. The introduction of rapid travel, especially by air, has changed the situation. It is now quite easy for an aeroplane to travel from West Africa or East Africa to India so rapidly that if a passenger had been bitten by an infected mosquito, he might be in a highly infective condition on reaching his destination. Hindle has found that *Aedes* mosquitoes sent from India are effective vectors, so there is no obvious reason why the disease should not spread like wild-fire in India and Far East if the virus was introduced by infected persons or mosquitoes. The situation created by modern rapid methods of travel therefore demands anxious consideration. The measures for the prevention of introduction of the disease to India are to take all rigid precautions against the conveyance of the mosquitoes from the endemic areas by aeroplanes, motor cars, trains, etc. Medical inspection of all passengers and crews for the detection of all possibly infected persons should be undertaken. Protective inoculation of all intending pilots and passengers in aeroplanes is a satisfactory method.

Immunity. Recovery from the disease is followed by a high degree of immunity. The duration of this immunity is fairly long, perhaps more than 5 years. Experiments with serum of both man and monkeys after recovery show that immune bodies are present in considerable strength. The serum of yellow fever convalescent patients, on inoculation, protects a susceptible animal against a fatal dose of the virus. This protective action appears on about the eighth day of illness. Passive immunity conferred by the serum usually passes off in about twenty days, though it may last longer. Convalescent serum when injected early to infected patients is said to diminish the severity of symptoms.

The presence of active immune bodies in the blood of recovered patients shows that the person has actually suffered from yellow fever, and this is a valuable test for diagnosis. For this purpose a monkey is injected with serum from suspected cases along with the virus. If infection occurs the case is probably not yellow fever. Effective protection is given by a vaccine prepared from the liver or spleen of the infected animal. The virus present in the tissue is destroyed by preserving it in 0.5 per cent. phenol or by simply keeping it in the ice chest. Two doses of such vaccine were found to protect monkeys for at least six months. Aragao used this mode of prophylaxis during epidemics in Rio in 1928-29.

Prophylaxis. The importance of the stegomyia carriers in the transmission of the disease is well founded. The Yellow Fever Commission found that the infection is conveyed by the bites of domestic mosquitoes. Carter later showed that two or three weeks must elapse after the introduction of a human infection into a place before the next group of cases can occur, owing to at least ten days being necessary for the development of the virus in the mosquito. Following strictly anti-mosquito measures, yellow fever has now been eradicated from Havana, Vera Cruz and Panama which were at one time the endemic foci of yellow fever.

To enable yellow fever to be controlled and eventually stamped out from an infected locality, energetic measures have to be carried out for the destruction of its vector *Aedes ægypti*. Connor in Guayaquil showed that a fall in yellow fever incidence coincided with measures taken to prevent contamination of tanks and water containers. The same worker reported equal success in Mexico, a certain area being freed from yellow fever by mosquito control. During an epidemic or during exacerbation of endemic yellow fever, non-immunes should immediately leave the locality. All cases of yellow fever should be reported to sanitary authorities. Any delay in recognising a case increases the danger of rapid dissemination of the disease and multiplication of infected centres.

Prophylactic inoculation. Experimentally, animals have been protected against yellow fever virus by injection of serum of patients recovered from the disease. Theiler (1931) tested the efficacy of immune sera against yellow fever virus in mice.

In his tests, the control animals all died, but the groups of mice used in tests of known immune sera behaved differently, some of them died while others survived. Sawyer and Lloyd (1931) using a different method in testing the efficacy of the protective sera obtained better results. In testing the sera, they etherised the mice lightly, injected starch solution intracranially and then injected a mixture of 0.2 c.cm. of the virus and 0.4 c.cm. of the serum intraperitoneally. A known immune serum completely protected the mice while in case of a non-immune serum all the mice died.

Workers in several countries have endeavoured, on the results of experimental evidence produced in support of immunity developed in yellow fever, to immunise human beings against yellow fever infection. The various methods that have been tried successfully may be classed as follows: (1) inoculation with immune serum; (2) inoculation with a vaccine containing killed or attenuated organisms; (3) inoculation with a mixture of virus and immune serum; and (4) inoculation with a biologically modified virus. The injection of convalescent serum from a recovered case of yellow fever, affords only a temporary protection; similarly vaccines containing killed or attenuated virus have given results of little promise. Simultaneous injection of a biologically modified mouse virus strain and immune serum has, on the other hand, given the best results in affording protection.

Findlay and Hindle (1931) recommended the use of combined living virus and immune serum for immunisation against yellow fever infection. They showed that whereas the duration of passive immunity rarely exceeded four or five weeks with immune serum alone, a more lasting immunity was obtained when a dose of virus was given at the same time as the immune serum, which in the case of monkeys has been tested up to a minimum of fourteen months. Successful vaccination of human beings against yellow fever has also been reported by Sawyer, Kitchen and Lloyd (1931). They gave by injection yellow fever virus attenuated by at least a hundred passages through the brains of mice, simultaneously with human immune

serum. Ten persons were inoculated, first a dose of dried mouse virus dissolved in distilled water being given, followed immediately by subcutaneous inoculation of immune serum in two places in the abdominal wall, the dose of the former being 0.03 c.cm. per kilo. and of the latter 0.3 c.cm. per kilo. body weight; they all developed protective power against yellow fever virus. Though as yet in the experimental stage, protective inoculation at present offers the most satisfactory method of immunity development.

Treatment. The treatment of the disease is more or less symptomatic. Experience has shown that a good purgative at the commencement of the attack is beneficial, *e.g.*, calomel in divided doses followed by a saline purgative. For cerebral congestion and headache, a hot mustard foot-bath may be employed. The feet and legs of the patient are immersed in a foot-tub full of warm water into which a pound of fresh mustard has been stirred. The bath should be kept hot during the whole procedure and a blanket kept over the patient and the foot-tub so as to favour free sweating. For high fever tepid or cold baths may be employed; antipyretic drugs such as phenacetin or antipyrin should be used very carefully because of the depression they produce. Vomiting, especially black vomit, is one of the troublesome complications that may confront the physician; it may be treated with a mustard plaster over the epigastrium and by giving the patient ice to suck.

During the first few days no nourishment is required; the patient should be allowed an abundance of fluid. About 30 gr. of sodium bicarbonate in a pint of water makes a good drink and may be given *ad lib.* There is every likelihood of acidosis developing in the course of yellow fever and all possible measures should be employed to check it.

As compared with other fevers the liver is characteristically affected in this condition. For such cases glucose should be given by the mouth whenever possible; in grave cases about 12 oz. of 5 per cent. glucose solution should be given intravenously.

Sternberg's treatment consists in giving 1½ oz. of a mixture

of 150 gr. of sodium bicarbonate and $\frac{1}{3}$ gr. of mercury perchloride in a quart of water every hour; this is very helpful in counteracting the hyperacidity of the gastric and intestinal contents. Strychnine may be indicated in the asthenic stage and camphor in oil should be given hypodermically whenever there is reason to suspect cardiac weakness. The diet should be prescribed on the lines employed in infectious fevers generally, and discretion and caution are indicated during the period of convalescence.

As regards specific therapy there has so far been none which can be relied upon. Neo-salvarsan in two doses of 0.15 gm. each at two hours' interval, is said to have given beneficial results. Noguchi tried anti-serum in the treatment of yellow fever but he used *L. icteroides* to immunise animals against yellow fever, which as is now known is not the causal organism of the disease, and trials of this serum in West African yellow fever have failed to prove its efficacy. Hudson, Bauer and Philip (1929) showed that convalescent sera from patients suffering from yellow fever protected monkeys from an infection with yellow fever and this finding may be useful for successfully preparing an anti-serum in the treatment of the disease in future.

SMALL-POX

Small-pox is an acute infectious disease characterised by fever and followed by an eruption which in about eight days passes through successive stages of papule, vesicle and pustule. A secondary rise of temperature occurs during the pustular stage of eruption. The disease is of great antiquity and of widespread distribution and occurs both endemically and epidemically. Rogers claims that the prevalence of small-pox in India depends upon the humidity and the temperature, i.e., the combination of high humidity with a high temperature is inimical to its growth. In India small-pox is responsible for an annual death rate of about 50,000; in recent years the case mortality has considerably decreased owing to efficient prophylactic vaccination which has modified the disease.

The disease in its typical form may be divided into four stages:—(1) The incubation period occupies 10 to 15 days. (2) The initial stage

of toxæmia lasts for 4 to 6 days with headache, giddiness, rise of temperature and petechial or purpuric rashes on the skin. (3) The stage of true exanthema is apparent about the third or fourth day. The characteristic rash appears on the face and hands, extending downward to the legs; later papules, raised and hard to the touch and reddish in colour take its place; then vesicles form and about the sixth day develop into pustules. Concurrently with these eruptions on the skin, lesions also appear on the mucous membrane of the nose, mouth, fauces, pharynx, larynx, trachea, bronchi, etc. (4) the stage of secondary fever manifests itself on the sixth or seventh day; from the eighth to the ninth day the lesions show signs of drying up and leave scales which separate and fall off about the fourteenth day. The secondary fever arises mostly as a result of the lesions of the mucous membrane of the respiratory tract where extensive denudation of the surface favours infection with pyogenic organisms.

There are two distinct types of the disease, the first is the classical type of small-pox with severe symptoms and a mortality rate of about 10 to 30 per cent., the second is the mild type or alastrim, in which the symptoms are much milder with practically no mortality. Ætiologically and in immunological reactions alastrim is indistinguishable from variola. Gordon (1925) found that materials from cases of alastrim and from those of variola alike gave the complement-fixation and agglutination tests to anti-vaccinia serum. Though these results were doubted by several workers they have substantially been confirmed by recent investigations.

Clinically small-pox presents several varieties. So long as the pocks remain distinct from one another the disease is termed *discrete* small-pox. In some cases the pocks are numerous and run together leaving hardly any healthy skin between them; the disease is then called *confluent* or *semi-confluent* small-pox. A form of modified small-pox or *varioid* occurs in cases where the person possesses a natural immunity, and where the virulence of the infecting virus is low. An acquired immunity conferred by a previous attack of the disease or by vaccination is also likely to modify the disease and render it milder. A *hæmorrhagic* type of small-pox has been described in which the hæmorrhagic state may come on before the stage of eruption or after it; hæmorrhage may also set in during the vesicular stage.

Ætiology and mode of infection. There have been many attempts to demonstrate a specific organism in small-pox lesions by ordinary bacteriological methods and many bacteria have, from time to time, been isolated but their exact ætiological role has not been established. The fact that the contents of a small-pox vesicle, though capable of conveying the disease, do not yield any visible micro-organism is against a bacterial hypothesis. Grunhagen first described amoeboid bodies in the vaccine lymph and in the contents of the small-pox pustules.

Guarnieri (1892) observed intracellular bodies in the lesions of the variola; these bodies have been called *Cytoryctes vaccinae* or *Cytoryctes variolae*. Guarnieri's views have, however, met with many dissentients. It has been argued that they are the products of the nuclei of the epithelial cells and leucocytes due to the action of the virus. Various other bodies considered to be of parasitic nature have been noted. Puschen drew attention to very numerous granules in variolous lymph and varicella and these granules were considered to be specific owing to the constancy of their presence and their absence elsewhere. These granules are infective and cultivable in tissue cultures, but it seems probable that they represent only a certain phase in the development of the virus.

It is now generally agreed that the specific cause of variola and vaccinia is ultramicroscopic and filterable. The viruses of vaccinia and variola are essentially the same, vaccinia having developed pathogenicity for bovines while variola is pathogenic to man. Attempts to prove the filterability of the small-pox virus have not been uniformly successful although active filtrates have been obtained by some workers. Levaditi and Nicolau (1923) succeeded in transmitting vaccinia virus through a collodion filter which is permeable to peptones and bacteriophage. The virus is widely distributed throughout the body when an infection occurs. Its persistence varies with the form of the disease; in vaccinia the scabs are virus-free in 14 to 15 days, but in small-pox the virus persists for 2 months. Cultivation of the virus *in vitro* has failed but tissue culture has been successful.

Infection takes place in nearly all instances through the respiratory tract, other modes of infection such as, direct ingestion of infected material or direct contact with the infected skin, are quite exceptional. The usual sequence of events is that the virus is coughed out in droplets which contaminate the air and thus infect the mucosa of the upper respiratory tract of the susceptible individual; from here it is distributed throughout the body. Another means of contamination of the air is by transudation of the virus through the skin, the organism reaching the surface by way of the sweat glands or hair follicles; this theory however lacks experimental proof. In cases of naturally acquired disease no local lesion arises at the site of contact of the infected material with nasal or buccal mucosa and this constitutes a fundamental difference between the natural and artificially inoculated disease. In the natural disease the virus apparently passes between the epithelial cells without affecting them, but its site of location is unknown. The constitutional symptoms in small-pox are undoubtedly due to elaboration of the toxin, but the presence of the virus in the blood and toxæmia are not always synchronous. The regular and rapid development of local lesions in small-pox suggests that multiplication of the virus occurs at those sites; a toxin is at the same time secreted

which inhibits the activity of the phagocytes and facilitates the growth of pyogenic organisms. From about the fourteenth day and onwards the pocks dry up and separate; the living virus is contained in the dessicated scabs and these are able to transmit the disease to a new host.

Immunity. Immunity to small-pox may be acquired by a previous attack of the disease, by variolation or by vaccination and revaccination. The immunity conferred by an attack of small-pox usually lasts throughout life and variolation also gives a similar immunity. That vaccination also protects against small-pox was first demonstrated by Jenner who showed that inoculation with cow-pox protects against subsequent inoculation with small-pox. Many investigations in this connection have been carried out and the results indicate that the material from the eruption of a small-pox case produces in calves a disease identical with cow-pox (vaccinia). If the virus is passed through the host of certain species, the activity of vaccinia virus is better maintained. After inoculation with vaccinia virus a lasting general immunity develops. In rabbits by whatever route the vaccinia virus is introduced, the animal becomes resistant within about ten days. The virus is rapidly taken up by the leucocytes and remains in the circulation for at least eight days. In monkeys after inoculation with vaccinia virus, perfect protection is obtained against variola and alastrim, but the protection afforded by variola or alastrim against vaccinia is only partial. Highest immunity is obtained if a living virus is used. Heat destroys the antigenic property of the virus very considerably, and it has been found that lymph heated to 100°C. has no immunizing effect at all. With raw lymph, immunity develops from the fourth day and becomes maximal about the tenth day.

Seat and nature of immunity. It is important in clinical work to form an estimate of the amount of immunity present in men after vaccination and revaccination. A practical method depends on the observation of immediate reaction produced; the earlier and less the reaction the greater is the immunity. The seat of immunity conferred by vaccination was at one time supposed to be confined to the ectodermal epithelial cells. The modern tendency is to regard immunity as general and humoral rather than local and cellular. It has been shown that the variolo-vaccine virus readily passes into the blood stream and can be found there within a few hours of the inoculation. From the blood stream it passes into the reticulo-endothelial system and becomes generalised throughout the body. Plotz (1927) on the other hand thinks that the immunity is dependent on two factors, the dose and the area involved. Others consider that it depends more upon the dose than area, though there is evidence to show that a minimal dose gives as strong immunity as a potent dose. Much difference of opinion exists as to the power of the killed

virus to produce immunity. Though immunity has been shown to result from the use of killed virus, on the whole there remains considerable doubt whether immunity of any practical value can be produced by the use of killed or attenuated virus.

Recently, much work has been done on the nature of specific antibodies produced by vaccination. Specific variolical antibody was first discovered by Sternberg in 1896. This antibody has been shown to be closely related to the production of immunity. After an attack of the disease, these antibodies may persist for years, and are said to be enhanced after revaccination. Andrewes (1928) found no evidence that the virus was killed by the antibody and no stable union was found to exist between them. Many observers have recognised the presence of a precipitating antibody in immune variolo-vaccine sera. Gordon (1925) obtained evidence of definite agglutination with immune sera and a calf-lymph antigen diluted 1 in 20, with rabbit-lymph antigen in dilution of 1 in 140, and also with variolous material. Complement fixing antibody has also been found by many workers and positive complement fixation tests are reported. This is however doubted by others who obtained no evidence of specific complement fixation when immune sera prepared from the rabbit with pure brain virus were tested against cutaneous vaccinia or brain virus antigens. According to them these reactions are due to the presence of concomitant bacteria.

Laboratory diagnosis. The diagnosis of small-pox offers no difficulty from clinical signs and symptoms. Two tests can be employed for diagnosis; the first is the intracutaneous inoculation of variolous material into unvaccinated rabbits in whom characteristic local swellings develop on the second day reaching their maximum about the fourth day, the lesions disappearing by the twelfth day. Paul's test consists in the production of keratitis in rabbits after inoculation of variolous materials into their eyes. Recently, a serological method of diagnosis has been developed. A suspension of ground up variolous material is mixed with an antivaccinal rabbit serum and incubated at 37°C.; a positive reaction is marked by the appearance of a finely floccular precipitate. The complement fixation test can also be done.

Prophylaxis. *Vaccination and revaccination.* Small-pox is a preventible disease and the advent of vaccination has greatly reduced the incidence and mortality of the disease. It is well known that the incidence of small-pox is entirely amongst the unvaccinated and when the vaccinated are attacked death occurs amongst only those who have outworn their primary vaccination protection. Even when through lapse of time or otherwise complete protection against an attack is lost, the power of

modifying an attack still remains so that the disease assumes a modified form.

The pustules of vaccinia emulsified in glycerolated saline constitute vaccine lymph and is largely used for vaccination. For human vaccination though calf lymph is generally employed, it has been shown that lymph taken from vaccinal lesions in other animals gives satisfactory results. The usual procedure of vaccination is to vaccinate in a single linear incision or scratch, not more than $\frac{1}{4}$ inch long, through the epidermis. Other methods of vaccinating are the multiple punctures or pressure method through a drop of vaccine ; the drill method, in which a superficial layer of the epidermis is removed ; the method advocated by the Union of South Africa is to make two or three parallel incisions, $\frac{1}{4}$ inch long and $\frac{1}{16}$ inch apart, through a drop of lymph, such incision being single or multiple. Vaccination may be through a drop of lymph or the lymph may be applied to the trauma either simply or gently rubbed in ; the former gives less local reaction. In all cases the procedure should be treated as a surgical operation and rigorous precautions should be taken against sepsis. The vaccinated surface should be protected from dirt and injury.

After vaccination there is an incubation period lasting about 3 days during which little change occurs at the inoculated site. A localised papule develops on the fourth day which becomes vesicular on the seventh or eighth day and matures on the tenth or eleventh day, followed by scarring and pitting, popularly known as foveation. The vesicles begin to dry up at about the eleventh day and the process is completed by about the fourteenth, the scabs falling off normally about the twenty-first day. Slight febrile disturbance may be noticed as vesiculation proceeds, with headache, malaise, enlargement of the axillary glands, and in some instances of the spleen. In revaccination the degree of reaction depends on the amount of immunity remaining after the primary vaccination. The less the immunity, the closer the revaccination approaches to a normal primary vaccination, and the higher it is, the less is the local reaction.

Strong evidence exists as to the protection afforded by

vaccination against small-pox and this holds true particularly with regard to protection against infection. Vaccination performed immediately prior to exposure to small-pox affords almost absolute protection against the disease; if done during the incubation period, it either prevents the development of small-pox or renders the subsequent attack mild. Similarly recent successful revaccination is said to afford an almost complete protection. The first vaccination should be performed between the fourth and sixth month of life and immunity lasts for 10 to 15 years. As the effect of vaccination appears to wear off with increasing age, it is advisable to perform revaccination at about 10 years and again at the age of twenty.

Complications of vaccination. Of the common complications of vaccination suppuration and tetanus may be mentioned. The introduction of putrefactive organisms to the inoculated site occurs either through incomplete sterilization of calf lymph or uncleanness on the part of the operator, or during after-treatment. Tetanus is a rare complication. A more serious complication is post-vaccinal encephalitis. After an incubation period of 10 to 14 days it ushers in with acute symptoms, mainly pointing to the affection of the cerebrum. The cause of encephalitis is unknown; it has been suggested that the disease is similar to that seen in encephalomyelitis following measles and in disseminated sclerosis, being caused by some neurotropic virus which is stimulated into activity either by vaccination or by some exanthematous infection. McIntosh (1928) believes encephalitis to be due to vaccinia virus itself.

Besides compulsory vaccination in endemic and epidemic areas, other methods should be adopted so as to prevent dissemination of the infected material from the sick person to those around him. It should be realised that infective material exists in the eruption and may be carried through the air, and persons coming in contact with the patient may themselves be infected or carry and retain dangerous material. The first step towards prophylaxis, when a case occurs, is to isolate the infected person and treat him in a hospital specially meant for the purpose. The infected premises and the infected clothing should be thoroughly disinfected. The small-pox patient should not be discharged from the hospital until all infected epidermis is removed.

Treatment. The treatment is mainly symptomatic. In no

disease is the careful management of the patient so imperative as in small-pox. Abundance of fresh air, cool surroundings, fluid diets, regulation of the bowels, tepid sponging are essential measures. In the *initial stage* the patient often complains of headache and pain all over the body. Lumbar pain is relieved by poultices or dry cupping ; small doses of aspirin or pyramidon may be prescribed to relieve headache. It is always advisable to crop the hair short or have the head shaved because it helps to maintain cleanliness and gives a better opportunity to make necessary applications.

The mouth and throat require almost constant attention. Antiseptic gargles and demulcent drinks are to be frequently given, especially when there is difficulty of swallowing. In the latter case it is helpful to spray the throat with 1 per cent. solution of cocaine or orthoform. The eyes should be frequently bathed with some antiseptic lotion, such as boric acid. Protargol or argyrol solution may be dropped into the eye once daily. Many eyes are lost due to development of corneal ulceration, but if detected early it yields to treatment. An ointment of yellow oxide of mercury with atropine should be applied twice daily should keratitis threaten. For sleeplessness and delirium and to allay discomfort of the secondary fever, opium is the drug of choice. Dover's powder in doses of 10 gr. should be given twice daily ; morphine may have to be given hypodermically. Chloral hydrate and bromides as sedatives are also useful.

In the *eruptive stage* the patient should be sponged, and this is especially valuable when the temperature is high and is accompanied by severe toxæmia and delirium ; tepid sponging has sometimes to be replaced by cold packs. In less severe cases a bath (at 98°F.) may be employed and a solution of potassium permanganate added to it. In the early stage of eruption cold wet applications give much relief ; a mask soaked in glycerine may be applied ; a carbolic acid compress is also useful. Some advocate the painting of the face with dilute tincture of iodine once or twice a day for the first 8 or 10 days and then vaseline, but it is better to use a 5 per cent. solution of potassium permanganate twice or three times a day until scabbing begins ;

after this it should be used less frequently. Many methods have been tried with a view to aborting the eruption and preventing pitting but none are effectual. Finsen recommended exposure of the patient to the effect of red light in order to prevent suppurative changes in the pocks, but this is too depressing. To mitigate the offensive odour emanating from the skin lesions dilute carbolic acid lotions may be used; starch poultices and alkaline washes are used for the removal of crusts.

Complications should be treated on the usual lines. Heart failure is combated by strychnine, digitalis, etc. Hæmorrhagic small-pox unfortunately proves invariably fatal. Convalescence must be prolonged, and patients are to be regarded as infectious until the scabs are separated and the skin condition improve.

RABIES

This is a cosmopolitan disease, which is caused by the bite of certain rabid animals. While in nature, the incidence of the disease is heaviest in the canine tribe (dog, wolf, jackal, fox, etc.), other animals can be experimentally infected. The causative agent belongs to the group of filterable viruses which travel along the nerve trunks from the site of the infection. Development of symptoms depends on the time taken to reach the central nervous system. The incubation period therefore varies with the distance to be travelled; in man, for a bite on the head, it is approximately twenty-seven days, on the arm thirty-two days, on the leg sixty-four days, but these figures are subject to wide variations.

The properties and mode of action of rabies virus were very thoroughly worked out originally by Pasteur himself. On the basis of experimental work he described two forms of the disease which he ascribed to different modifications of the virus, termed 'street virus' and 'fixed virus.' The street virus was simply the infective agent of rabies, which is met with in the infecting fluids or tissues of animals developing rabies under natural conditions, and was proved by its transmissibility to be a living entity. Such virus inoculated subdurally into a rabbit produced the disease after an incubation period of fifteen to twenty days. With repeated subdural inoculations from rabbit to rabbit, the virus gradually altered its character, giving a shorter period of incubation until, after fifty passages, the incubation period was six to seven days. This was called 'fixed virus' by Pasteur. At this stage

the virus has become fixed and permanent and the change is an irreversible one. The essential differences are its reduced pathogenicity for man by subcutaneous injection, non-occurrence of Negri bodies and shortening of the incubation period. The view generally held is that the neurotropic virus, in becoming fixed, has become more habituated to growth in association with a cellular nervous tissue, and less able than street virus to establish infection by subcutaneous implantation. Remlinger (1928) is inclined to the view that the germ exists in the saliva in a different form to that in which it is present in the brain. There is however very little difference in the disease, once produced, whether by the street or fixed virus.

The essential pathological feature of rabies is the occurrence of 'Negri bodies', discovered by Negri in 1903, and there is little doubt regarding their specificity. Various opinions have been expressed as to whether the Negri body is a parasite itself, a degeneration developed around the parasite or reaction on the part of the nucleus of the nerve cell to the parasite. It is found most constantly in the ganglion cells of the cerebral cortex, chiefly in the hippocampus major, which is now regularly examined for the diagnosis of rabies. There may be one or more bodies in the cell; they vary in size from 1 to 15 μ , and contain within a capsule 20 to 25 rounded bodies; in the centre of each of these bodies is a corpuscle. The Negri bodies are more prominent in the later stages of the infection, progressively diminishing in size as the street virus becomes transformed into the fixed virus, until they finally disappear. The position as to the true nature of the Negri body was judiciously summed up at the recent International Conference on Rabies, where the decision was reached that insufficient evidence existed to determine whether the Negri body was a parasite or merely a cell product.

The virus is primarily associated with the central nervous system, but later on the salivary glands, the pancreas and the intestinal glands become infected. The blood is never infective. In the dog, the saliva becomes infectious four days before the onset of symptoms. Poor and Steinhardt (1913) showed that the filtrate of glycerinated salivary gland was infective, and Remlinger found that the virus could pass through a Berkefeld filter. Cultivation of the rabies virus has not been successful.

Of the various modes of transmitting the disease experimentally, the most certain is the subdural or intracerebral route and the least certain is the intravenous. The subcutaneous route, which is the route of natural infection, yields fifty per cent. of positive infections. Scarification is rarely successful, and therefore infection by licking of an abrasion by a rabid dog is very unlikely, while infection through intact skin or mucous membrane may be considered impossible.

In man, the course of the disease is similar to that in the dog. Fear and anxiety are prominent features from the onset. As the

disease progresses excitability increases. Sight of water or the very thought of it or the sound of running water will bring on pharyngeal spasm. Respiration becomes laboured and noisy; consciousness remains practically till the end. Paralytic manifestations follow the excitable state, and death occurs within 3 days of the onset.

Immunity. It is natural only in cold blooded animals and may be acquired in susceptible animals by treatment with attenuated virus. This can be conferred prior to infection or during the incubation period after the infection. Pasteurian treatment is therefore both a prophylactic and curative treatment. Pasteur's original desiccated cord treatment for production of immunity is hardly used now. With the recent discovery that the dead virus forms as effective a vaccine as the living virus, carbolised or etherised cord has been employed. The great advantage of the dead virus vaccine is the elimination of neuro-paralytic accidents. Passive immunization in rabies is hardly of any value and hence it is doubtful whether anti-rabic serum has got any antitoxic character. Such a serum however has been used in conjunction with antigen as a sero-vaccination method of treatment.

Prophylaxis. It is important to insist on muzzling of dogs and of quarantining imported dogs. A dog bite should be allowed to bleed freely, and then washed with 1 in 1,000 perchloride of mercury solution and cauterised with strong nitric acid. If there is any suspicion that the dog is rabid, the patient should be given Pasteur's treatment.

Preventive inoculation. It has already been stated that the power of the virus is altered when passaged through the nervous system of certain species of animals. By inoculation of the virus into rabbits its virulence can be increased up to a certain strength beyond which no further exaltation can be obtained and this is known as the 'fixed virus.' For the preparation of such vaccine rabbits and sheep are inoculated subdurally with this fixed virus daily. After death the spinal cord is removed with aseptic precautions, cut into pieces and suspended in caustic potash solution and kept in a dark room at a constant temperature of 23°C. Cords of different days and hence containing virus of varying degrees of virulence are obtained. The usual dose is a portion of cord 2 to 3 mm. in length prepared by trituration and suspension in salt solution.

This original method practised by Pasteur has now been greatly modified. Pasteur began his treatment with fixed virus which had been dried for fourteen days. Other workers have found that it is

not necessary to begin with such extreme attenuation of the organism as the fixed virus is greatly modified in its virulence for men. In fact, many observers have advocated the use of unmodified virus in large doses. Hogyes thinks that satisfactory results can be obtained by dilution of the fresh fixed virus with salt solution. He uses dilutions varying from 1 in 100 to 1 in 1,000, beginning with the highest dilution and reaching the lowest between the fourteenth to the twentieth day according to the severity of the case. Babes used spinal cord heated to 80°—60°—45°C. for 10 minutes in order to attenuate the virus to varying degrees. The Public Health Service, America, uses a vaccine beginning with cord of the eighth day and proceeding rapidly to those of the third, second and first day. Vaccines containing the virus in the dead state have been prepared. It gives equally successful results and is now largely used. In Semple's vaccine the virus is killed with 1 per cent. phenol; in Remlinger's method the virus is killed with ether; in Fermi's sero-vaccination treatment, a 5 per cent. suspension of fixed living virus is exposed to 1 per cent. phenol for 1 to 10 days and this vaccine and an immune serum prepared from horses are mixed in varying proportions and injected twice daily. The general opinion is that there is not much difference in the protecting power of the various methods provided a good strain of fixed virus is used. Stuart and Krikorian (1932) made a comparison of the protective power of treatment by living fixed virus, carbolyzed virus and etherized virus on groups of animals, and the results did not indicate the superiority of one method over the other. In view of such facts much work is now being carried on, both in India and elsewhere, to find out the best methods of producing an antigen that will give the maximum therapeutic effect.

The vaccine in use in the Pasteur Institute, Calcutta, is Semple's carbolyzed vaccine made from sheep which have died of fixed virus infection. The vaccine consists of a one per cent. emulsion of brain tissue in 0.5 per cent. carbolyzed saline solution. This vaccine should be used in all cases that have been bitten by a rabid or a suspected rabid animal and also for those cases which have been licked by a rabid or suspected rabid animal on any fresh cuts or abrasions. It is useless to start this treatment when the symptoms have once developed, but if begun during the first week of infection the chances of failure are least. In this Institute, the results of treatment with this vaccine seem to be fairly satisfactory. Out of a total of 10,058 cases during the year 1932, 7,532 were given a full course of treatment, 1,631 were given advice

only as no treatment was considered necessary, and in the remainder the treatment could not be continued. The statistical table during the year shows a failure rate of only 0.38 per cent. and a total death-rate of 0.68 per cent.

For bites, the usual dosage is 5 c.cm. of the vaccine for fourteen days daily, and for licks, 5 c.cm. for seven days. The vaccine is injected into the loose subcutaneous tissue of the abdomen; the whole dose of 5 c.cm. is given in two places, *i.e.*, half the dose (2.5 c.cm.) being injected on either side of the middle line. In the great majority of cases no untoward effects are seen, but a local reaction at the site of the inoculation may be expected to develop during the second week of the course. This is best treated by local application of hot fomentations or the applications of a hot water bottle, and if the reaction is severe calcium lactate may be given.

The untoward symptoms met with are mild neuritis and sometimes acute ascending paralysis. This post-vaccinal paralysis may appear at any time during the course of treatment or some time after the completion of the course; most patients recover spontaneously.

Pregnancy is not a contraindication to treatment. Certain precautions are however to be observed in persons undergoing treatment; they must avoid alcohol and refrain from strenuous exercises such as dancing, tennis, riding, etc. Subjects of malarial fever in the tropics should take a daily dose of quinine. These precautions have to be observed during the course of treatment and continued for at least 10 days after the completion of the course.

Treatment. The treatment is merely symptomatic to relieve the suffering of the patient as there is no drug known which can cure the condition. When symptoms have set in the patient should be removed to a dark room and protected from all disturbing influences, such as draughts of air, sharp noises and light. The diet should be liquid; dysphagia is always marked and recourse has to be had to nutrient enemata. To control the paroxysm, hypodermic injections of morphine or hyoscine may be given; milder antispasmodics are of no avail. Inhalations of

chloroform give more relief than many antispasmodic drugs. Forcible restraint during the paroxysms is often required.

Antirabic serum. Antirabic serum has not proved successful in the treatment of rabies in man. In animal experiments, after removal of cerebrospinal fluid by occipital puncture and introduction of rabicidal serum by the same route, success seems to have been obtained. King (1932) suggests the combination of antirabic serum along with chloroform on the analogy that chloroform is said to have the effect of promoting the action of antitetanic serum by weakening the hold of the toxins on the lipoids of the nerve cells and thus facilitating the combination between toxin and antitoxin. It is yet in the experimental stage.

LYMPHOGRANULOMA INGUINALE, CLIMATIC BUBO AND ALLIED CONDITIONS ; GRANULOMA VENEREUM

Lymphogranuloma inguinale and climatic bubo. These are now recognised to be caused by an identical ultramicroscopic filtrable virus and are nearly always communicated venereally. Minute ulcers develop on the penis, 3 or 4 weeks after exposure to infection, usually in uncircumcised subjects, followed by involvement of inguinal glands.

Much light has been thrown by the observation and experimental work of recent years on the nature of the two diseases, lymphogranuloma inguinale and climatic bubo. Hellerstrom and Wassen (1930) showed that an ultramicroscopic virus existed in the gland pulp and pus of the inguinal bubo which could be passaged in monkeys by intracerebral inoculation. The subsequent experimental work of Hellerstrom, Levaditi and Findlay added considerable knowledge with regard to the virus.

The consensus of opinion at the present time is that not only lymphogranuloma inguinale and climatic bubo but the conditions known as chronic elephantiasis and ulceration of the vulva, esthiomene, the genito-ano-rectal syndrome and inflammatory stricture of the rectum, are infections caused by the same specific ultramicroscopic virus. Stannus (1933) states that all the different names so long given to this disease describe only regional syndromes of a single infection, and he proposes, for want of a better nomenclature, to describe them as the sixth venereal disease. Such terms as poradenitis, poro-lymphitis, poradenolymphitis, etc., have also been suggested depending on the nature of the lesion, but there is as yet no commonly accepted term.

The virus is present in the affected glands in man and in the sterile pus aspirated from a bubo. It can be transmitted to a number of experimental animals. Monkeys are highly susceptible to intracerebral inoculation developing symptoms of meningo-encephalitis after an incubation period of 4 to 22 days. The virus becomes generalised and can be demonstrated in the blood, liver, spleen, kidneys, lymphatic glands. After inoculation on the prepuce and in the groin, a typical inguinal bubo develops. Guinea-pigs can be infected by groin inoculation with the formation of buboes. In mice intracerebral inoculation produces meningo-encephalitis but local inoculation fails to produce buboes. In man also Levaditi has shown that preputial inoculation produces a typical inguinal bubo. The contagion is usually communicated venereally, but extragenital lesions have also been described, *e.g.*, on the fingers of surgeons or, in young children. In the male a small papular, nodular or more commonly a herpetiform primary lesion is situated in the coronal sulcus. Generally multiple foci of suppuration in the inguinal region occur but a single big abscess may develop. The possibility of co-existing infections, such as syphilis, chancroid, or gonorrhoea must not be lost sight of.

At one time climatic bubo was supposed to be confined to the male sex alone but this has been shown to be erroneous. In the females the primary lesions occur in the posterior part of the vulva or most commonly within the lower third of the posterior wall of the vagina. The greatest brunt of the infection therefore falls on the intrapelvic glands, *i.e.*, the glands lying in the recto-vaginal septum, the ano-rectal or pararectal glands. If suppurative changes are not marked periadenitis and infiltration of the connective tissues occur which fix the uterus to the surrounding structures. In other cases the lymph glands undergo softening, fistulas develop which open into the vagina, rectum or skin surface around the anus. When the infection becomes chronic it spreads to successive groups of pelvic glands with the production of extensive lymph blocking; it also spreads by a retrograde lymphangitis into the connective tissues and organs whose lymph drains to these glands. At the same time due to the presence of the virus, a specific inflammatory reaction develops all round the area. Thus are produced several conditions which are included under the term genito-ano-rectal syndrome or esthiomene. If the reaction is limited to the para-rectal tissues, inflammatory stricture of the rectum is the prominent sign, if on the vulva, elephantiasis of the vulva develops, or the lesion may be more extensive with the production of the whole genito-ano-rectal syndrome.

Ehrlich's reaction has proved of great value for the diagnosis of cases of lymphogranuloma inguinale or climatic bubo. The test is done by intradermal injection of a suspension of pus or gland pulp from an accepted case of lymphogranuloma inguinale, the material should be

heated to 60°C. on two consecutive days and then kept at a low temperature; an intracutaneous injection of 0.1 c.cm. is followed by a local inflammatory reaction with a central zone of necrosis in 48 hours in positive cases. Lymphogranuloma inguinale antigens give positive reactions in cases of climatic bubo and conversely the skin of a lymphogranuloma patient reacts to an antigen prepared from a case of climatic bubo.

Granuloma venereum. Granuloma venereum or granuloma inguinale, though not of established ætiology, is conveniently discussed here as the symptomatology and treatment bear a close resemblance to certain virus diseases. It is a chronic, infectious, ulcerative process of unknown ætiology usually involving the genitalia or neighbouring parts and showing no tendency towards spontaneous healing. The disease is common among young negroes and is widespread in tropical climates. Most of the cases recorded are believed to be due to extension from a primary genital sore though extragenital ulceration has also been noticed. In India the disease seems to be confined to the eastern side of the peninsula. In the hospitals of the Madras city and Vizagapatam a considerable number of cases are treated. On the other hand, the disease has been rarely encountered in the large skin outpatient department of the Calcutta School of Tropical Medicine, and a few cases have so far been reported from other parts of India.

Donovan (1905) first described a short bacillus as the causative organism of granuloma inguinale. It was found in all parts of the ulcers but was particularly abundant in the deeper ones, where all other organisms were absent. These 'Donovan bodies' were at first believed to be protozoa but are now regarded as probably of bacterial nature. Though the ætiology of the disease is still uncertain the Donovan bodies are such a constant histological finding in the typical ulcer that one is justified in expecting their demonstration in every case. This micro-organism (though the suggestion has been put forward that it is a cell inclusion body, *i.e.*, evidence of cellular reaction to an unidentified virus) plays a part in the ætiology of the disease, but there is, however, no satisfactory evidence that it is the primary invading organism or that it is the only organism maintaining the specific nature of the lesion. McIntosh (1926) was successful in transmitting the disease from one individual to another and constantly found the presence of Donovan bodies in the experimental lesion. Campbell (1928) on the other hand, contests the view of McIntosh and argues that in the transplanted tissues other organisms might be present, and he was unable to transmit

the disease by inoculation of the culture into laboratory animals or human beings, including himself.

Treatment. *Lymphogranuloma inguinale.* The patient should be put to bed early and kept on a nutritious diet. If the glands suppurate aseptic aspiration is indicated, excision of the glands is not advisable in these cases as secondary infection may occur. Chemotherapy has not proved successful. Solganal has been used in doses of 0.1 to 0.2 gm. intravenously every second day, and satisfactory results are obtained after two to six weeks' treatment. Lohe and Rosenfeld (1932) obtained good results by intragluteal injection of an oily suspension of solganal in doses of 0.2, 0.3 up to 0.6 c.cm. of 2 to 20 per cent. twice weekly. A series of 20 injections with a total of $1\frac{1}{2}$ gm. of the gold salt is usually necessary. In case of kidney disease or dermatitis and when gold is contra-indicated, vaccine treatment combined with local application of X-rays gives satisfactory results. Good results are also reported from intravenous injections of such antimony preparations such as neostibosan, fouadin, stibenyl and tartar emetic. Intramuscular injection of serum from convalescent patients has also been tried. It is given in doses of 5 c.cm. every day and a total of about 50 to 100 c.cm. of serum may be given.

Protein shock treatment by intravenous injections of T.A.B. vaccine, in doses gradually increased from 100 to 500 million organisms, at four or five days' intervals, has given good results. Recovery has been reported by daily intravenous injections of 0.03 to 0.1 gm. of methylene blue in 1 per cent. solution. Vaccines made from infected glands have been tried. Frei's antigen has been reported favourably in doses of 0.2 c.cm. gradually increased to 1.6 c.cm. at 2 to 4 days' intervals.

Granuloma venereum. As there are no constitutional symptoms, no particular care is necessary as regards the management of the patient. If there is anaemia iron and arsenic along with the specific treatment are indicated. If there is ulceration an ointment containing 1 per cent. antimony has been advocated, but this treatment is very painful and does not seem to have any effect on the ulceration. Surgical treatment was much practised in earlier days. Excision of the lesion

along with a considerable portion of the healthy tissue, with or without cauterization, may give some amount of success. Irradiation by X-rays has also been tried but has proved unsatisfactory.

Specific treatment. Intravenous injection of tartar emetic was first introduced in 1913 by Aragao and Vianna, and very successful results were obtained with it. In Dutch Guinea de Vogel (1907) found that the results of antimony treatment of granuloma inguinale were very encouraging; in a total of 5,736 cases, 86.1 per cent. were cured after one series of injections and 12.8 per cent. after a second series. Numerous other workers have obtained similar results. Manson-Bahr and Anderson (1927) have estimated the total amount of antimony necessary for a complete cure, which varies from case to case, and is roughly between 17.5 to 17.9 gr. Though tartar emetic is considered almost a specific for the disease, the results obtained have not been uniform. In the early cases complete cure is possible and recurrences are rare, but in the advanced type of case, improvement is not satisfactory and relapses are frequent.

The actual dosage has varied with different workers. In the majority of cases it is well to begin with a dose of 2 c.cm. of 1 per cent. solution of tartar emetic, gradually increasing the dosage to 5 to 10 c.cm. at daily intervals. This may be sufficient to cure a case, but in very extensive and long-standing cases a larger number of injections may be necessary. In chronic cases two or three courses may have to be given at two or three weeks' interval. Having once begun the injections, the treatment should be continued. As is usual with antimony compounds, untoward effects have been observed. Coughing fits during or immediately after the injection and pain in the joints are signs of intolerance to the drug. Jaundice has also been observed.

In order to obviate the toxic symptoms that are observed after the intravenous injections of tartar emetic, other antimony preparations have been employed. Antimony sodium thioglycollate is given to patients who cannot tolerate tartar emetic.

The dose is 0.05 to 0.1 gm., dissolved in 10 to 20 c.cm. of sterile water every third or fourth day until 15 to 25 injections are given. Intravenous or intramuscular injections of triamide of antimony thioglycollic acid have been tried.

Recently the pentavalent compounds of antimony have been tried. Manson-Bahr is of opinion that stibosan (von Heyden 471) is more efficacious than tartar emetic. Giglioli (1928) used stibenyl with good results. The initial dose is 0.1 gm. increased by 0.1 gm. to 0.6 gm. in 20 c.cm. of sterile saline injected intravenously. It is said to be effective in cases resistant to tartar emetic and toxic reactions have been rarely encountered.

Fouadin, a trivalent compound of antimony, has lately been employed. Williamson and others (1933) consider it superior to the pentavalent compounds. The drug is available in ready-made stabilised solution and is given intramuscularly, and even subcutaneous injections are followed by very negligible local reactions. The initial dose is 1.5 c.cm. gradually increased to 5 c.cm. every day or every alternate day and a total of 40 to 60 c.cm. constitutes a course. In a certain percentage of chronic cases the condition does not improve with antimony treatment, but remains stationary. These cases may be due to development of antimony-fastness, similar probably to arsenic-fastness in syphilis. Such cases may react to non-specific protein therapy, and protein shock treatment by T. A. B. vaccine with antimony may prove effective.

PART V

REMEDIES USED AGAINST MISCELLANEOUS TROPICAL DISEASES

CHAPTER I

NUTRITIONAL DISORDERS

BERIBERI

The term 'beriberi' has been applied to a condition of peripheral neuritis, occurring principally among rice-eating populations in the East. While it manifests itself in many forms, it can be classified into two well-marked types :

(a) *The dry type*, characterised clinically by great wasting, anæsthesia of the skin, finally resulting in paralysis of the limbs.

(b) *The wet type*, in which the most marked symptom is excessive œdema which may affect the trunk, limbs and extremities. In these cases the heart usually becomes enlarged and death may result suddenly from heart failure. In this type the mortality is high.

Beriberi is a vitamin B deficiency disease associated with the over-milling of rice. The incidence of beriberi in the Japanese navy in 1912 was 1 per 1,000 while in 1919 to 1921, the figure rose to over 4 per 1,000. This was apparently due to an increase in the white rice ration which was later reduced with beneficial results. When the issue of unpolished rice to the Dutch East Indian Army was stopped the incidence of beriberi rose from 1.8 per 1,000 in 1918 to 26 per 1,000 in the first eight months of 1922. In the Infantile Beriberi Hospital in Manila the admission rate fell from 7.29 per cent. in 1915 to 0.45 per cent. in 1927, and this improvement was due to the issue of *tikitiki* extract (made from the pericarpal layer of rice grain) on a large scale to the poorer classes. The recommendation of the Far Eastern Association of Tropical Medicine Congresses in 1923 and 1925 clearly support the vitamin

deficiency theory. McCarrison is not satisfied that vitamin deficiency is the sole agent in the causation of beriberi. He holds the view that two factors are in operation in the causation of beriberi:—(i) A nutritional or intrinsic, factor; and (ii) an unknown extrinsic factor peculiar to certain tracts of country or to certain individuals. As regards the first factor he finds that it is rice relatively less deficient rather than relatively more deficient in vitamin B which is responsible for the human disease. Graham (1927) stated that supposing the figure 100 represents the amount of vitamin B necessary to keep pigeons in health on any given diet, then true beriberi will occur at figures 75 to 90 while a figure of 50, or lower, will cause *polyneuritis columbarum*. This condition is however quite distinct from true beriberi in pigeons. In the former the heart is atrophied, while in the latter cardiac hypertrophy and degeneration are present. The condition of the heart is considered to be the essential distinguishing feature. The extrinsic toxic factor is of metabolic origin, but a considerable amount of research has been carried out on the possible association of a micro-organism with beriberi. Bernard claims that beriberi is an acute febrile illness and that peripheral neuritis, with or without oedema, only occurs later in the cases that survive. Bernard (1931) isolated *B. asthenogenes* which he claims to be an important aetiological factor. Animal experiments, complement fixation tests, etc., support this view but two additional aetiological factors are demanded, *viz.*, a gastrointestinal condition favouring the action of the organisms and a lowered resistance resulting from faulty diet. If one of these factors is absent, even though the other two are present, beriberi does not result.

Bernard's view regarding the toxic infection and faulty diet has been supported by other workers and some have also associated endocrine disturbance. Matsumura (1927) described a 'beriberi bacillus' resembling *Bact. coli communior* which was isolated from the intestines in experimental animals and from the faeces in 74 per cent. of human sufferers. Positive agglutination tests were obtained. It was claimed that the bacillus is the principal aetiological factor in experimental beriberi. The

possibility of there being a toxin in rice itself has received little consideration. Ohmori (1917) attempted to prove that cold alcoholic extract of rice contains a toxic substance, while Acton and Chopra (1925) have shown that damaged rice may be classified as 'epidemic dropsy rice' and 'beriberi rice' according to whether the water-soluble toxin or the alcohol-soluble toxin predominate. Braddon considered that beriberi is mainly caused by a toxic substance which develops in stale rice as a result of fungus growth. The fungus acts from the exterior of the grain inwards, in a similar manner to the ergot of rye. Van Dieren (1907) draws attention to the fact that the symptoms of beriberi resemble pellagra, ergotism and lathyrism and suggests grain intoxication as the cause. More recently, Teru Uchi and his collaborators have advanced evidence of the presence of 'oryza toxin' in rice. These workers describe the results of certain experiments carried out on pigeons, fowls, dogs, rabbits, monkeys and also 4 men, which are claimed to prove the existence of rice toxin. Simpson (1934) however could not confirm this work. The consensus of opinion appears to be that beriberi is associated with vitamin B deficiency, but that another factor, probably of a toxic nature, is also present.

The water-retention theory was first put forward in 1928 by Mebius and Wenckebach who showed that oedema occurs in heart muscle, chiefly intracellular in site. Excess of water interferes with the normal fluid exchange and consequently with the contractility of the myocardium. The presence of vitamin B controls the osmotic pressure and its absence leads to water retention. It is considered by some that disturbance of lipid metabolism is responsible for the symptoms of the disease. Findlay suggested that the enlargement of the cortex of the supra-renals in beriberi results from an increased storage of phosphorised lipoids, which can only be used by the nucleus of the nerve cell in the presence of vitamin B, so nerve degenerations ensue. Langen concluded that the symptoms of beriberi are the consequence of a disturbance of the lipid metabolism, and this is due to lack of a substance necessary for the synthesis of the phosphatides, namely vitamin. Kimura showed that the nerve changes are degenerative and

not inflammatory ; they commence in the axis cylinders and in acute cases primary injury to the central nervous system may occur. Honda found less affection of the vagus and sympathetic nerves than of spinal nerves. The heart undergoes fatty degeneration.

Infantile beriberi has drawn a good deal of attention in the literature during recent years. The importance of this subject can be realised from the fact that in the Philippines 16,500 deaths occur annually from this cause (about 28 per cent. of total deaths among infants under 1 year). Most of the cases occur in breast-fed infants but exceptions are recorded. It is maintained by some that the mothers of such infants are themselves sufferers from beriberi but according to others in 25 per cent. of cases no symptoms or signs of the disease could be detected in the mother. Clinically, the picture resembles the adult type with œdema and cardiac failure but apparently neuritis (except for that of the laryngeal nerves, causing aphonia) is usually absent.

The most important advances in the clinical study of beriberi are undoubtedly those dealing with cardiology. In 1928 Wenckebach gave a full description of the heart in beriberi. From the onset of the disease the right side of the heart is enlarged and the same is true of the left side but to a lesser extent. The increase in the size of the heart chiefly on the right side progresses rapidly with cardiac failure. Aalsmeer (1931) described what is now known as the 'adrenalin effect', viz., a marked fall in the diastolic blood pressure (practically to zero) after the injection of adrenalin in beriberi patients. This fact is a useful diagnostic criterion.

Prophylaxis and treatment. There is no doubt that the eating of polished rice is a factor of greatest importance in the causation of beriberi ; one would naturally think that the disease could be quickly and easily stamped out by similarly supplementing the diet with food rich in vitamins or by consuming only unpolished rice. This is not always possible.

The difficulty of supplying a sufficient quantity of vitamins in a palatable form to a rice-eating population, if only polished rice is available, is also great. Jansen and Donath (1926) isolated

pure vitamin B from rice bran. They found that one part of this substance in 500,000 parts of washed polished rice protects *Munia maja* (a finch) against polyneuritis. Clinically, beriberi has been treated with this product with striking results. The excellent results obtained in Philippines from the administration of *tikitiki* extract have already been mentioned. The preparation is an alcoholic extract made from the pericarpal layer of rice grain and it is issued by the Public Welfare Board in large amounts. The dosage is as follows: To mothers, in addition to a balanced diet, a tablespoonful of the extract is given after meals; for babies 3 to 4 teaspoonfuls are sufficient in mild cases, but in severe cases 5 to 7 teaspoonfuls are required. Work on similar lines has been done in the Dutch East Indies. Here the public health authorities issue rice-husk vitamin in four forms: (1) Tablets, each containing 7.5 gm. of rice husk absorbed by kaolin; 1 to 3 tablets a day protect an adult eating completely decorticated rice, while for treatment 8 to 12 tablets daily are necessary. (2) A powder similar to the tablets. (3) Extract of antiberiberi vitamin. A daily dose of 1 to 10 c.cm. is sufficient for adult protection. (4) Ampoules (2 c.cm. each) containing 1 mgm. of vitamin which is the daily adult dose. Later, it was found that the above dosage had to be increased somewhat, but toxic effects may sometimes follow the injections. Satisfactory results have also been obtained from the use of various 'oryzanin' preparations and from Wenckebach's 'eviunis.' The substitution of diets containing sufficient amount of vitamin B, in place of those lacking in it, is practised as a preventive as well as curative in not too advanced cases. Vedder (1916) recommended for this purpose the use of beans, peas and other legumes at least once a week together with fresh vegetables and fruits. White potatoes and fresh meat should be given at least once a week but preferably daily. Findlay advised the use of yeast, which contains a large amount of vitamin B. This is now available in the form of marmite, which can be added to soups, etc. Sudley advises 100 to 150 gm. of fresh palm oil daily in mild cases as an effective measure, and also in severe cases if combined with the use of red rice and fresh

mealies. Ogata obtained good results from soya beans as a protection against beriberi.

Various drugs have been tried. Urotropine has been claimed as a specific in doses of 7.5 gr., 4 times a day, for 15 to 21 days. Others have obtained good results with Lugol's iodine solution when a vitamin-rich diet has failed. The similarity between the adrenalin effect in Basedow's disease and beriberi has suggested the presence of thyroid dysfunction. In the treatment of sudden heart failure the usual cardiac tonics fail, and adrenalin is definitely harmful since it causes a marked drop in the diastolic blood pressure, already low in beriberi, and an increase in the venous pressure. According to Wenckebach pitressin raises the diastolic blood pressure in beriberi from almost zero to 75 to 90 mm. and the venous pressure suddenly falls. This beneficial effect may last from 25 minutes to 1½ hours. On the other hand other observers have found that pitressin is not always successful, because the relief of the right heart may throw a sudden burden on the left heart with fatal results. Venesection is an important and a valuable aid in the relief of cardiac failure in beriberi.

EPIDEMIC DROPSY

Rice-eating people are prone to suffer from a condition of œdema which is frequently epidemic and not connected with the usual cardio-renal causes. It was pointed out by Megaw that the condition in one extreme presents the syndrome of epidemic dropsy (fever, rash, gastro-intestinal symptoms, capillary dilatation, glaucoma, etc.) and at the other extreme the picture of chronic beriberi with peripheral neuritis. While there may be some resemblance between the two, epidemic dropsy is now considered as a distinct and separate clinical entity.

The dry or paraplegic form of beriberi is associated with peripheral neuritis with early loss of knee jerks. The patient is emaciated and ataxic and the calf muscles are extremely tender and wasted. It is not possible to confuse these cases with epidemic dropsy. But in the wet form of beriberi in which the

patient is swollen all over and the symptoms of paraplegia are not well marked the two diseases resemble one another and sometimes difficulty arises in differentiating the two conditions. In fact the occurrence of this wet form of beriberi led to the belief that epidemic dropsy is nothing but a form of wet beriberi. The distinctive features are that in epidemic dropsy there are no symptoms of peripheral neuritis excepting pains and aches in the muscles especially of the calves. Fever is usually present which is seldom present in beriberi. Gastro-intestinal irritation, indigestion and diarrhoea which are very common in epidemic dropsy are not encountered in beriberi. The erythematous rash and vascular nodules (sarcoids) are characteristic features of epidemic dropsy. Common complications like glaucoma, abortions, hæmorrhages, etc., of epidemic dropsy are not seen in beriberi. Sucklings are affected in beriberi, but infantile epidemic dropsy is unknown.

According to Mazumdar (1933) epidemic dropsy appeared first in Calcutta in the year 1877. It appeared again in 1878 and 1879 the outbreak being limited to certain quarters of the city and the death rate was high. A small outbreak in a few houses only occurred in Calcutta in 1901. No further cases were reported, till the outbreak in 1907. The feature of this outbreak was said to be the presence of neuritis, deep-seated pains in the feet and legs were generally present and distinct tenderness of the calf muscles was present in a fair proportion of cases. The essential symptom was oedema of the lower extremities, the upper extremities and the trunk being subsequently affected in severe cases. The fever was mild, seldom exceeding 101°F.; cardiac disturbances (palpitation, irregularity of the heart beat, rapidity of the pulse and murmurs) were numerous; anaesthesia of the skin was noticed in this outbreak; weakness and unsteadiness of gait and slight paralysis of the limbs with subsequent wasting of the muscles was also met with in severe cases; the knee jerks were impaired or lost in many instances. Fifteen deaths were recorded out of about 300 cases, there being a mortality of 5 per cent. Death was brought about sometimes suddenly and sometimes slowly. All ages and both sexes, the weak as well as the strong, the well-to-do along with the poor were equally attacked. The outbreak continued throughout the cold weather in 1907-08 but gradually subsided. The next epidemic was in 1909 and after that epidemics occurred in 1919, 1927, 1930, 1931-32 and 1934. The epidemic usually starts in the beginning of August and goes on through September and October and sometimes November and December. It has been observed that this syndrome shows a peculiar periodicity. In certain

years, a widespread epidemic is met with, followed by a quiet period. These waves of morbidity are difficult to explain. Each epidemic brings forth its own peculiarities and cases of one year greatly differ in severity, signs and symptoms from those of another year. The morbidity rate as well as the incidence of mortality vary enormously. In some epidemics the death-rate is very high while in others it is exceedingly low. Although all members of a family are on exactly the same diet, the severity of symptoms varies enormously in different individuals. Children under five and persons over fifty either escape entirely or are only slightly affected.

Ætiology. Epidemic dropsy, unlike beriberi, is not associated with vitamin deficiency but rather with a toxic factor found among the rice-eating people and having its origin in rice grain which has been stored under unsatisfactory conditions. In the presence of excessive heat and moisture such rice becomes diseased and develops toxic products. All cases of epidemic dropsy seen by the author occurred among those whose main dietary consisted of rice and in almost every case it was established that the rice was diseased. A spore-forming proteolytic bacillus of the *vulgatus* group is commonly found in the diseased grain. In this connection it may be mentioned that Bernard of Saigon found a very similar bacillus and described an infection occurring in animals when fed on these bacilli. There is no close connection between avitaminosis and this disease, because if this were the case it would occur in an epidemic form when associated with famine conditions and this certainly has not been so in Bengal. The findings of Acton and Chopra (1927) regarding this bacillus occurring in the urine and stools of patients have been lately confirmed in many cases. Rice in the form in which it is harvested is enclosed in a tough indigestible husk before it is husked. In this condition it is protected from the attacks of microbes and moisture, but when stored under unhygienic conditions and exposed to excessive moisture and heat it is liable to deteriorate. The poisons are most readily formed in rice grains which after having been deprived of their vitality by parboiling and of most of their aleurone and other protections by excessive milling, are then badly stored in a humid and warm atmosphere. In such conditions they are attacked and damaged by fungi and bacteria, and particularly by a strongly proteolytic bacillus of the *vulgatus* group.

Some of the toxins formed are soluble in water and affect the heart, besides producing a fall of blood pressure, bronchial constriction and swelling of the limbs, experimentally. Some are soluble in alcohol, which act as neurotoxins and have no effect on the respiration or blood pressure. Respective amount of water-soluble and alcohol-soluble bases differ in different grades of rice. Those in which water-soluble toxins predominate are termed epidemic dropsy rice and those in which alcohol-soluble ones predominate, beriberi rice.

Rice test. The test for diseased rice introduced by Acton and Chopra is very simple. Dry grains from the suspected supply are soaked in water (or glycerine) in a petri dish laid on a black surface. Healthy rice is translucent; the diseased rice shows areas of white opacity and softening, usually starting at the embryonic site. The proportion of grains which show such degeneration determines the degree of infection in the rice. When the grains are badly diseased, the rice can be crushed up into a powder by the fingers. It is, however, necessary to differentiate such grains from the barrows of the larvae of weevils. Section of diseased grains shows a liquifaction of starch cells.

Signs and symptoms. Dyspnoea is an early feature, complained of before gross evidence of the cardiac damage appears. Oedema occurs to a greater or lesser extent in all cases. Anæmia is a prominent feature in all cases. The blood pressure is generally low and the pulse compressible, probably due to widespread dilatation of the capillaries causing oedema of the heart muscle. The condition of the heart can be classified into three groups: (a) *Acute or fulminating*: in which the patient has the heart affected from the very start, failure progresses and death may occur within four to seven days. These cases resemble the picture of an acute left-heart failure. This type, with a high mortality, was common in the epidemics of 1926 and 1927. (b) *Subacute or chronic*: here the heart is less rapidly affected, and failure, from which recovery is usual, is a slow process. These cases resemble the picture of a combined right and left-sided failure, with slight cyanosis, jugular distension and general systemic venous congestion. This occurred in the 1932 epidemic. (c) *Formes frustes*: here the heart either wholly escapes, or is very slightly affected. This type was seen in one or two epidemics. The existence of these three distinct types cannot be explained in terms of the varying degrees of histological changes in the heart wall itself. But it is easy to understand the mechanism of these three modes of cardiac failure, by recalling the picture of a general capillary dilatation. The degree and severity of circulatory failure along with a secondary cardiac weakness are directly proportionate to the degree and extent of capillary dilatation that exist. The acute fulminating type of failure starts with a very deep and extensive capillary distension and stasis, somewhat similar to that in surgical shock or acute histamine poisoning. The blood is locked up in the capillaries, and thus is side-tracked from the circulation. Consequently the veins, the heart and big arteries are relatively empty, and sudden syncope and death may result. On the skin an erythematous rash is frequently met with which may be associated with the formation of sarcoids here and there. There may be pigmentation of the face and extremities.

While cardiac involvement is the rule, its severity is not uniform. In certain epidemics, severe diarrhoea is the predominant symptom and the cardiovascular symptoms are of a mild nature. In patients with constipation, the cardiac features usually progress rapidly and

become serious, often leading to a fatal end. In yet another group, mild cardiovascular symptoms are associated with a high rate of ocular complications such as glaucoma ; there is as a rule only slight diarrhoea and cedema of the legs in these patients. Diarrhoea is probably produced by the toxic bases in the intestines which not only damage the capillaries and produce cedema, but also produce exfoliation of the mucous lining of the gut.

The intoxication starts with the ingestion of the affected rice. In the stomach and duodenum local irritation is produced which may proceed down to the rectum, causing areas of congestion and necrosis of the mucosa. Local injury to the rectal mucosa causes occasional vascular swellings which bleed profusely. The absorption presumably takes place through the liver which also shows the typical lesions and the antitoxic function of the liver is severely tested but fails, and finally the toxin reaches the general circulation. Although symptoms may commence as early as twenty-four hours after feeding, the effects of this intoxication are very severe and serious and may continue for some weeks after a rigid stoppage of the suspected food-stuff. This suggests a massive storage of the toxins, or a linkage with the cells of various tissues, such as is known to occur in heavy-metal poisoning, with lead or mercury, for example.

Treatment. Rational therapy might be summed up as follows:—

1. Stimulate elimination of the toxins by the bowels.
2. Neutralize or break down the toxins in the bowels into inert harmless products.
3. Prevent absorption of the toxin.
4. Stimulate the antitoxic power of the liver so that the toxins are broken down into simpler products.
5. Stimulate the defensive mechanism of the body whereby the ductless glands may produce hormones destructive to the toxins.
6. Quicken up the process of elimination by the kidneys.
7. Add to the diet appropriate vitamins which may render the toxins inert.
8. Counteract the 'capillary crisis' throughout the body and thus hasten the process of circulation.
9. Support the heart by tonics.
10. Relieve the venous congestion by leeches or venesection.

In practice, however, all these ten points cannot be dealt with for want of exact knowledge, but the prospect is far more hopeful than might at first sight appear. We have, in the past, relied exclusively on cardiac tonics, in one shape or another, and have ignored the other vital therapeutic points. Since the heart is 'sinned against as well as sinning' this narrow view of therapy could not possibly give the best results. The 'cardio-capillary crisis' is best dealt with by that group of drugs which has a sustained vaso-pressor effect, combined with the power to counteract the increasing permeability of the capillary walls. It is fortunate that in ephedrine we possess a potent remedy whose selective seat of action is in the capillaries, and an extended use of ephedrine has fully confirmed the success. The digitalis group of drugs has failed, because this capillary crisis is left untouched and until this is corrected no cardiac tonic can maintain adequately the circulatory process. In calcium we possess a means of decreasing the permeability of the capillary walls.

Rice is entirely cut out from the dietary. It is definitely established that the progress is much slower if rice is allowed as a part of the diet. Diarrhoea, if mild, needs no treatment, but if severe 15 to 30 min. of liquor ferri perchloridi with a little glycerine are distinctly helpful; liq. strychnine hydrochlor. may be added when there is weakness of the heart. Apart from the astringent action of iron on the gut it also acts on the hæmopoietic system and stimulates blood formation. In cases where the heart is involved and there is decompensation, digitalis gives unsatisfactory results. Injections of small doses of adrenalin, such as 3 to 4 min., give only temporary relief in some cases and ephedrine by itself fares no better.

The drug which is most effective in controlling the heart symptoms is tincture of ephedra, prepared from an Indian species of ephedra, *E. vulgaris* Rich. (*E. gerardiana* Wall.), first introduced by the author. The Indian variety of ephedra contains larger quantities of pseudo-ephedrine and comparatively less ephedrine as compared with the Chinese varieties. The

vaso-pressor effect is stronger in the case of ephedrine which acts almost entirely on the vasomotor nerve endings, while pseudo-ephedrine has been shown to have some stimulant action on the musculature of the arteries and a similar action on the myocardium. It is this stimulation of the myocardium by pseudo-ephedrine, and the stimulation of the accelerator mechanism by ephedrine which makes tincture of Indian ephedra a very valuable remedy when the heart is failing. Digitalis is not only ineffective but may be distinctly harmful especially in the early stages. When œdema of the lungs sets in it is better to perform venesection and let out 10 to 12 oz. of blood, so as to relieve the over-loaded right heart and stagnant pulmonary circulation.

PELLAGRA

Pellagra is an endemic disease characterised by dermatitis and pigmentation of the skin especially of the exposed parts of the body, marked emaciation and certain nervous manifestations. The eruption consists of symmetrical patches of erythema on the back of hands, forearms, and extending up to the neck.

It is well known that pellagra is a disease of the poor in rural districts subsisting on limited choice of food. It has been shown to be associated with the use of maize as a staple article of diet, while its occurrence in populations who subsist on wheat or rice is comparatively rare. The above facts throw some light on the causation of the disease which may be briefly stated as follows: (i) firstly, it may be due to some factors in the dietary, either a deficiency of vitamins or of certain essential constituents, or to elaboration of toxins; and (ii) secondly, it may be the result of some infectious process. The latest view, however, is that the absence of some essential food factor, whatever its true nature may be, is the principal cause operating in the ætiology of the disease, though an infectious process may be associated with it.

Vitamin deficiency. Just as beriberi and scurvy are now recognised as food deficiency diseases due to the absence of certain essential vitamins in the diet, substantial evidence has been put forward that pellagra belongs to the group of food deficiency diseases. In this connection may be noted the classical work of Goldberger and his co-workers who furnished some evidence in favour of the food deficiency theory and showed that there is absence of a pellagra-preventive factor (P. P.) in the diet of people suffering from the disease.

Among the earlier workers, Deeks (1912) and later Funk suggested that pellagra is produced by certain deficiencies in the diet. Goldberger and his associates (1914) conducted experiments on eleven prisoners by giving them rich carbohydrate diet with deficiency of protein elements. The diet consisted of highly milled wheat flour, maize meal, corn starch, white rice, cane sugar, etc. After about six months, six of them developed symptoms identical with pellagra, but in a control series of experiments with normal diet none developed the disease. Later (1925) the existence of a hitherto unrecognised factor necessary in the diet to prevent or cure pellagra was announced. It was shown that yeast and other articles of diet which are known to contain vitamin B, contain in addition to the antineuritic heat-labile vitamin B another water-soluble complex, *i.e.*, the P. P. factor or pellagra-preventive factor. Chick and Roscoe (1927) showed that vitamin B is not a single factor but consists of two parts, B₁ and B₂, the absence of B₁ causes beriberi while deficiency of B₂ produces ophthalmia and dermatitis.

The richest sources of vitamin B₂ are yeast and yeast extracts, liver, eggs, milk, meat, and green vegetables, while fruits, legumes and cereals are relatively poor. Vitamin B₂ has thus a distribution in food-stuffs somewhat similar to that of antineuritic vitamin B. In general the food rich in vitamin B₂ are those containing proteins of high biological value, but its presence in abundance in protein-free extracts made from yeast, egg white and liver is proof of its separate existence apart from the proteins with which it is associated. Ordinary canned tomatoes are deficient in P. P. factor, but may prevent pellagra if given in sufficient quantity and so also the commercial wheat germ.

Though the P. P. factor is probably present in all the foodstuffs which contain antineuritic vitamin, it is however variable, as certain strains of yeast have been found to be potent sources of anti-pellagra factor though poor in antineuritic vitamin. It has been held that certain processes of preparation eliminate the pellagra-preventing vitamin from the diet. In milling maize the vitamin content of the grain is removed as from analysis of the vitamin content of milled maize it has been found that the P. P. factor is deficient according to the degree of milling. Excessive milling of wheat gets rid of vitamins, and the bread made from highly milled flour is dietetically deficient. Similarly the practice of using alkalis in the preparation of bread is another factor in the food deficiency problem. Others however think that the bacterial or mould diseases of the corn grain are responsible for the destruction of the vitamin contents.

In recent years cases of secondary pellagra have been described, which stress the importance of vitamin in the dietary. Patients suffering from chronic maladies of the digestive tract develop pellagra as a secondary condition, especially alcoholics and those who do not take a well-balanced diet. In these cases the primary digestive disturbances most frequently consist of chronic diarrhoea or diarrhoea alternat-

ing with constipation and accompanied by pellagra dermatitis, stomatitis, etc. These conditions are said to be due to deficient absorption of vitamins as the result of a pre-existing disease of the digestive tract.

In the light of recent studies of the vitamin B₃ content of cereals the theory of vitamin deficiency however breaks down. If pellagra was caused by a simple deficiency of vitamin B₃ it should occur chiefly where people subsist on poor diets containing rice, rather than maize, as the latter has been shown to contain a high proportion of vitamin B₃. But among the rice-eating people, beriberi and not pellagra is the menace, while pellagra is of common occurrence among those whose principle article of consumption is maize

Amino acid deficiency. The association of pellagra with maize consumption has given considerable support to the theory that the disease might be caused by lack of proteins of high biological value. The commission which investigated the occurrence of pellagra among the Turkish prisoners in Egypt during the Great War showed that a certain amount of protein is necessary for rebuilding of tissues. It has been found that the nitrogen contained in certain amino acids is utilised while others do not serve this purpose. In this respect animal protein is superior to maize protein. Forty grammes of animal protein daily are considered as the minimum biological protein value, *i.e.*, the amount necessary to maintain the nitrogenous equilibrium of the body. The protein of a diet is estimated by its assimilable or biological value and not by its gross weight. The biological protein value of any diet can be obtained by dividing the total quantity of a substance by the following factors: for animal protein 1, rice protein 1.27, pulse protein 1.82, wheat flour protein 2.55 and maize protein 3.4. Hence to keep the body in nitrogenous equilibrium with maize protein alone, about 136 gm. of such protein have to be consumed. In the case of Turkish prisoners in Egypt their rations had a biological protein value of 33.5 and hence a large number of cases occurred among them. It has also been suggested that in a susceptible subject the protein requirement may be sufficient while at rest, but during hard labour or during a time when his metabolism is faulty, pellagra may set in.

Goldberger and Tanner (1922) showed that a low protein value of diet was not necessarily associated with the development of pellagra. They found that in the causation of pellagra certain amino acids were deficient in the diet consumed by the patients. The protein of maize flour for instance, zein, is deficient in certain amino acids, such as tryptophane and lysine. Benefit has been reported from the administration of cystine and tryptophane to these patients and in preventing the occurrence of pellagra.

Animal protein as a class contains a more varied assortment of amino acids than vegetable proteins. It is generally true that nitrogenous equilibrium can be maintained on a smaller intake of animal

than of vegetable protein. The good effects on pellagra noticed after the addition of meat, milk and eggs are probably due to a supply of a richer variety of essential amino acids. The theory that pellagra arises as a result of an amino-acid deficiency has led to many investigations with the object of finding out the relative biological values of the proteins of the common foodstuffs. The results of these experiments show that pellagra-preventing foods, such as meat and milk, have high protein values while maize has a low protein value. It is also significant in this connection to note that values obtained for maize proteins by several workers have not been found to be inferior to those of wheat or other cereals. Wilson (1932) examined the B_3 contents of various diets which have been known to be associated with either the causation or cure of pellagra. It is claimed that vitamin B_3 deficiency has no connection with the occurrence of the disease, as it was found that 150 gm. of meat added to a pellagrous diet of sufficient caloric value cured the disease while 210 gm. of maize were unsuccessful in that respect though the vitamin content of both was the same. Pellagra-producing and -preventing diets showed that there is no consistent relation between the vitamin B_3 value of diet and the incidence of the disease. On the other hand definite connections were shown to exist between the protein value of diets and pellagra. This protein value, as has already been mentioned, is dependent upon the amino acid content, and in this respect the vegetable proteins are generally less efficient in maintaining the nitrogen equilibrium than those in meat and other foods.

The action of these amino acids in the prevention and cure of pellagra brings to light some interesting facts. Cystine has been known to promote the growth of vitamin B and is probably connected with oxidative processes and with detoxication of cyanogen compounds. All of these functions appear to be disturbed in pellagra. Hopkins isolated glutathione, a combination of cystine with glutamic acid from yeast, muscle and liver. Cystine is also present in the antipellagra diet recommended by Goldberger, and it seems, therefore, reasonable to think that lack of cystine in the dietary may play a part in the causation of pellagra. In addition the part played by the mineral constituents of the foodstuff, such as iodine, iron, copper, manganese, etc., needs investigation which may throw further light on the subject.

Maize toxin. In spite of many satisfactory theories regarding the aetiology of pellagra, the usual association of the disease with the consumption of maize still remains to be explained. The possible toxic effects of maize, spoiled or unspoiled, have therefore been much discussed. The occurrence of the skin lesions on exposed parts of the body in pellagra led to the idea that maize might contain a photo-sensitizing substance analogous to that contained in buckwheat. Jobling and Arnold (1923) produced experimental evidence that toxic substances are produced in the intestine as a result of a maize diet; on injection of the extract of the material into animals they were found to be sensitive to

light with swelling and oedema of the eyelids. The search for a toxic substance has lately been made.

Mellanby thinks that toxic substances (toxamins) in cereals give rise to pathological conditions that are seen in pellagra and after administration of appropriate vitamins these toxamins can be neutralised. The cutaneous symptoms according to him are due to vitamin B₂ deficiency, which can be remedied by giving such vitamins in the diet, and that the nerve lesions are caused by the presence of toxamine, more especially present in the maize. Roscoe however is not inclined to believe in the existence of any toxamine in maize. Maize contains, weight for weight, the same amount of vitamin B as wheat and more than what rice contains; if maize were definitely toxic then the greater the amount of maize consumed the worse would be the symptoms of pellagra, but it is agreed that the opposite is the case in such instances.

Sabry (1931 and 1932) made an extensive study into the part played by maize toxin in the causation of pellagra. He disapproves of the vitamin deficiency theory and is of opinion that pellagra is due to a toxin which may occur in maize or in any other cereal but always occurs in a specific cereal, namely beans. The toxin of pellagra according to him, is causally related to the hyper-pigmentation that occurs in the disease and he believes it to be a dioxypyhenylalanine. He obtained very satisfactory results with intravenous injections of sodium thiosulphate. The usual procedure was to give intravenously 10 c.cm. of a 10 per cent. solution daily, the number of injections varying from twenty to sixty. Chick (1933) has recently advanced a view which is perhaps a combination of several factors. She postulates that pellagra may be caused by a toxic substance derived from the maize diet which can be corrected by sufficient quantity of protein or perhaps by sufficient vitamin B which is present in these proteins.

Infection theory. Sambon (1906) maintained that pellagra is a protozoal disease, but this has not been confirmed. No satisfactory evidence has been adduced to show that pellagra can in any way be considered a directly infectious disease. Some investigators have found *B. welchii* and other anserobic organisms in large numbers in pellagrous stools, and have suggested the provision of sanitary privies for preventing the spread and finally eradication of the disease. Goldberger and his colleagues are of opinion that such facts as complete absence of the disease among the nurses and attendants in the hospital seem to refute the theory that pellagra is at all infectious. It seems that dietary instead of a specific infection is probably the cause. Experimentally it was found that even ingestion of skin scales, nasopharyngeal secretions and epidermal secretions of the pellagra patients failed to produce the disease in a number of volunteers and they remained completely healthy during an observation period of six months.

Certain facts have recently been brought to light which show that in many countries where pellagra is very common, e.g., in Egypt, some

associated infections of the intestine may be found. Biggam and his associates (1933) in a large series of cases found that 94 per cent. of these patients were infected with helminths. Lane is of opinion that in addition to the deficient nutrition caused by dietetic deficiency, helminthic infection may also be responsible for such condition. Many workers have reported that schistosome infections predispose to an attack of pellagra and so also coexisting infection with amoebic or bacillary dysentery.

Treatment. The available evidence at present suggests that this disease is not contagious, isolation of the diseased individuals is therefore useless. A proper well-balanced dietary is the essential factor in preventing the occurrence of pellagra.

The disease shows periods of quiescence and exacerbations. Absolute rest and removal from the surroundings are of great benefit. Hydrotherapeutic measures have also been advocated; drinking of large quantities of water, cold abdominal compresses, hot packs and saline baths are said to alter favourably the course of the disease.

Diet. The dietary in treatment is the most important factor to be considered. In Italy where there was an epidemic of pellagra following the consumption of diseased maize, special measures were undertaken by providing grain-drying appliances for bakeries and other hygienic procedures together with dietetic treatment of individuals. This considerably reduced the incidence of the disease. Statistical records of treatment of pellagra with food containing sufficient amount of P.P. factor are very convincing. In this respect the addition of 2 to 4 oz. of skimmed milk or 1 to 2 oz. of wheat germ or $1\frac{1}{2}$ pints of canned tomatoes or 1 oz. of pure dry yeast, per person per day to the food supply, has been known to reduce greatly the incidence of pellagra.

Milk, though not rich in pellagra-preventing factor, is one of the most important article of diet in the cure and prevention of the disease; about 1 quart of milk daily should be given if other articles such as meat, vegetables and fruits are not taken in sufficient quantities. Vegetables and fruits are not rich in the P.P. factor. In the treatment of a case, meat, eggs, tomato and yeast together with milk are recommended; dried yeast in doses of 15 to 30 gm, daily in addition to the usual dietetic

measures gives a satisfactory result. Goldberger and Tanner recommend the following diet in pellagra which they found very beneficial. They give 200 gm. of lean meat daily together with brewer's yeast in the form of a dry powder in doses of 50 gm. daily during the active stage and about 15 gm. during the period of convalescence. Rice husk has also been recommended, daily doses of 50 c.cm. of the watery extract are given, or a preparation of rice husk known as 'oryzanin' may also be employed.

Drugs. Drugs have only a secondary importance in treatment. Arsenic in large doses has been regarded as a drug of value especially as a tonic. Fowler's solution in doses of 5 min. may be given three times daily. Similarly, other arsenical compounds, atoxyl, soamin and salvarsan have also been recommended.

From the fact that wheat germ when given orally is known to cure pellagra; intravenous administration of a 10 per cent. solution of wheat germ in normal saline has been tried. This is said to improve the condition of the patient. Administration of liver extract has also been recommended and this should be carried on along with the usual dietary treatment. Liver extract may be given by the oral route or by the intramuscular or intravenous channels. In patients with severe stomatitis and glossitis it may be difficult to feed them and in such cases liver extract is said to have a great effect in reducing the local lesions. Ventriculin has also been tried but without any conclusive results.

Massive doses of iron are reported to have given satisfactory results. Biggam and Ghalioungui (1933) treated twenty-six typical cases of pellagra with iron; for the nervous manifestations they prescribe Bland's pill in doses of 150 gr. twice daily for a period of 6 to 8 weeks together with a well-balanced diet.

Intravenous injection of sodium thiosulphate is said to give satisfactory results. Sabry (1931) recommends 10 c.cm. of a 10 per cent. solution to be given intravenously and the number of injections varies from twenty to sixty.

LATHYRISM

Lathyrism is a common disease in certain parts of India, especially the United Provinces, the Central Provinces and several districts of Behar. In 1868 Irving stated that nearly 7 per cent. of the population of certain districts of the former were afflicted with the disease and Acton in 1922 found that in Rewah there were 60,000 cases chiefly affecting men in the early prime of life.

In India it has been held for a long time that lathyrism is due to certain poisonous substances occurring in the pea *Lathyrus sativa* (*khesari dal*). Buchanan in 1904 stated that continued consumption of *khesari dal* for some months together contributed to the causation of the disease. *Lathyrus* is a vetch, and the peas of three species, *L. sativa*, *L. clymenum*, *L. cicera* are used habitually as an article of diet in India and Algeria by the people. When consumed in moderate amount they do not produce any symptoms, but in times of famine increased consumption has given rise to epidemics of severe poisoning especially among the poorer classes who subsist on them. Besides in India outbreaks have also occurred in Italy, France and elsewhere in Europe. Occasionally similar symptoms have been produced in cattle. In the laboratory, feeding experiments give varying results as different species of animals vary greatly in their susceptibility to the poison. Fowls, pigeons, and partridges eat the lathyrus pea freely and with apparent immunity; ducks are readily affected. Some animals fatten on this pulse while others are immune. Horses are particularly susceptible and have often died. The outstanding symptom in animals is muscular weakness; in acute poisoning with large doses the motor nerves are depressed but in feeding experiments with repeated doses such an effect may not be observed. In chronic poisoning the deep reflexes are increased and in monkeys and horses spasmodic attacks may occur irregularly in addition to the paretic symptoms. Death results from paralysis of the respiratory muscles.

In man the symptoms are usually precipitated by exposure to cold, wet and fatigue. Sometimes there may be prodromal symptoms, such as pain, numbness and cramps. As a rule the patient suddenly feels the legs and loins heavy, there is dragging of the legs, increased reflexes and more or less inability to walk. Later, there may be extreme spasticity and rigidity of the leg muscles; the case may progress to such a condition that he can only move his hands and feet in a sitting posture. Sensory disturbances and muscular wasting are not generally evident which point only to a partial degeneration in the cord. But in many cases symptoms such as loss of control of bladder and rectum, tingling, formication, lightning pains, diminution of tactile, heat and pain sensations and marked muscular wasting have also been recorded.

The exact nature of the lesion, occurring in man is not known. In experimental animals no lesion of the spinal cord or nerves have been found, but well-marked degenerative changes in the ganglion cells of the grey matter of the cord, in the vagal and accessory nuclei of the medulla, in the lateral columns and motor nerve roots of the spinal cord, and in the recurrent laryngeal nerves together with thickening of the walls of the arterioles and capillaries in the spinal cord have been described in horses.

Though the disease has been attributed for a long time to the consumption of the lathyrus pea in sufficient quantity over a sufficient period of time, the exact factor responsible for its production is not yet settled. Acton (1922) describing some cases in Rewah stated that *Lathyrus sativa* peas caused paralysis and death in ducks, but after the pulse had been steeped in water the animals lived and thrived on it. This is due to the fact that the poisonous principle is soluble in water, and can be removed by soaking the grain for 24 hours in three changes of water. It has been found however that some crops will apparently produce lathyrism while others will not and the experimental work by various workers has given discordant results as to the poisonous properties of lathyrus. Howard, Simonson and Anderson (1925) in an elaborate study of the subject concluded that *khesari dal* (*Lathyrus sativa*) did not contain any poisonous bases at all, and did not produce symptoms of paralysis in ducks that had been fed exclusively on this vetch, provided it had been freed from a closely allied vetch, *Vicia sativa* (*akri* or *akti*). When *Vicia sativa* was given to ducks and monkeys in the proportion of 10 to 50 per cent. in the food, it produced symptoms of nervous disease very similar to those of lathyrism, followed by death. They concluded that lathyrus is chemically free from any poisonous alkaloids and that these grains are harmless and even nourishing to these animals. Though some of the symptoms resemble those occurring in human lathyrism they are not prepared to state, in the absence of definite pathological proof, that *akti* is the cause of lathyrism in man.

Acton and Chopra (1927) reinvestigated the problem of the part played by *Lathyrus sativa* in the causation of lathyrism; they concluded that lathyrism is due to a contaminating weed *Vicia sativa* in *khesari dal* and not to any poison in the latter. The non-germinating seeds of *Lathyrus sativa* freed of *akti* contain no alkaloid or toxic substances and similarly the seeds that have germinated for 48 hours and previously freed from *akti* likewise produce no toxic symptom in experimental animals. The toxic principle divicine resides in the contaminating weed. This is probably closely related to barbituric acid which forms a toxic principle in many drugs such as, veronal, luminal, etc. Divicine can be split into barbituric acid by hydrolysis when the two NH_2 groups are replaced by an H and O group and it is probably due to this hydrolysis of barbituric acid that some toxic substance is formed which acts

on the central nervous system. It has been found that doses of 50 mgm. of this toxic base can produce paralysis of the hind legs of guinea-pigs. The reason why lathyrism is not prevalent throughout the year is the fact that in ordinary years *khesari dal* is free from this contamination and hence no lathyrism occurs, but during the period of famine the diet of poorer classes of people is wholly made up of an imported variety of lathyrus contaminated with *akki*, as it is the cheapest food available at the time. Moreover when a deficient diet, such as a whole diet of *khesari dal* is consumed, the general resistance of the body is lowered so that the poison can act more powerfully on the individuals.

Young (1927) made a contribution of a different nature. As a result of extensive investigations he found this *akki* contamination to be so rare that it could have but little, if any, effect in producing symptoms of lathyrism. In his cases lathyrism occurred when *Lathyrus sativa* predominated in the diet. In addition an analysis of the diet of those people showed that there was marked lack of fat soluble vitamin A, and he is inclined to believe that lathyrism may be to some extent, a deficiency disease. Stockman (1929) conducted a series of experiments on different species of animals and stated that lathyrus peas contain a poisonous principle and it is the cause of lathyrism, but as it is present in very small amount, its isolation in a pure state and in sufficient quantity has proved to be extraordinarily difficult. Many samples of lathyrus peas are non-poisonous or practically so unless consumed in large quantities. In human epidemics not all those who consume the peas are affected. This is due to the fact that there is great difference in the susceptibility of different species and of individuals of the same species of animals to these poisons, and hence results are variable.

Stott (1929) on the other hand, carried out investigation on horses by feeding them both with *Lathyrus sativa*, *Vicia sativa*, and keeping one as control. At the end of 4½ months all ponies were in the same excellent condition and had put on weight. It therefore appears that experimental proof of the factor responsible for the production of lathyrism is not corroborative, and further investigation into the problem is necessary.

Prophylaxis and treatment. The prevention of the disease depends on the improvement of the economic condition of these people and abolition of the system of bondage that exists in some states of India at present. Howard suggests that *khesari dal* should be planted in drills and the contaminating *Vicia sativa* removed by weeding. This should be done not only in places where lathyrism is rife but also in those areas from where the imported grain is sent to the famine stricken areas. But in view of the divergent views on the part played by *vicia* in the

spread of the disease, no successful measures can yet be devised. Nourishing diet is obviously of value. There is no specific treatment. The paralysed parts should be kept warm; massage and electricity are indicated.

INFANTILE BILIARY CIRRHOSIS

In the tropics the liver is particularly liable to be affected in a variety of conditions. Malaria, kala-azar, amoebic dysentery, are all known to cause derangement of the functions of the liver. The frequency with which hepatitis or even abscess of the liver follows an attack of amoebic dysentery, if left untreated, is too well known. Malaria and kala-azar are known to produce cirrhosis of the liver with ascites. Various parasitic infections of the liver, such as hydatid cyst, bilharzial cirrhosis, etc., are of common occurrence in the tropics. The treatment of these conditions naturally lies in removing the cause of the disease. Reference to these has been made in appropriate chapters.

Besides the various affections of the liver enumerated, a form of cirrhosis of the liver, affecting especially children under one year of age, has been noticed. In India it is common in Bengal, Madras and Bombay Presidencies. As a rule it runs a more or less protracted course of about eight to ten months; sometimes the disease may terminate in death in 2 or 3 weeks.

The clinical picture of a case may resemble greatly the features of acute yellow atrophy or the hypertrophic cirrhosis described by Hanot. The recognition of a case of infantile biliary cirrhosis does not, as a rule, offer much difficulty. The classical signs of hypertrophic cirrhosis of the liver, such as enlargement of the liver, ascites, dilatation of the abdominal veins, jaundice, clay-coloured stools are present in the majority of cases. Some cases however are known to begin with symptoms of catarrhal jaundice followed by signs of acute necrosis and acute insufficiency of the liver. Ultimately the patient develops deep jaundice, oedema of the eyelids and lower extremities with a considerable amount of ascites, enlargement of the liver and sometimes of the spleen. The known causes of catarrhal jaundice, such as, congenital syphilis, enteric fevers, Wells disease and many chemicals including organic arsenicals, phosphorus, cinchophen, etc., may be excluded as causative agents in this condition. It has been stated that the condition is due to infection with a virus. Though definite proof of this is lacking, it is possible that the acute necrosis that occurs in these cases is due to superadded

toxæmia as a result of previous damage of the liver cells by the virus. That similar conditions may be produced by other agents is well known. Opie (1910) observed that acute necrosis of the liver results from combined action of chloroform and *Bact. coli*. Hurst and Hurst (1928) produced similar changes with the combined action of manganese chloride and *Bact. coli*. Findlay showed that the extent of damage to liver cells was far greater when arsphenamine was used. Similarly, other observers have noticed secondary infections with *Streptococci*, *Bact. coli*, *Bact. faecalis*, etc., in a large number of cases of cirrhosis of the liver in infants. Moon (1932) showed the presence of streptococci in the histological specimens of the liver in these cases. It thus appears that many of these cases may have a super-added bacterial infection in an already damaged liver.

The cases which develop the typical character of hypertrophic cirrhosis usually do not offer much difficulty in diagnosis. They usually show enlargement of the liver, as well as of the spleen, with ascites, well dilated veins on the chest and abdomen, irregular temperature, anæmia and marked emaciation. This form of cirrhosis is said to be more common among the children of the well-to-do families and it tends to run in certain families. Poynton and Wyllie (1926) stated that cirrhosis in infants is frequently associated with infantilism. Many of these cases undoubtedly present pictures of infantilism with stunted growth, delayed dentition and inability to stand or speak.

Although the ætiology of the condition is unknown, there is good ground for belief that some sort of toxin is at work. The toxin is said to be conveyed to the smaller bile ducts by the hepatic artery, resulting in the production of biliary cirrhosis with degeneration of the cells in the first instance and subsequent increase of intercellular connective tissue. Malaria, kala-azar, alcohol, etc., which are known to cause hypertrophic cirrhosis of the liver, probably do not play any part here.

Treatment. Treatment of this condition is far from being satisfactory. Whenever the disease is seen to run in families, the child should be removed from the endemic locality and artificially fed. Diet is of particular importance. A fat-free diet is generally advised, but not sufficiently defatted to impoverish the nutrition of the child; fruit juice and sugar should be added along with it. These cases show marked disturbance of the carbohydrate metabolism. The liver is poor in its glycogen store as it has been shown that on fasting, the blood sugar level is very low. Glucose along with insulin temporarily improves the condition of the patient; for this, 5 units of insulin should be injected coupled with 4 dr. of glucose by the mouth and repeated as the condition requires.

Constipation and tympanitis if developed should be treated on usual lines.

CHAPTER II

METABOLIC DISORDERS

DIABETES MELLITUS

Diabetes is a disease which should prove to be of great interest to any one working in India not only because it is extremely common here, more particularly in Bengal, but also because the disease was known to the ancient Hindu writers as early as the 6th century B.C. Charaka (2nd century A.D.), the most renowned Hindu physician of his time, described some of the cardinal symptoms of diabetes (including the presence of sugar in the urine) in his *Charaka Samhita*. It appears that Charaka collected his materials from a much earlier work of *Agnivesa* who again based his writings upon the teachings of his master *Atreya* (6th century B.C.). It is a disease which may be said to have its home in the tropics. What gout is to the nobility of England, diabetes is to the aristocracy of this country. Among the ancient Greek writers, the symptomatology and prognosis of diabetes are to be found in the writings of Celsus (25 A.D.). The name diabetes (which means 'to pour through a syphon') was given by Arateus in 30 A.D. Among the European writers Thomas Willis, an English physician of repute, first noticed the characteristic sweet taste of diabetic urines in 1670, thus establishing the basic principle for diagnosis between diabetes mellitus and diabetes insipidus.

Ætiology. The consensus of the present day opinion is that a pancreatic lesion plays the most important part in the ætiology of diabetes and that the root cause of diabetes centres round the islands of Langerhans, though the nature of the factor or factors giving rise to the diseased condition of the islet cells has not yet been clearly understood. The predisposing causes which directly or indirectly are likely to throw undue strain on the islet cells of the pancreas and cause their hyaline degeneration and atrophy sooner or later are many, the more important among them being sedentary habits, lack of physical exercise, ill-balanced diet, overeating, too much mental work, infections, etc.

Heredity is also believed to be an important factor. In some of the writer's series of cases, diabetes could be traced to run for three or more generations.

Climate is also believed by many to be one of the factors. It has been stated that tropical and sub-tropical climates lower the carbohydrate tolerance of individuals. Basset-Smith has observed that under the influence of the tropical heat, there is a tendency to the retention of carbonic acid in the alveolar air in people at rest and also to the production of glycosuria and acidosis particularly in the well fed.

Coming to the incidence of diabetes among the different races of India the writer is of opinion that Bengalee Hindus appear to be more prone to diabetes than any of the other races, the proportion being 54 per cent. among the total cases.

Infections of any kind may prove to be a direct cause of diabetes, probably owing to some kind of damaging effect on the pancreas by the toxin. Lawrence and Buckley have proved by experiments that diphtheria toxin will practically annul the action of insulin.

Symptoms. Clinically two principal forms of diabetes are recognised, acute and chronic. The acute form is generally found among young people and usually runs a rapid course. Mild chronic forms of the disease are usually common in middle aged persons but such cases may gradually develop into the severer form and then the disease runs the usual rapid course.

Most cases of diabetes complain of unwonted lassitude, loss of strength, loss of weight, polyuria and thirst as symptoms at the onset of the disease. Constipation is almost always a constant feature. Loss of sexual desire or even sexual impotence is also a common symptom and frequently an initial one.

Diagnosis. The diagnosis of true diabetes mellitus is often an easy matter when the patient presents the usual signs and symptoms, but there are many cases in which considerable difficulty is experienced and elaborate laboratory methods of diagnosis are necessary.

The average normal fasting level of blood sugar in man is 0.1 per cent. After a meal consisting of carbohydrates, the blood sugar rises reaching a maximum level of 0.17 per cent. within one hour and coming down to the normal level again, usually within 1½ to 2 hours. The reason why it comes back to the normal level is because a part of the extra sugar is changed into glycogen and stored as such in the liver and part of it undergoes combustion in the muscles and tissues. In the diseased condition, the picture is quite different for owing to the inability of the diabetic individual to store sugar as glycogen or burn it like a normal person, the circulating blood of the diabetics contains excess of glucose. Thus in mild cases, the fasting level is usually found to be 0.13 per cent. or over. In more severe cases, it is of course proportionately higher, according to varying degrees of defect in the storage mechanism. Thus for practical purposes, it is

usually assumed that a 'fasting level' of 0.13 per cent. or over indicates a condition of diabetes mellitus.

In many cases of potential diabetes and even in cases of mild diabetes, however, the fasting level of blood sugar may be perfectly normal and the urine may be aglycosuric even after meals owing to a varying *leak point*. In such doubtful cases, the *glucose tolerance test* should be done and the behaviour of the blood sugar after a glucose meal should be investigated. A healthy normal person should conform to the following :—

- (1) The fasting blood-sugar level should be normal.
- (2) The maximum rise of blood sugar after ingestion of 50 gm. of glucose should take place within one hour and should not go beyond 0.17 per cent.
- (3) The drop of the blood sugar to the normal level should take place within 1½ hours after the glucose is taken.
- (4) No glycosuria should occur.

A diabetic blood-sugar curve after a glucose meal deviates from the above according to the varying degree of defect in the storage mechanism, judged according to the rise of the initial (fasting) level of blood sugar, a tendency to a much heightened curve and a much delayed return to the normal level.

Treatment. The fundamental principle underlying the successful treatment of diabetes is based on the knowledge that a careful adjustment of the diet, with or without the use of insulin as an adjunct, will prevent hyperglycæmia and hence eliminate glycosuria and thus will tend to give rest to the already overworked and diseased islet cells of the pancreas. There is plenty of evidence in the literature to prove that if hyperglycæmia can thus be prevented, the progress of the disease will be arrested gradually, the distressing symptoms of the disease will disappear and in the majority of cases the 'tolerance' of the patient will improve considerably.

Thus it appears that the treatment of diabetes mellitus falls mainly into two main groups:—

(1) *Dietetic treatment.* This means that the patient should be given only that amount of food which is absolutely necessary to meet the minimum metabolic requirements of the body. This is known as the *basal diet*.

(2) *Insulin treatment.* It should be remembered that insulin treatment is only a valuable adjunct to the dietetic treatment for which it can, in no sense, be considered to be a

substitute. The indication for insulin treatment will be considered later on.

I. Dietetic treatment. In calculating a basal diet for diabetic patients the following points should be considered:—

(1) The caloric value of the diet should not be less than 25 calories per kilo. of the patients' body weight.

(2) The protein content of the diet should not be less than the proportion of about 0.75 gm. per kilo. of the body weight.

(3) The ratio of fats to carbohydrates in a diabetic diet should not be more than 2.5 to 1. This proportion is necessary to balance the ketogenic component of the diet with the anti-ketogenic component and is aimed at preventing acidosis.

Bose's formula for calculating the basal diabetic diet is given below:—

Total caloric requirement of the patient	=	Weight of the patient in kilo. \times 25
Protein requirement in grammes	=	$\frac{\text{Total caloric requirement}}{85}$
Carbohydrate requirement in grammes	=	$\frac{\text{Total caloric requirement}}{80}$
Fat requirement in grammes	=	$\frac{\text{Total caloric requirement}}{12}$

Thus a diabetic individual weighing 72 kilo. will require the following diet.

Total caloric requirement	=	72×25	=	1800 calories.
Protein requirement	=	$\frac{1800}{85}$	=	54.0 grammes.
Carbohydrate requirement	=	$\frac{1800}{80}$	=	60.0 „
Fat requirement	=	$\frac{1800}{12}$	=	150.0 „

It will be seen from the above that the protein ratio of the patient is in the proportion of 0.75 gm. per kilo. of the body weight. The proportion of fat to carbohydrate in the diet is also in the proportion of 2.5 to 1.

The number of gramme of carbohydrate, protein and fat and the caloric value of the diet required being thus ascertained, the patient's diet is framed by the use of food tables.

For ready reference, a sample diet chart (suitable for a diabetic patient weighing 72 kilo. as mentioned above), having the above proportions of food principles is appended below :—

Bran bread (or wholemeal atta)	3 oz.
Butter	2 oz.
Eggs	2 only
Fish or chicken	4 oz.
Mutton	4 oz.
Green vegetables	12 oz.
Milk	8 oz.
Cream	1 oz.
Ghee	2 oz.

Approximately, Carbohydrate = 60 gm. ; Protein = 54 gm. ; Fat = 150 gm. ; Calories = 1800.

On a diet calculated as above, the average diabetic patient of the mild type usually becomes sugar-free in about four days and the blood sugar comes down to the normal level in about a week's time. If however the patient does not become sugar-free or does not maintain the blood sugar at the normal level on the above diet, insulin treatment is usually indicated.

II. Insulin treatment. As mentioned before, insulin treatment in cases of diabetes should be considered as a valuable adjunct to the dietetic treatment in order to get the full benefit of the insulin and the quantity of diet allowed. It should also be kept in mind that unlike most drugs, insulin has no fixed dosage and that no hard and fast rule can be laid down regarding the dosage of insulin, inasmuch as it may vary in individual cases, according to the severity of the case, the complications, the diet prescribed and various other factors.

Another important factor which should be considered is that the amount of glucose utilised per unit of insulin varies in different cases. It has however been roughly estimated that one unit of insulin usually causes 1 to 2 gm. of carbohydrates to be utilised in a moderately severe case of diabetes. In a milder case, the carbohydrate utilisation per unit of insulin is somewhat greater. This fact should be borne in mind in selecting the proper dose for a given patient.

Roughly speaking, the total amount of available glucose calculated from the patient's diet minus the total amount of glucose passed in the urine will indicate the carbohydrate tolerance of the patient and the amount of glucose which is over the limit of tolerance, *i.e.*, the total amount excreted in the urine) must be covered by an adequate dose of insulin calculated in the way mentioned above.

A few general hints on insulin treatment

1. There are no hard and fast rules regarding the dosage of insulin in a particular case as it varies with the complications and the amount of fasting hyperglycæmia. It is always best to begin with a small preliminary dose (about 10 units).

2. Insulin is certainly indicated in all cases of severe diabetes mellitus with pronounced hyperglycæmia and marked glycosuria with or without ketosis.

3. Insulin is also indicated in the milder forms of the disease where a careful dietetic regime has failed to remove glycosuria or reduce the fasting hyperglycæmia, say below 0.15 per cent.

4. It is always best to give insulin injection, 20 minutes to half an hour before meals.

All forms of hard or strenuous exercises should be forbidden for at least 3 to 4 hours after insulin injection.

6. Roughly speaking it may be assumed that one unit of insulin causes 1 to 2 gm. of carbohydrates to be utilised in a moderately severe case of diabetes. In milder cases the carbohydrate utilisation per unit of insulin is greater.

Insulin Hypoglycæmia, its Symptoms and Treatment

Early symptoms. (1) Unaccountable nervousness. The patient feels some impending danger. (2) Listlessness. (3) Tremulousness or actual tremors, particularly of the extremities. (4) Dim vision sometimes diplopia. (5) Great desire for food—a sinking feeling in the pit of the stomach. (6) Vasomotor disturbances—pallor of the face alternating with flushing and sweating. (7) Palpitation of the heart.

Late symptoms. (8) Mental confusion—low muttering delirium. (9) Loss of deep reflexes. (10) Muscular twitchings and convulsions. (11) Coma.

Treatment. The treatment is simple if undertaken early. The patient should be put to bed. A tablespoonful of glucose powder dissolved in water and given by the mouth is the best but if it is not at hand, ordinary table sugar will form quite a good substitute. Orange juice 4 to 8 oz. may also be given, if available. If the symptoms persist after $\frac{1}{2}$ hour more sugar should be taken. If the milder symptoms are overlooked or not given heed to and they are allowed to pass on to the coma stage, $\frac{1}{2}$ to 1 c.cm. of solution adrenaline chloride (1 in 1,000) should be given intramuscularly. Glucose may be given intravenously, if necessary.

Hypoglycæmic and diabetic coma. A diabetic patient may become comatose because he has either too little or too much insulin. Two kinds of coma are generally recognised and the signs and symptoms following one should be distinguished from the other.

In insulin (or hypoglycæmic) coma the normal colour of the skin is generally preserved or it may be very white. The respirations are shallow but the breath does not smell of acetone. The urine is usually sugar-free and does not contain aceto-acetic acid but may contain both if the bladder has not been emptied for some hours. The blood sugar is below 0.07 per cent. or may be as low as 0.04 per cent. In diabetic (or hyperglycæmic) coma on the other hand, the symptoms are fortunately quite characteristic. The skin is usually flushed, the respirations are deep and the breath smells of acetone. The urine always contains large amounts of sugar as well as aceto-acetic acid and the blood sugar is over 0.2 per cent. and may be even as high as 0.5 to 0.8 per cent. In hyperglycæmic condition, if the patient is not deeply comatosed the initial dose should be 50 units but if coma be deep 70 or over 100 units of insulin should be injected at a time. But if the patient is used to large doses of insulin, the initial dose should be at least half as great as the doses recommended for ordinary cases. Administration of sugar is always desirable along with the

injection of insulin to avoid hypoglycæmic coma. In cases of deep coma, 600 c.cm. of a 2 per cent. solution of sodium bicarbonate should be given with 50 gm. of glucose. Along with the insulin and glucose treatment estimation of blood sugar where possible and particularly the testing of urine for sugar every three hours should always be done to note improvement of the patient. A repetition of treatment may be necessary where improvement is slight or even absent. The second course of treatment usually begins six hours after the first one. If the patient is better, half the initial dose of insulin should be given; if no improvement follows the initial treatment, the previous dose should be repeated; and if the patient is worse, the dose should be half as much again.

The risk of precipitating a hypoglycæmic coma should always be borne in mind while carrying on insulin treatment for diabetic coma. The most usual sign in such cases is a relapse into deep coma after a partial recovery of consciousness. This emergent condition demands prompt treatment. One c.cm. (ten units) of pituitrin or one c.cm. of adrenalin should at once be injected and this is to be followed by an intravenous injection of 300 c.cm. of 20 per cent. glucose solution. The treatment raises the blood sugar and the patient regains consciousness. In the following lines a general outline of treatment is given.

1. Put the patient in bed in charge of a trained nurse. Keep him warm with blankets and hot water bottles, if necessary. If there are indications of circulatory collapse, give digitalin, caffeine, camphor or other suitable drugs.

2. Evacuate the large bowel by an enema. If there is much vomiting gastric lavage should be done.

3. Give insulin as soon as possible. No hard and fast rule can however be laid down regarding the initial and the subsequent dosage of insulin and the mode of its administration in as much as it depends on the depth of the coma, the general conditions of the patient, the blood-sugar level and various other factors. As a general rule, it may be said that in a case of moderate severity, an initial dose of 40 to 50 units or more of insulin may be given subcutaneously or intraven-

ously, followed by the same amount of glucose in grammes, administered by mouth if the patient can swallow, or intravenously if the patient is totally unconscious.

4. In severe cases, where there is severe dehydration due to loss of fluid and collapse, prompt treatment is essential to save the patient from death, and the case is to be treated on similar lines as in cholera. Introduction of saline intravenously, subcutaneously and rectally should be done as early as possible. It is best to combine 10 per cent. glucose with normal saline. One pint of this solution will contain 60 gm. of glucose and should be given very slowly by the intravenous route immediately after the insulin injection. The injection of 0.5 c.cm. of adrenalin chloride solution (1 in 1,000) in addition sometimes helps in restoring the feeble pulse. This may be repeated after 4 hours according to the state of the collapse. If the patient's condition improves sufficiently, only insulin and glucose should be continued. The dose of insulin will however have to be varied according to the state of the acidosis and hyperglycaemia, judged from the urine and blood-sugar test. The dose of glucose should also vary according to the amount of insulin given. Rectal saline should also be given. Solution of the same strength as used for intravenous injection may be given. Sodium bicarbonate (1 dr. to a pint) may be added to the fluid with advantage ; 4 to 6 oz. of this fluid should be introduced per rectum very slowly every 4 hours.

OBESITY

Obesity is excessive accumulation of fat in the body. For practical purposes it may be defined as a condition in which there is an increase of about 20 per cent. of fat over that found in an individual of average weight. The weight of the person therefore is 20 per cent. over the normal for his age and height. The condition of obesity is frequently met with in tropical climates, and particularly among certain classes in India who indulge in foods rich in carbohydrates and fats and take little exercise. The condition runs in families and

there appears to be an hereditary tendency towards its production.

The effects of such a condition on the physical and mental processes of an individual are obvious. Fat-laden persons are known to be more liable to microbic infections. An extraordinary degree of impairment of muscular efficiency and signs indicative of cardiac embarrassment can be found in these people. Fatty changes in the heart muscle and abnormal blood pressure are frequent accompaniments. As a general rule, obese persons avoid effort, both mental and physical, and their critical faculties are to a considerable extent dulled. In addition certain other common maladies such as constipation, dyspepsia, osteo-arthritis, etc., are frequently observed in these cases. The effect of obesity in causing sterility in women has been recognised. It has an additional importance from the æsthetic point of view.

It is customary to describe two varieties of obesity :—(1) Exogenous obesity, in which there is a faulty balance between the intake of food and the output of energy, and (2) endogenous obesity which is due to obscure constitutional factors, such as endocrine or metabolic disturbances. In practice, however, it is found that a clean cut distinction cannot be made between the two varieties and many cases of obesity present the features common to both conditions.

Exogenous obesity. It is almost an axiom that obesity is due to over-eating. In these cases there is a great disparity between the intake of food and the output of energy in the shape of muscular work. Poulton (1931) observed that most people keep the same weight from year to year which means that the amount of food taken is exactly balanced by the amount burnt in the body. Three processes are responsible for this, namely (i) the so-called basal metabolism of the individual, (ii) specific dynamic action of the foodstuffs, which means that when food is taken its metabolism in the body leads to increased burning, and (iii) exercise which increases combustion to supply the extra energy required. Hence to maintain the normal weight there must be a close relationship between the food taken and the activities of the individual. If the quantity of fuel taken as food is much in excess of what the organism requires there will arise a tendency to obesity, and when this is continued for a long time it may result in deposition of considerable fat. Obesity in the adult is in a very large proportion of cases due to over-eating. During childhood and adolescence, the amount of exercise one takes precludes any deposition of fat. As youth merges into middle age, violent exercise is replaced imperceptibly by exertion of a less drastic

nature. Hence it naturally follows that when utilization of foodstuffs is no longer so large, the amount of food during the period should be curtailed. If that is not done, an accumulation of fat occurs in many cases.

Certain foodstuffs are particularly liable to cause accumulation of fat in the body. In addition to the use of fat-forming foods, malt liquors are also known for their fattening properties. Intemperance in the use of alcohol is also an important factor, for alcohol is readily oxidized and thus allows the fat already formed to remain undisturbed. A suggestion was put forward by Weber (1928) that exogenous obesity may be the result of pancreatic stimulation following the ingestion of too much carbohydrates.

Endogenous obesity. Constitutional obesity. While it is possible to attribute corpulence in some persons to dietetic excesses it is well known that certain obese people eat remarkably little and yet have a tendency to accumulate fat. Strouse and others (1924) observed that obesity might occur in certain persons on intakes much below the necessary caloric requirements, the cause of which is imperfectly understood. It is, therefore, believed that this type of obesity is brought about by a qualitative anomaly in metabolism, *i.e.*, an abnormally increased transformation of carbohydrates into fat, and thus even with caloric intake which is much below the normal, such a patient will convert fat from the carbohydrates and store it as such. The part played by heredity in causing so called constitutional obesity is not definitely understood. It is said that the maternal factor is more important in this connection, but how far it is due to constitutional cause or over-eating, remains to be settled.

The endogenous type of obesity is said to be more common in women than the exogenous variety. This is in conformity with the fact that sudden increase in weight is commonly observed in women at puberty, after child birth and at the menopause. In man this change during the middle years is less sudden. Nevertheless changes in the testes, hypertrophy of the prostate and analogous changes in other endocrine glands may occur; this is probably due to a general lowering of the activity of the catabolic glands. As a result of this many people show a tendency towards accumulating fat.

Endocrine obesity. The part played by endocrine glands in the causation of obesity is important and interesting. Obesity associated with thyroid deficiency with the clinical picture of myxoedema is well known. In these cases the classical features are coarse facies, thick lips, puffy eyelids, dry skin, etc. Thyroid deficiency is unquestionably responsible for a large number of cases. The pituitary gland also plays an important part in the causation of obesity. Hypopituitarism (Frolich's syndrome) is a commonly recognised condition. It has also been shown that so-called pituitary obesity can be experimentally produced by injury to the hypothalamic region. Langdon Brown (1931)

stated that the pituitary plays an important rôle in the production of some forms of obesity, but the relationship of the pituitary gland to obesity is complicated by the fact that lesions of the hypothalamic region produce identical changes.

Gonadal insufficiency is also responsible for a certain number of cases. Furthermore there exists a close relationship between the thyroid, pituitary and the gonads. Lambie (1931) described various syndromes resulting from the interaction of gonadotropic, thyrotropic and growth-promoting factors of the anterior portion of the pituitary gland. The commonest example of these cases is a combination of pituitary and thyroid obesity. Such conditions as Dercum's disease (*adiposis dolorosa*) and the Lawrence-Biedl syndrome have been described.

In women, among the endocrine glands, thyroid and ovaries have been chiefly incriminated as the cause of obesity. There is no doubt that these glands play a great part in the life of a woman. Many cases of obesity in women are known to show a rapid loss of weight after thyroid treatment. The part played by the ovary is not definitely understood. In menopausal obesity ovarian hormone has given variable results.

The influence of insulin as a cause of obesity was originally suggested by Faltz. Poulton (1931) discussed this theory of excessive production of insulin as a cause of obesity. It is suggested that diabetic patients treated with insulin develop obesity and that insulin along with carbohydrates helps to fatten lean people. The sugar tolerance is increased in some cases of obesity which is compatible with an increased output of insulin. This theory has not been universally supported.

Treatment. Whether alimentary or endocrine in origin, the treatment of obesity is entirely a matter of dieting with the exception of some cases of hypothyroidism.

Diet. The underlying principle is to give a diet of caloric value below that required for the optimum weight of the patient. As a general rule it should be 20 to 25 per cent. below his normal requirement. Great care should at the same time be taken in preserving the proper nitrogen equilibrium of the patient which is of great importance. The diet should be arranged in such a way that the patient is forced to burn his own fat without the loss of his body proteins. This is not difficult to accomplish provided the diet contains sufficient proteins and is of a low caloric value. Usually, 1.5 gm. of proteins per kilo. of the body weight will answer the purpose. It should also be remembered that carbohydrates in the food, besides being the chief source of energy for the

maintenance of the body temperature and for the production of work, are most efficient protein spacers and every use should be made of them to preserve the nitrogen balance at an economic level. At least 50 per cent. of the energy contained in the food should come from the carbohydrates. Thus, in calculating a reduction diet, the caloric value of the protein allowance should be calculated first and to this should be added an amount of carbohydrate sufficient to bring the caloric value up to the desired total caloric intake. Fats need not form an item of any importance in the dietary of obese persons.

According to Browning (1934) the essential factors in the choice of a dietary are —

(1) **Preservation of nitrogen balance.** To do this the proportion of protein to carbohydrate should be about 1 gm. of protein to 0.6 gm. of carbohydrate with a total of not less than 60 gm. of protein.

(2) **Minimum fat intake.** As already stated fat is cut down from the dietary so that the patient is forced to burn his body fat to supply the metabolic need.

(3) **Avoidance of hunger.** This can be avoided by giving high proportion of fruits and vegetables which have low caloric value.

(4) **Maintenance of water balance.** Sometimes the patient shows a tendency to store water in the tissue though he may be losing a good deal of fat. This is prevented by giving a salt-free diet and increased quantity of protein.

(5) **Adequate mineral and vitamin content.** The loss of mineral content with the use of the recommended diets is not great. If the fat is very much restricted, there is likelihood of the vitamins A and D being reduced below the standard level. This can be remedied by giving carotene and irradiated ergosterol. A cup of yeast extract once a day will supply vitamin B.

(6) **Physiological factor.** It is in many cases difficult to induce a patient to change to a diet of small quantity and simple character. Under these circumstances a slow reduction is preferable to a drastic one, the foods should be distributed over the various meals allowed, to make them as palatable as possible.

A very efficacious diet (modified by Douthwaite, 1934, from Williams) is given as follows:

On waking. A glass of water. *Breakfast.* Tea or coffee, sweetened with saccharine; one slice of dry toast, no butter; 3 oz. of cold tongue, boiled sole, haddock, or whiting; fresh fruit. *1 p.m.* A tumbler of

water. *Lunch.* 4 oz. of chicken or meat (except pork), but no gravy; vegetables as given below, cooked without fat; salad without oil; one square of vita-weat; fresh fruit. *5 p.m.* Tea without milk or sugar.

Dinner. Bouillon; fish; 2 to 3 oz. of game or meat (except pork), no bread-sauce or bread crumbs; vegetables as mentioned below; salads; one slice of toast; dry wine; fresh fruits; coffee with saccharine. *Condiments are allowed.* Worcester and anchovy sauces, ketchup, pepper, mustard, vinegar, walnut pickle, horse radish, salt sparingly.

Vegetables allowed. Green vegetables (except peas), celery, seakale, asparagus, and salsify.

Another form of dietary has been devised by Evans and Strang (1929); one gramme of protein per kilo. body weight is given along with some carbohydrate to maintain nitrogen equilibrium.

Evans and Strang Diet (about 650 calories)

Breakfast. One egg and 1 oz. of bread. *Lunch.* One egg and 4 oz. of vegetables as below. *Dinner.* One cup of bouillon and 3 oz. of lean meat; 4 oz. of vegetables. *Vegetables allowed:* Lettuce, cucumber, spinach, asparagus, endive, celery, mushrooms, tomatoes, sprouts, watercress, cauliflower, radish, cabbage.

Water as much as needed; no fried foods; a teaspoonful of bicarbonate of soda daily.

It is essential to eat the whole amount mentioned in this diet. A modification of this diet is given by Dodds (1934) which allows only 8 calories per kilo. Though efficacious it is rather drastic. There is a tendency to acidosis with Evans and Strang diet, which may be relieved by the use of sodium bicarbonate.

Kenyon's modification (1933) is to give 1,000 calories which allows high protein, vitamin and mineral salt.

Breakfast. One portion of fruit; one egg and white of one egg; coffee, tea, bread substitute (for example, Heudebert's breadsticks). *Lunch,* 3 oz. lean meat, fish, or fowl; $\frac{1}{2}$ pint 5 per cent. vegetables; one portion fruit. Tea. *Dinner.* 3 oz. meat, fish, or fowl and vegetables as at lunch. *9-30 p.m.* Half-cup orange juice; 1 oz. lemonax. In addition, $1\frac{1}{2}$ glasses skimmed milk daily (for calcium content); one capsule haliverol t. i. d. (for vitamin content).

A fruit portion—one orange; half a grape-fruit; one medium apple; two medium peaches; one small pear; one cup strawberries; one cup blackberries.

It is important to control the body weight by weekly measurements. When the desired weight has been obtained, the diet is slowly increased.

Exercise. The therapeutic factor next in importance to the restriction of food is the stimulation of the metabolism by physical exercise. Exercise hastens the metabolic rate and leads to increased oxidation of the ingested food, or, if sufficient food is not available, of the body fat. The exercise should be gradual and regular and should not be carried up to the point of exhaustion.

Cold bath. The other factor which also serves as a useful physical stimulus to metabolism is a cold shower or plunge bath and should be advocated where there are no contra-indications for it, such as, severe myocardial degeneration, arteriosclerosis and high blood pressure.

Endocrine therapy. As it is possible to control obesity with dietetic restrictions in many cases, endocrine therapy should not be indiscriminately resorted to. Thyroid has been too frequently used to stimulate metabolism and reduce weight. In those cases where the basal metabolic rate is below normal, the patient will probably lose weight after thyroid medication. Unless properly controlled, even in cases of myxoedema, the weight after an initial fall may be increased after administration of thyroid. In thyrogenous obesity and other forms where metabolic stimulation is required, thyroid should be used in doses of half a grain twice daily; this is gradually increased to 1 gr. three times a day. Some cases may require much larger doses. Other endocrine preparations such as pituitary, or combination of thyroid and pituitary, or treatment by extracts of genital glands have been advocated, but the effect of such therapy after oral administration seems to be uncertain.

Drugs. It has been shown that certain nitrophenols are capable of causing a marked increase in both the temperature and oxygen consumption. Cutting and his co-workers (1933) found that by using a drug of this nature, which is 2:4 dinitrophenol, the metabolic rate of animals could be raised by 50 per cent. by a dose of 10 mgm. per kilo. body weight. In

human beings the drug in doses of 3 to 5 mgm. per kilo. body weight daily raised the metabolic rate by 40 per cent. and this was accompanied by an average loss of weight of 2 lb. a week. As this compound has been known to be toxic, Dodds and Pope (1933) working with dinitro-o-cresol (dekrysil) found that it would produce the same effect in much smaller doses—1 mgm. per kilo. daily. Douthwaite (1934) has used this drug in doses of 1 mgm. per kilo. thrice daily, and later once daily; though the constitutional effects were not marked with smaller doses, the loss of weight was very insignificant. These drugs are in the experimental stage and should, therefore, be used with caution.

In addition to these measures, other methods of therapy have a great bearing on the final success in treatment. Excretion of waste products of metabolism should always be favoured, and with this end in view the activities of bowels, kidneys, skin and lungs should be watched

CHAPTER III

TROPICAL NEURASTHENIA

The term neurasthenia has been defined in various ways by different neurologists and psychiatrists. Collier considers the condition to be a pathological weakness without discoverable lesion, manifested by rapid and great fatigue, physical or mental, or sometimes both. It is characterised by functional exhaustion of the tissues especially those of the nervous system due to excessive or undue waste of nervous energy. psychic or motor, and in some cases to acute intoxication. The condition, no doubt, is essentially one of emotional unbalance with loss of mental stability, associated with undue irritability to external impulses. Neurasthenics always experience a sense of fatigue or muscular weakness and complain of being unable to do mental labour, the least concentration being followed by vertigo, headache, etc.

According to Dercum this readiness of fatigue is the primary and fundamental symptom of neurasthenia. Beard in his treatise on "The Nature and Diagnosis of Neurasthenia" brings out the literal meaning of the term as a state of nervous exhaustion and he divides the condition into definite separate clinical groups as cerebral, spinal, gastric, cardiac and sexual. His views though open to discussions ultimately succeeded in gaining a general acceptance from a large number of modern psychiatrists. It is generally held that such a condition of neurasthenia does never exist, but nevertheless a great variety of conditions in the tropics where any specific cause cannot be discovered is termed as an idiopathic disease 'neurasthenia.' The modern idea however is that there is some underlying factor causing the train of symptoms constituting neurasthenia. Investigation into the subject reveals that neurasthenia is associated with certain existing causes. Tropical neurasthenia responds to treatment more readily than the ordinary kind, change of climate being especially beneficial.

As neurasthenia is considered to be a condition of nervous exhaustion one should have some knowledge of the working of the nervous system and of nervous energy in particular. The working of the mind and the display of energy arising from the normal physiological processes within the body are all due to an outflow and sometimes of an overflow of the energy inherent in and manufactured by the highly

complex protoplasm (neurokyme) of the neurones of the higher nervous system, and this is attended by structural changes, *e.g.*, chromatolysis in the cells. Neurasthenia was for a long time attributed solely to exhaustion of the nerve centres presiding over general nutrition and particularly of the brain and nervous system. Actual loss of substance in the cells and especially in the nucleus has been noted by many workers. Impaired metabolism with accumulation of waste products in the system gives rise to auto-intoxication affecting especially the nervous system and the functions over which this system presides are correspondingly impaired. In this condition if the patient persists in imposing upon his weakened organism even slight tasks, a vicious circle of pathogenic activity is formed which encourages a further waste of energy.

Left to itself neurasthenia tends to persist, unless its cause is removed. Under proper prophylactic measures and judicious treatment the prognosis is favourable, especially in the cases where organic changes have not had time to undermine the functions of the organs secondarily involved.

Ætiology and incidence in the tropics. From a study of the causes of neurasthenia, the condition has been well classified as :

I. Primary or independent of any discoverable exciting causes, this has been termed 'congenital' or prenatal. Heredity acts only as a predisposing influence through parental neurosis or psychoses. No gross visceral damage, nor any evidence of serious illness or infection is met with in this type. The signs and symptoms are chronic in nature or a recurrent one. A careful history will reveal that the individual belongs to a stock of similar victims and this is essentially one of a familial nature. This type of neurasthenia is very common in the tropics and mostly met with among children in the same family. They manifest it more and more with age, at a period of life during which great exertion and anxiety combine to increase the wear and tear of the central nervous system and indirectly of the organism at large. Climatic influence in the tropics and the faulty upbringing of children in such families account for the development of such a state of mind and brain in them. They can carry on the ordinary routine of life but any slight deviation from it will surely throw them out of gear resulting in signs and symptoms of nervous exhaustion. The picture may be well drawn of such a neurasthenic as suffering from various bodily pains (paræsthesias), abnormal sensations of the brain, heart and stomach (hypochondria). The appetite is capricious, ravenous one day and bad the next day. In short, the whole condition is one of 'irritable weakness with hypochondrial trend.'

The underlying psychopathology of these primary neurasthenics is that the cell units and the neurokyme in them are not sufficiently strong to keep in check and in store the potential energy responsible for the normal body functions. A continuous drainage of such energy

demanded by an increased body activity, with which the inherently defective neurones cannot successfully keep pace, throws the whole system out of balance resulting in a condition of neurasthenia.

II. The second group constitutes a larger number of ætiological factors and they all come under the type of secondary neurasthenia, secondary to some primary causes such as physical ill-health with lowered vitality, condition of life incompatible with environment, overwork, emotional stress. It is rightly said that it is not the work but the worry that kills. Sudden physical and mental shock, continued conditions of fear as seen in maniacs when they are not actually suffering from any disease, sometimes predispose to an attack of neurasthenia.

Besides the factors mentioned there are others met with. People in the tropics live in a climate in which humidity is added to heat and this will act as a primary causative factor. There are diseases also which are peculiar to the tropics and are seldom seen elsewhere. All these affect the daily lives of the people in a way different to the people of temperate zones. The maladies and the physical agents such as extreme changes of weather, occurring in tropical countries are responsible for the chronic ill-health of people and should be considered as factors bringing about a series of signs and symptoms constituting the so-called condition of neurasthenia. Such causes may be conveniently classified as (a) exciting, (b) predisposing, and (c) general endocrine dysfunction.

(a) **Exciting causes.** The debilitating after-effects of acute fevers in the tropics, exposure, indiscretions in diet, insufficient or improperly selected food, etc., are potent factors of after-neurasthenic symptoms. All convalescents after acute maladies either promptly recover without after-effects or may suffer from chronic ill health for a long time with symptoms of neurasthenia. Various forms of enteric fevers, dysentery, cholera, intestinal helminthiasis, etc., give rise to disturbances of the gastro-intestinal functions. The continuous absorption of toxins elaborated lowers the resistance of the organism as a living entity (not only of the nervous system), undermines the metabolic dynamism and prepares the soil for neurasthenia.

Individuals so predisposed represent by far the majority of cases. Women suffer almost invariably with uterine diseases in connection with neurasthenia. Excessive fecundity, dysmenorrhœa and menopause are thought to exercise a marked exciting influence. Disorders of the female organs which affect the nutrition of the nervous system, such as an excessive hæmorrhage or suppurative process, may also be important factors in inducing functional neuroses.

Of all the causes those connected with the male sexual organs have been credited with the most active ætiological rôle such as prostatitis, posterior urethritis, seminal vesiculitis, etc., and general disorders and habits such as gonorrhœa, syphilis and masturbation.

(b) **Predisposing factors.** A continued high atmospheric temperature with excess of humidity makes people in the tropics ease-loving

and much less hardy than those of the temperate climes. A little super-added physical or mental strain often brings about a nervous breakdown and makes a man physically unfit to cope with his environment. People working in the open spaces get easily tired owing to heat of the sun and cases are on record where many a people after long continued illnesses as malaria, kala-azar, etc., and apparently healthy, have succumbed to heatstroke.

Due to climatic influence in the tropics and to keep body temperature below the surroundings a large quantity of blood is regularly required to flow in the peripheral circulation especially in hot weather. People lose appetite in the hot weather, metabolism and ordinary physiological functions and biological processes are depressed lowering body vitality and making them an easy prey to nerve exhaustion. Again in hot weather, people are prone to remain indoors to protect themselves from hot blasts of air. The resulting ill ventilation with all its effects tells upon the health of the people. Anæmia and other diseases of the blood due to improper aeration of the blood-cells result. People use nets to prevent the biting of disease-producing mosquitoes and this is considered to be sleeping under unhygienic conditions leading to general depression of body vitality.

The social conditions of people living in the tropical countries contribute a great deal to the causation of symptoms of neurasthenia—

(a) **Heredity.** It accounts for a good number of cases. This has already been dealt with in discussing primary or congenital neurasthenia. Women are more prone to this type. If, as maintained by sexologists, marriage is an important factor to prevent neurasthenic symptoms in grown up unmarried girls, definite cases are on record where married, multiparous women suffer from neurasthenia without any other obvious discoverable causes. Other social conditions as early marriage, early and repeated pregnancies associated with ill-nutrition and strain and stress of life and other maladies make people of the tropics frequent subjects of neurasthenia.

(b) **Diet.** People in tropical climates live on a diet which can be hardly borne by those of temperate countries and so it is held by authorities of public health that such a quality of diet cooked with highly-spiced articles, mustard oil with its irritating allyl isothiocyanate, etc., is responsible for gastric troubles such as hyperchlorhydria, gastritis, peptic ulcers, etc. The digestion is enfeebled and delayed and is associated with atonic constipation and gastralgia is sometimes complained of. Hyperchlorhydria is sometimes observed and gastropnoia is not infrequent. Meteorism, alternating constipation and diarrhoea, colicky pains due to defective intestinal digestion and the resulting fermentation are prominent features of the later stage. In these cases, auto-intoxication is an important feature.

(c) **Exercise.** That diet and exercise should go hand in hand is an old adage. Fat and forty-year-old Indians are often diabetics.

Visceroptosis and cases of prolapse-uteri in quite young Indian girls are the result of lack of proper exercise and such girls always suffer from vague symptoms of neurasthenia such as indigestion, attacks of abdominal pain (hypochondria) associated with various endocrine dysfunctions and particularly of the thyroid and adrenals. All these predisposing causes combined with toxins of acute and chronic illnesses characteristic of the tropics play an important rôle in the causation of neurasthenia.

(d) **General endocrine dysfunction.** The endocrine system may be thrown out of order, as a result of the patient suffering from some acute disease such as enteric fever, cholera, bacillary dysentery, small-pox, etc. Long-continued illness such as malaria, kala-azar, chronic genito-urinary diseases or absorption of the toxins arising from putrefactive changes in the gut may occasionally put an undue stress on the glands such as the thyroid and adrenals. That the ductless glands play an important rôle in the genesis of neurasthenia is probable. The thyroid and adrenals play an important part in oxidation and in protecting the body against auto-intoxication, and any condition which exhausts these organs must necessarily impair the general dynamism and lower the vascular tension, the underlying cause of neurasthenia in many cases. It must be clearly understood in this connection that cases classified formerly as neurasthenia are due to disorder of the internal secretions. In dysthyroidism there are recurrent states of neurasthenia and great prostration. Pituitary disorders too create symptoms of neurasthenia. Insufficiency of the adrenals also produces neurasthenia characterised by extreme asthenia, inability to think clearly, and as a rule associated with low blood pressure.

Diagnosis. Bennett (1918) was of opinion that there is practically always in true neurasthenia a long prodromal period, the pre-neurasthenic state, characterised by well-defined morbid manifestations indicative of aberrant functioning of the emotional centres. The immediate cause of this instability is the reaction of environment on the patient's mind. This state is not actual neurasthenia and may not develop into it, but neurasthenia is its culminating development. Neurasthenia is a definite syndrome and should not be confounded with the nervous asthenia resulting from abuse of stimulants, drugs or tobacco as being symptomatic of organic diseases. Neurasthenia should be clearly differentiated from obsessions, hysteria, melancholia and hypochondriasis. The heart and blood vessels are usually the first to reflect the central functional disturbance in neurasthenia.

Reviewing the innumerable factors responsible for bringing about the condition of neurasthenia, there is no doubt that it is a malady not without obvious causes. A proper diagnosis should be made, largely by a process of exclusion. All possible gross organic diseases are to be excluded and careful investigation is most essential regarding the daily life of the neurasthenic together with complete physical examination of

the subject. If this procedure is not adopted several diseases of the body and mind will be wrongly diagnosed as neurasthenia. Amongst them early phthisis with symptoms of indigestion, feeling of ill-being in an apparently healthy young man, diabetes, Addison's disease, disseminated sclerosis, cerebral tumour, cerebral arteriosclerosis and encephalitis lethargica, general paralysis of the insane and dementia præcox deserve special mention.

A line of demarcation should be drawn between real organic diseases and the functional disorders of the nervous system. Besides the diseases mentioned which simulate symptoms of neurasthenia there are many more which cannot be discussed here for want of space.

Treatment. The prognosis and the line of treatment depend chiefly on a right diagnosis of the cause of neurasthenia. Cases of secondary neurasthenia always make a complete recovery after removal of the primary causes and all that is needed is proper rest and treatment of those diseases. There may occur periods of improvement but relapses occur readily.

The treatment of cases of neurasthenia does not merely consist in the application of specific drugs against such diseases as are responsible for its development. Although the importance of such a procedure should always be recognised, general tonics such as phosphorus (glycerophosphate of iron, both organic and inorganic), arsenic (with all its synthetic preparations) and strychnine combined with nourishing and proper dieting, regular and graduated exercise and open-air life, rest mental and physical, distraction and removal of baneful influences as far as possible constitute the prominent features of the treatment.

The benefits of rest in the average case may be secured by spending four to six additional hours in bed, by retiring early and getting up late. Or, if it is convenient, a couple of hours' rest during the day may replace the morning hours of rest. Each phase of the non-pharmaceutical treatment must be regulated to suit the patient's means and strength. Travelling is always useful, changes of scene greatly tend to alter the morbid trend of the mind.

Isolation is beneficial when neurasthenia is accompanied by very marked symptoms of lowered nutrition and muscular weakness and when a prolonged rest in bed is insufficient to arrest emaciation. Over-feeding is sometimes, obligatory and

may be carried out by the addition of milk and eggs to an ordinary mixed diet between meals.

Gastric functions should be analysed and diet adjusted accordingly along with administration of dilute hydrochloric acid before meals where hypo- or anacidity is found. Any foci of infection present should be properly dealt with.

Women mostly suffer with a train of abdominal symptoms due to lack of tone of involuntary muscles of the various abdominal organs and such diseases are cecal stasis, prolapse of abdominal viscera and various other pelvic organic diseases. Patients with visceroptosis are very commonly met with complaining of vague abdominal pains. A skiagram always settles the diagnosis. The patient should be advised proper abdominal exercises, small but frequent dieting, a well-fitting abdominal belt and sometimes electrical treatment with sinusoidal current. Cases are on record which show that this line of treatment has cured many such neurasthenic patients. Chronic cecal stasis should be treated by regular abdominal massage and by drugs such as cascara, senna leaves or pods stewed with prunes, etc. Sometimes surgical measures are adopted to cure patients with neurasthenia. Removal of the appendix, fixation of the floating kidney, gastropexy and a few pelvic operations in females have been known to cure neurasthenic patients.

In cases of neurasthenia, resulting from sexual abuse, rest of function is essential. Local treatment, especially of the verumontanum has been widely advocated, but some believe that such treatment only acts by suggestion. Sexual neurasthenia is often ascribed to a definite pathological condition of the genito-urinary tract especially in the vicinity of the verumontanum but some authorities do not agree on the point. Electricity has been advocated by many. Static electricity, slowly interrupted faradic current or diathermy may be conveniently employed.

Hydrotherapy has also been highly recommended. Winternitz's method of cold pack along with the application of warmth (122°F. or 50°C.) over the epigastrium or the application of cold over the spine is credited with marked efficacy.

Sleep is favoured by taking a warm bath for ten minutes followed by a glass of hot milk just before retiring.

Medicines. Few medicines are of value; the elaborate process of nutritional repair, favoured by the aid of the above-mentioned procedures, renders drugs relatively unnecessary.

Neurasthenia is recognised to be a vasomotor neurosis, the prominent feature of which is relaxation of all arteries, due to exhaustion of the sympathetic centre and the resulting loss of propulsive power of the arterioles. The tissues thus become imperfectly oxygenated and nourished, hence mental torpor, habitual fatigue, adynamia and gastro-intestinal atony result. There are various functional disturbances associated but certain degree of hypothyroidism is always present. Hence small doses of desiccated thyroid is recommended by some, usually in combination with strychnine, and full amounts of an assimilable form of iron such as Blaud's pill. Strychnine is supposed to be almost a specific in neurasthenia. Doses should be gradually increased and excess of 6 mg (1/10 gr.) may be given in daily doses. Arsenic, iron and other tonics are often valuable. Of the glandular products, thyroid gland (Armour's) in 1 gr. doses (which equals 5 gm. of fresh gland) or pituitary (whole) 2 gr. three times a day are very efficient. Corpus luteum in large doses is sometimes very effective in women.

Laxatives are important to counteract the auto-intoxication. The intestine should be flushed with calomel and a saline purgative at the start. Later, cascara, rhubarb, or aloin are suitable. The endless complaints and fault-finding nature of neurasthenics are in most cases symptomatic. Psychotherapy is usually effective in such cases. Sympathy and consideration on the part of the attending physicians, always gain the patient's confidence and ensure his co-operation which is of primary importance in the curative measures instituted.

Under proper prophylactic measures and judicious treatment however, prognosis is usually favourable. The just merit of each individual case should be taken as the guide to treatment.

CHAPTER IV

POISONOUS ANIMALS

SNAKE VENOMS

The subject of snake venoms is of special interest in India. In a population of 373,000,000 at least 20,000 to 25,000 deaths occur every year from snake bites; the fatality rate being 35 to 40 per cent. The number of deaths from the same cause is likewise considerable in Burma, Indo-China, China, Australia, Africa, West Indies and Tropical America, but the exact rate in these areas cannot be estimated accurately. The temperate parts of the globe are far less severely affected. In Europe the only poisonous snake is a variety of a small pitless viper; its bite mostly produces local symptoms and is rarely fatal. The most dangerous species to man are found in the tropical regions of Asia and Malaysia. In India, during the last 30 years or so a great deal of attention has been directed towards the classification of different snakes, the study of the chemical and biochemical nature of their venoms, their toxicity and the preparations of antivenines. Interesting investigations have also been carried out in America, Japan, Australia and Germany on the neurotoxic and hæmolytic principles. In passing it may be mentioned here that the discordant results obtained by various observers are in all probability due to variation in the chemical composition and the relative proportions of the active principles present in different specimens of the venom.

Classification and Identification of snakes.

Most of the deaths reported from snake bite in India are from the bites of the Cobra (*Naja naja*), Indian Daboia (*Vipera russelli*) and Phooras (*Echis carinata*). The last in order come some varieties of Kraits which rarely bite, though their poison is very deadly.

The poisonous effect of a particular snake is dependent upon (1) the toxicity of the venom, (2) the possession of fangs, (3) the amount of venom present in each of the glands, and (4) the dose injected. The snakes possessing anterior fangs are only to be regarded as poisonous to man.

Wall (1913) classified all the snakes into three groups according

to the shape and situation of the teeth in the upper jaw, (1) *Aglypha*, these are harmless snakes having no poisonous fangs, (2) *Opisthoglypha*, these snakes have grooved fangs situated at the back of the upper jaw, (3) *Proteroglypha*, this group has specialised grooved fangs in the front of the upper jaw. The last is really the poisonous group since the fangs dig deep into the tissues during the act of biting.

In poisonous snakes the maxilla is very small, freely movable, the front tooth on each side is specialised by being large, grooved and canalculated to form a fang. On examination of the mouth, the prominent anterior fangs are seen projecting or lying folded on the roof of the mouth and covered with a fold of the *levator vanti dentis* in which lie concealed the reserve fangs. The table below gives the chief characters of the different types of snakes.

How to recognise poisonous and non-poisonous snakes.

According to Cazaly (1914) the poisonous and non-poisonous snake can be differentiated as follows:—At first put the unknown snake into one of the four groups mentioned in the table below: Place the snake on its back and examine its belly. If there are no ventrals or only narrow ventrals, the snake falls into group I or II. The snakes in both these groups are non-poisonous and harmless. If on the other hand the ventrals are broad, the next step is to inspect its head. If it is scaly the animal belongs to group IV which includes all types of vipers. If the snake has broad ventrals and a shielded head, it falls into group III, which consists of both poisonous and non-poisonous types of cobras. If any doubt exists regarding a cobra, examine the scales on the upper lip. If the third supralabial scale touches the nasal shield and the eye, the specimen if not a cobra is a krait. There is usually a tendency to call all the small-sized snakes as kraits. Indian adult kraits are usually 2 to 3 ft. in length and may grow up to about 4 ft. The banded or Burmese kraits may reach nearly 6 ft. in length. The chief identification mark of a krait is a distinctly enlarged row of the vertebral scales along the middle line of the back; if these scales are of the same size as the other ones, then it is not a krait at all. The other features of the kraits are that there are usually cross bands, and their subcaudals are usually entire. Lastly, to make quite certain examine the scales on the lower lips. A krait has only 4 infralabial shields and the 4th one is the largest. The group IV of vipers is recognised by the head being covered with fine scales similar to those covering the whole body. The scales are usually of the saw type. A common Indian snake *Lycodon aulicus*, the bite of which is practically harmless, is often mistaken for a krait; it only evokes a transient local irritation. The pit vipers have a 'Loreal pit' situated between the nose and eyes. The vipers are characterised by a triangular head, vertically elliptical pupil and a short stumpy tail with a thick-set body. The maxillae are freely movable and each one carries a large anterior fang.

Table showing chief characteristics of the four groups of snakes in India

Group.	Dorsal surface.	Head.	Teeth.	Belly.	Particular features.	Remarks.
I	Covered with fine scales.	Shielded or scaly.	Fangs absent.	Covered with scales, no ventral plates	Entire body covered with scales only.	Usually olive green, brown or black in colour, harmless to man, found every where in India.
II	do.	do. Separate from the body.	do.	Transverse ventral plates do not extend completely across; several dorsal scales extend on either side of ventral	Head surmounted by a prominent snout.	Length 10 to 20 feet. Very stout. Varieties: pythons, boas, earth snakes and iridescent snakes. More or less harmless.
III (a) Cobra	do.	Covered with shield, with a hood	Fangs fixed, curving backward, canalculated	Broad, transverse shields stretch across ventral surface, last row of dorsal scales only seen when placed on the back.	Maxilla freely movable. Third supralabial shield touches the eyes and the nasal shield. Black spots on the whole body.	(a) The Cobra (<i>Naja naja</i>) (b) King Cobra or Hamadryad (<i>N. bungarus</i>). Majority in group III are poisonous and common in India and Burma.

Group.	Dorsal surface.	Head.	Teeth.	Belly.	Particular features.	REMARKS.
(b) Kraat	Distinctly enlarged middle row of scales along the vertebral line.	Covered with shield with head.	Fangs fixed, curving backward, canalculated. Shorter than that of cobra.	Broad, transverse shields stretch across ventral surface, last row of dorsal scales only seen when placed on the back.	Only 4 infralabials and the fourth one largest. Subcaudals are entire. Cross-bands on the whole body. Pit absent.	Very poisonous. Usually small size, Indian species up to 2-4 feet, Burman banded kraits up to 6 feet in length. (a) Common krait (<i>Bungarus caeruleus</i>). (b) Banded krait (<i>B. fasciatus</i>). Length 5-6 ft. Very common in Indian plains. Poisonous next to cobra. It is called <i>Vipera russelli</i> . Size up to 5½ feet.
IV (a) Pitless viper 1. Indian Daboia	Scales.	Head triangular, fine scales similar to those on back.	Longer than that of cobra, up to ½", covered with levator vaginæ muscles.	do.	Covered with triple row of oval markings on the back. Tail stumpy. Eyes elliptical, maxillæ freely movable. Nostrils large.	Common in N. W. F. P., South India and Rajputana, etc. Called <i>Echis carinata</i> , <i>Phoosar</i> or Kuppur.
2. Indian Saw scaled viper	Saw type scales.	do	do.	do.	Undulating crescent markings on the back. Venom action only localised. Tail short.	Common green viper (<i>Lachesis gramineus</i>) Himalayan viper (<i>Ancistrodon himalayanus</i>).
(b) Pit-vipers.	do.	Pupils vertical.	do.	do.	Loreal pit between the eyes and nostrils. No other species possess this pit.	

The pharmacological action of snake venoms. The venom when fresh is a transparent and clear fluid. It is faintly acid in reaction and its consistency varies from that of water to that of the white of an egg. Cobra venom is a transparent, amber-coloured or almost colourless fluid having a specific gravity of 1.110. It is acid in reaction and slightly disagreeable in taste. The crotalus venom varies from a pale to an emerald green and orange or straw colour. It has no taste and its specific gravity varies from 1.030 to 1.044. The venom rapidly becomes alkaline in reaction on account of the disappearance of a volatile acid during decomposition. When dried under a bell jar on concentrated sulphuric acid or in the sun, it loses about 50 to 70 per cent. of water and is converted into a yellowish scaly mass and can be easily powdered. If kept in hermetically sealed ampoules and in a cool dark place it keeps its potency for a long time. The toxic principles of the venom reside in albumins which are thermostable, and a coagulable proteid which is thermolabile. The former is in excess in cobra venom and is associated with 'neurotoxin', and the latter is in excess in viper venom and is associated with 'hæmorrhagin'. The viperine venom contains another substance probably a cytolytic one releasing thrombokinase from platelets, etc., which causes intravascular clotting. As far as is known, the following substances mainly enter into the composition of the venom—fibrin ferments, proteolytic ferments, cytolsin acting upon the red cells, leucocytes, epithelial cells, nerve cells and agglutinins, and neurotoxin having a selective action on all the nerve tissue, especially on the respiratory and vasomotor centres. The toxic effects of different venoms are briefly stated in the table below :—

Class	Nervous system.	On blood and blood vessels.		
		Hæmolysis.	Coagulation.	Hæmorrhages.
Hydrophidæ (Sea snakes)	Paralysis of resp. centre & muscular system.	very slight.	slight reduction.	Nil.
Colubridæ (Cobras).	do.	moderate.	Nil.	Nil.
Viperinæ (True vipers)	Paralysis of vasomotor centre.	pronounced.	Intravascular clotting, in high concentration and in incoagulability in low concentration.	Very pronounced
Crotaline (Pit vipers)	do.	do.	Intravascular clotting less pronounced; coagulability pronounced.	do.

As regards the action of different venoms on man it has been observed that the neurotoxin in cobra venom has a special affinity for the respiratory centre and for the neighbouring ganglia of the 9th, 10th, 11th and 12th cranial nerves, and has a curare-like effect on the motor end plates of muscles. The krait neurotoxin has a selective action on the anterior horn cells of the spinal cord.

Phisalix and Pasteur (1928) noticed that animals vaccinated against rabies were refractory to the action of venom of the cobra and viper and *vice versa*, in other words the virus contained an antigen both for rabies and for the venoms. It has been further shown that the exposure of the venom of *Vipera aspis* to the ultraviolet rays does not diminish its virulence but increases it in certain cases. The ultraviolet rays however destroy the antirabic power of the venom. A temperature of 100°C, although destroys the toxin and the antivenomous properties of the viper venom, it does not produce any effect upon its rabicidal properties.

The venom of the Indian cobra. A large example of *Naja naja*, the Asiatic cobra, is six feet in length. The colouration of the typical form is yellowish to dark brown with a black and white spectacle-marking on the hood (seen when fully spread) and a black and white spot on either side of the lower surface of the hood. This form is more commonly found in Southern India and Ceylon. There are several varieties in India without hood markings.

Acton and Knowles (1914) found that an adult cobra of 4 feet 2 inches injects about 211.3 mgm. of the venom at a single bite, while the M. L. D. of cobra venom for a man of 60 kilo. is about 15 mgm causing death in three hours (see table). This shows that the cobra generally injects about 10 to 15 times the M. L. D. In the case of a common krait about 5 mgm. is injected at a single bite. The M. L. D. for monkeys is 0.15 mgm. and for a man it is estimated to be 1 mgm., it therefore injects about 5 to 10 times the M. L. D.

Chopra and Ishwariah (1931) investigated in detail the pharmacological action of the venom of the Indian cobra (*N. naja*) and reported that the M. L. D. of this venom varies with different species of animals. It is less toxic to frogs, cats and rats but fatal to dogs, rabbits and men. When injected intravenously the venom produces immediate fatal effects. If the dose is large, the animal dies within a few minutes from respiratory failure. The venom being colloidal in nature, its absorption is slow if injected hypodermically or intramuscularly and hence the symptoms are much delayed and death may be delayed from 4 to 24 hours. When given by the mouth the venom is not absorbed by the intact mucous membrane and does not produce any marked toxic effects. It has been shown that the venom is identical to the salivary secretion, and is a digestive enzyme. It does not affect the activity of the salivary, gastric and pancreatic secretions of man *in vitro*, though it slightly increases the muscular tone of the gastro-intestinal tract in cats and rabbits. The sublethal doses produce a small but persistent

Table showing M. L. D. for different types of snakes .

Snake	Approximate dose at a single and good bite, in mgm.	M.L.D. for rat, in mgm.	M.L.D. for monkey, in mgm.	Estimated fatal dose for man, in mgm.
Common Cobra (<i>Naia naia</i>)	211.3	0.12	2.4	15.0
King Cobra (<i>Naia bungarus</i>)	100.0	0.05	1.8	12.0
Common krait (<i>Bungarus candidus</i>)	5.4	0.20	0.15	1.0
Banded krait (<i>Bungarus fasciatus</i>)	42.9	0.10	1.5	10.0
Indian Daboia (<i>Vipera russellii</i>)	72.0	2.5	7.5	42.0
Phoorsa (<i>Echis carinatus</i>)	12.8	1.0	0.5	5.0
Green pit viper (<i>Lachesis gramineus</i>)	14.1	0.5	16.0	100.0

rise in the blood pressure in experimental animals. The rise is not due to the stimulant action in the accelerator mechanism of the heart or due to the action on the myocardium. In experimental animals no concentration could produce any definite stimulation or reviving effect on the failing heart. Large doses appear to act directly on the heart muscle and produce depression followed by cessation of its movements. The rise of blood pressure appears to be due to the temporary stimulation of the vasomotor centres. The subsequent marked fall of the blood pressure is due to late paralysis of the vasomotor centres. The main action of the venom is on the respiratory centre which is initially stimulated followed by paralysis. Histopathological studies of the brains of cobra-poisoned mice, as studied by Scharenko, showed that the toxin paralysed the vasomotors followed by a local stasis and subsequent corresponding necrosis.

It has no action on the motor end-plates of the diaphragm and other muscles involved in the mechanism of respiration. The action of the venom is exclusively on the nervous mechanism and this was demonstrated by Chopra and Chowhan (1931) by a detailed study of its action on protozoa. It was observed that the venom of the Indian cobra is toxic to protozoa. The paralysis of the movements of *P. caudatum*, which appears to possess a rudimentary neuro-motor apparatus, by cobra venom is confirmatory evidence of its selective action on this organ. It was further shown by them (1932) that the venom of Russell's viper, which is poor in neurotoxic principles, does not produce any effect on the activity of the movements of *P. caudatum*. The action of this venom is mainly on the endothelial cells of the vascular system and as these protozoa have no organised vascular system, they are immune to the toxic action of viper venom, while the animals which have a well-developed vascular system are severely affected by this venom.

The venoms of the Indian daboia and other vipers. These vipers are considered to be next to cobra in the order of their toxic action. The most important Indian pitless viper, called the Daboia or *Vipera russelli* is locally known as *uloobora* or *tic-polonga*. The other important viper is *Echis carinata* also known as the saw-scaled viper, Phoorsa or Kupper. The daboia is found in all parts of India, Ceylon, Burma, Siam, Sumatra and Java, whilst the saw-scaled viper is frequently met with in the N. W. F. P., Sind, Rajputana, Central India, Madras and Ceylon. Vipers (commonly called adders) are found in various conditions, in open woods where there are slopes and gullies exposed to the sun, on heaths and moors. Heaps of loose stones or tumbled walls are favourite prowling places and hunting grounds for food. Like the American rattle snakes and copper head, they prowl into the farms during the late summer, when the grain has ripened, in search of small rodents and are often discovered under sheaves or thrash piles. In the mountains they occur up to elevations of at least five thousand feet. They return to specific places to hibernate, but in congregating at their dens in the autumn are not so easily seen as they hide under the early fall of leaves where their body hue and pattern blend with the ground. The small size of the viper enables it to work its way through comparatively small holes.

The venom of the Indian daboia is a clear orange coloured oily fluid, having a specific gravity of 1.077 and when dried it yields orange coloured scales or masses. There has been considerable doubt regarding the action of the viper venom. Wall (1863) and Cunningham (1896) were pioneers to study the action of cobra and viper venoms. Mitchell and Reichert (1896) showed that the intense local irritant action and the sense of burning pain felt after the bite of a viper are due to the large quantity of globulin (as much as 25 per cent.) present in it, while the albumoses, which is responsible for the nervous symptoms,

is present only in very small quantities. Viper bites lead to severe pain, abscesses, gangrene and often multiple hæmorrhages and later ascending paralysis of the central nervous system. Lamb and Hanna (1903) made some observations on the properties of the Indian Daboia venom. Rogers (1904) working on the antidotes of colubrine and viperine venoms recorded that a small dose of Russell's viper venom intravenously could kill by a rapid fall of the blood pressure without any intravascular clotting, but with a loss of coagulability. This condition could always be produced by injecting a sublethal dose while a large lethal dose produced a fatal circulatory failure. He proved, by cutting the spinal cord, and by direct observations on the portal circulation, that the essential cause of death was paralysis of the vasomotor centre, the heart continuing to beat to the end. The African puff adder, the American rattle snake and the Indian pit vipers, all produce death in the same manner so that vasomotor paralysis is the main action of viper venoms and, in addition, there is a hæmorrhagic effect which is most marked in the case of the rattle snakes. Acton and Knowles (1914) showed that daboia venom contains a hæmorrhagin which destroys the endothelial cell lining of the finer blood vessels and consequently gives rise to ecchymosis and extravasation of blood, the convulsions seen early in viperine poisoning being due to small hæmorrhages in the cerebral cortex; a *cytolysin* which dissolves the red blood corpuscles releasing a fibrin ferment (*thrombase*) which causes intravascular clotting, pulmonary embolism and death from asphyxia. The slow and delayed symptoms after the venom is injected are probably due to low dosage. The fatal dose for a monkey of 25 kilo. weight is 7.5 mgm. and for man the M. L. D. is 42 mgm., death occurring in 24 hours. The average dose given at a single bite is about 72 mgm., which is about double the minimal lethal dose. Crimmens (1931) stated that the diamond black Rattlesnake of Texas may discharge 9 to 40 lethal doses of the venom at one bite. In the case of the *Echis* the M. L. D. for a monkey is 0.5 mgm. and for a man is 5.0 mgm. and the approximate dose of the venom injected at a single bite is about 12.3 mgm. Here also the snake injects almost double the fatal dose. Chopra and Chowhan (1934) investigated the pharmacological action of the venom of the Russell's viper, and found that the hæmorrhagic phenomena appear at the outset of poisoning and are very extensive in character. Death is preceded by spasmodic and irregular respiration, convulsions and asphyxia indicating the involvement of the vagal centre owing to deficient blood supply. In all post-mortem examinations recorded, the lungs show symptoms of asphyxia, petechial hæmorrhages and infarctions. The right side of the heart is full of dark blood and the left side is empty and tonically contracted; the blood is not coagulated. In animals which have died of daboia poison the kidneys show inflammation, mottling of the cortex and extensive hæmorrhages. The serous cavities such as the pericardium, the pleura and the peri-

toneum are full of sanguinous fluid, probably produced by injury to the delicate endothelial cells of the capillaries leading to excessive leakage of the blood.

The daboia venom has a marked tendency to produce thrombosis and gangrene at the site of the bite and death is due to secondary shock. The systemic blood vessels, especially the peripheral ones, are found to be contracted and those of the splanchnic area are widely dilated as in histamine shock. That the nervous centres are not much affected is shown by the fact that in decerebrated animals exactly the same results are produced. If the action is prolonged, these measures are of no avail since the normal relative permeability of the vessel walls to the protein constituents of the blood is lost. The capillary leakage goes on to such an extent that anything injected leaks out of the vessels. The symptoms of shock in daboia poisoning are not due to reflex impulses, but are due to the local dilatation of the capillaries of the splanchnic area. The paralytic action of the venom seems to be confined to the capillaries only and is similar to histamine.

In the case of *Lachesis*, Vellard and Vianna (1932) found that intramuscular and subcutaneous injections in dogs produce an initial incoagulability, due to rapid destruction of fibrinogen and of the complement by the protease of the venom, subsequently there is absence of formation of thrombin due to the action of the venom on the hepatic cells and hæmolysins are also increased. After intravenous injection there is at first intravenous clotting, followed by incoagulability of the blood in about five minutes. It was further shown that while the venoms of *Lachesis* and *Trimeresurus* are anticomplementary, the cobra venom has less and slower anti-complementary action and *Crotalus* has no action on the complements at all. A certain incubation period precedes the anti-complementary action. Malcolm, Smith and Hindle found that the M. L. D. (for mice) of the venoms of the pit viper (*Trimeresurus sumatranus*) and *T. vagleri* to be 0.5 mgm. and 2.45 mgm. per kilo. body weight, and that of the sea snake (*Latecauda colubrina*) to be 0.118 mgm. but they doubt that the total yield of the venom for any of these three species is sufficient to render the bite dangerous to a healthy adult person.

The mechanism of the bite. There are four distinct phases when a poisonous snake bites.

(1) *The strike.* In this phase the snake throws itself forward with great rapidity and violence, the distance covered not generally exceeding one-third of its length. The vipers strike with greater velocity than the colubrids, some of which—especially the hooded species—raise the head from the ground, so compensating to some extent for the limited mobility of the fangs.

(2) *Opening of the mouth and elevation of the fangs.* Most poisonous snakes commence the strike with closed jaws, but as the head approaches the victim the mandibles are depressed by a rapid contrac-

tion of the digastric, cervico-mandibular and vertebro-mandibular muscles and simultaneously the fangs are elevated or rotated forward by the forward swing of the pterygo-palatine-transverse arch produced by the contraction of the spheno- and parieto-ptyergoid muscles. The fangs of the colubridae are invariably grooved and are generally shorter than those of the viper, and their capacity for forward rotation is much more limited.

(3) *Closure of the mouth and the injection of the venom.* Closure of the jaws follows, a result brought about by the simultaneous contraction of the anterior, middle and posterior temporal muscles which strongly elevate the mandibles. In the colubrids the venom gland is also compressed by the superior and inferior portions of the anterior temporal muscles, producing torsion of its capsule with the expulsion of venom from the gland along the duct, the papilla of which becomes approximated to the groove at the base of the fang. Fixation of the jaw is important in effective biting by colubrides, as emphasized by Acton and Knowles. In the vipers there is an entirely different anatomical arrangement of muscles acting on the venom gland; expulsion of its contents is instantaneous and independent of fixation of the lower jaw.

(4) *Retraction of the fangs.* Immediately following the insertion of the fangs, and actually accompanying the discharge of venom, contraction of the retractor muscles (the parieto- and spheno-palatine and the internal and external pterygoids) which operate on the pterygo-palatine-transverse arch occurs, dragging the elevated fangs downwards and backwards through the tissues.

The pathology and the character of the wound. The shape and the severity of the wound depend upon the vascularity of the area and the anger with which the snake attacks. The wound may be absolutely blind if the animal happens to bite through thick clothes, but if through the bare skin the puncture resembles that made by a large hypodermic needle. There are generally two punctures of the fangs $\frac{3}{8}$ to 1 inch apart.

Pain. Immediately after the bite pain is usually local, severe and scalding in character. Later, the pain may increase and radiate along the whole length of the limb followed by numbness and heaviness of the bitten limb.

Swelling. It usually occurs within 10 to 20 minutes after the bite and is intense, brawny and indurated in character. The swelling is very painful, does not pit on pressure and rapidly extends higher up along the body.

Discoloration. The skin may become bluish black in colour due to the action of the venom on the haemoglobin and may end in blisters, abscess and gangrene.

In the act of the bite the fangs penetrate the tissues and the venom is injected synergistically. The snake grips the tissues tightly in its

month, the subtemporal muscles contract with great force, the levator vagina of the palate is elevated and the venom glands are squeezed. The venom finds its passage along the grooves of the fangs into the wound. It is almost always injected into the subcutaneous tissues, with a considerable degree of torsion and compression. In cases where hands and feet are involved the teeth may even penetrate the deeper tissues and tendon sheaths. In the case of the Death Adder, the fangs are very long, more curved and rotated forward. The bite here is much more powerful due to the highly developed temporal muscles, hence the venom is deposited much deeper into the tissues. The injected venom is usually very concentrated and irritant and is not absorbed unchanged. This irritant part of the venom induces engorgement of the perilymphatic spaces and later on congestion of the tissues and veins which renders the part more suitable for absorption of the venom. The venom passes from the perilymphatic spaces into the lymphatic vessels and then makes its way into the general circulation.

Symptoms produced. The Indian Commission on snake bites in (1886) estimated that the average lapse of time between the infliction of a bite and the cessation of the respiratory function varies from 10 minutes to one hour (average 42 minutes), without artificial respiration. In the case of the Russell's viper death takes place in 2 to 7 days usually due to paralysis of the vasomotor centre and circulatory failure. Death occurs from secondary shock, while in the case of *Echis carinata* death is due to multiple hæmorrhages and consequent failure of the circulation and it may be still more prolonged.

(a) *The cobra and the krait.* The local symptoms consist primarily of pain at the site of the bite, radiating along the limb and later followed by œdema, paresis and numbness. As the venom is absorbed, partial paralysis of the limb and peculiar tremors occur all over the body; incoordination in speech, ptosis, drooping of the head, collapse, giddiness, reeling sensation, staggering gait, complete paralysis of all the voluntary muscles and blindness are produced. The breathing may become shallow and rapid and later diaphragmatic in character and may end in asphyxia with convulsive seizure. There is profuse salivation followed by paralysis of the tongue and the larynx. There may be obvious dysarthria often vomiting and involuntary passage of urine and fæces before cessation of respiration. The pupils remain active to light up to the end. The heart continues to beat for a much longer time after the stoppage of respiration. The krait of Northern India is one of the most deadly snakes. It has also been observed that the patients lose the taste for powdered chillies, raw onions and bitter *neem* leaves after a cobra bite. The symptoms produced are similar to those produced by the cobra venom but there are no convulsions. The symptoms produced by the bite of the Australian Colubridæ are often not so severe as those of the Indian. There is a

feeling of faintness and irresistible desire to sleep, which is soon followed by paresis of legs, vomiting and cardiac paralysis. The pupils are widely dilated and are insensible to light. Should the patient survive the coma, the recovery is complete and no sequelæ follow.

(b) *The Russell's viper and the echis carinata.* The local symptoms are more prominent and severe in character and the victim feels as if a live coal is placed on his skin. He may even scream with the intensity of the pain. There is marked ecchymosis and persistent oozing of the blood from the site of the punctures and it is proportionately more profuse as compared to the depth of the wound inflicted. There is a marked fall of the blood pressure, small thready pulse, collapse, nausea, vomiting, widely dilated pupils which are insensitive to light. The loss of consciousness is more or less complete, from which temporary recovery sometimes occurs. Should the effect of the diffused toxins wear off, the local condition of the wound becomes aggravated. In severe poisoning convulsions set in in due course and death ensues from failure of the circulation. The post-mortem examination reveals congestion of the meninges and the lungs are full of fluid blood. On incising the bitten area clotting and hæmolysis of blood are seen which give the appearance of a red-currant jelly to the tissues. In delayed and less poisonous cases, blisters, abscesses, gangrene and secondary bacterial infection may occur. Multiple hæmorrhages, extensive petechial spots, epistaxis, hæmaturia, hæmoptysis, subconjunctival hæmorrhages and purpura are not uncommon.

Treatment. From time immemorial snake charmers all over the world have claimed the ability of overpowering snakes. They allege that they possess specific remedies against the poisons either in the form of charms or organic drug substances, sometimes obtained from the body of the snake itself which possess the power of extracting the poison out of the wound. The indigenous medicine in India has a long list of drugs claimed to possess specific antidotal properties against snake poison. Mhaskar and Caius (1931) tested about 300 of such reputed remedies, but none of these proved effective. The author has received a large number of preparations and secret remedies consisting of leaves, powders, pills, snuffs and eye salves, which are claimed to be effective remedies against snake bite, but they fail to neutralise or counteract the effect of the venom in experimental animals. The methods of administration recommended for these cures appear to be rationally unsound as it is highly improbable that the rapidly acting venom will be neutralised

by giving the drug by the mouth or application to the mucous membrane of the nose and conjunctiva or the skin. The venom of most of the snakes when injected intramuscularly is absorbed into the general circulation within 20 to 30 minutes and within a few minutes by the intravenous route. Most of the venoms have a selective action on the vital centres and fatal effects occur so rapidly that the patient is dead before any help is possible. It follows, therefore, that to be effective at all, the treatment should be vigorously and promptly applied and it is only in the case of locally acting and slowly absorbed venoms that such methods could be of any use.

On a patient being brought for treatment for snake bite, it should be ascertained whether the snake was seen or killed and identified. In this connection it is necessary to find out, (a) has the snake actually bitten and (b) was the snake a poisonous one. The first thing to do is to tie a proximal ligature on the limb and then to examine the area of the supposed bite. If there are no fang marks and no venom on the skin then obviously there is no danger, but fang marks on the skin or venom on the mucous membrane or on the skin with scratches may be dangerous. If the snake is available examine its mouth for the typical poison fangs in the anterior part of the upper jaw; also see if the head has the shape of an arrow as occurs in vipers. If the snake is found to be a non-poisonous one, the patient may still be suffering from acute, and even fatal shock due to fright, but an assurance that the bite was not dangerous, and simple treatment for shock, will always rapidly allay the symptoms.

If the snake has not been accurately observed or killed, the site of the bite should be closely examined for signs of the typical two punctures of the fangs a short distance apart, but it should be remembered that occasionally only one fang may have penetrated the skin, in which case the dose injected is likely to be a small one. If some time has elapsed after the bite, local swelling due to hæmorrhagic effusion will be present, and this is likely to be greater in viperine than in colubrine venoms, but on incising the bitten area some effusion will be evident within a few minutes after the bite. In any case,

treatment should be applied at once without waiting for symptoms of poisoning to appear, as by delay the chance of saving the patient is likely to be lost. When dealing with a case of bite from a poisonous snake, efforts should be directed firstly to prevent absorption of the poison, and secondly to neutralise as far as possible its toxic effects. Thus ligature, burning and suction of the wound are some of the very antique remedies which have been practised in India for quite a long time and number of other schemes have been practised.

The chicken method is used in some parts of India. Young chickens are obtained, their tail feathers are pulled off and the rectal portion of the tail is scarified or made raw with a sharp instrument and applied locally on the bitten and scarified wound. After being in contact with the wound for a few minutes the chicken is said to drop dead; another chicken is likewise applied and the process is continued till the chickens cease to die. The raw rectal surface of the chicken is believed to absorb the poison from the wound. This method might be of value where the poison remains localised and is slow in action as in cases of *lacheis* and *echis*. The cock's flesh while still warm has also been applied to neutralise the venoms of snakes; chickens' brains have been made use of for similar purpose. The fresh flesh of pigeons, swallows, burnt feet of fowls, and various fantastic things are alleged to be good against the snake bites. All these claims have been found to be baseless.

Snake poisoning consists in the hypodermic or intramuscular injection of a series of poisonous principles which act chiefly upon the nervous and the circulatory systems. Moreover the virulence of the poison depends upon the quantity of the venom injected and the size of the animal. The same quantity of the poison will thus have a more serious effect upon a child than upon an adult. The absorption of the venom depends upon the depth at which the venom has been lodged during the act of the bite and also depends upon the vascularity of the area bitten. Wounds are dangerous if near the face, neck, upper arm, trunk and thigh, and less dangerous if is on the toes of the feet or fingers. The smaller the quantity of the poison introduced into the circulation, the milder the symptoms. The first indication for treatment is therefore to prevent the passage of the poison as far as possible into the general circulation. The success of this procedure depends on the proper identification

of the snake and immediate application of first aid. In case of non-poisonous snakes the bitten area may be simply cleaned and treated aseptically.

The treatment of snake bite has been divided by Metcalfe (1927) into:—(a) Preventing the passage of snake poison into the general circulation, (b) neutralising the venom at the site of the bite, (c) neutralising the venom that has been absorbed into the general circulation by specific antiserum treatment, and (d) the treatment of the special symptoms and secondary complications.

The prevention of the passage of the poison into the general circulation. The methods consist in application of a ligature, incision of the wound, cauterisation and suction of the venom from the site of the wound.

1. *Ligature.* By ligature is meant the application of an elastic and a tight binder between the seat of the bite and the heart so that absorption of the venom into the general circulation is prevented and time for the use of local and general remedies is gained. This method was first used by Kemfer and later by Fontana (1781) who published his work "Traite sur la venin de la vipere" in Florence. Continued and intermittent ligatures have been advocated. In the latter the cord is loosened for a few minutes from time to time, careful watch being kept for the appearance of any constitutional symptoms, the onset of which calls for tightening of the ligature again. It has been shown that 6 or 10 times the fatal dose of the venom of the black snake (*Pseudechis porphyriacus*) could be injected into the legs of a rabbit without fatal results, if an elastic ligature is applied immediately after the injection of the venom; the ligature in such cases was tight enough to obliterate the circulation for about 20 minutes. On incising the bitten area, the blood and lymph were found to be clotted at the site showing that the poison is thus temporarily locked up and could only be absorbed slowly. In the case of cobra and krait venoms which contain no fibrin ferment, the ligature only delays the absorption of the venom as long as it is on and thus only prolongs the death interval. In the case of saw-scaled viper and the Russell's viper, where the venoms contain a

greater proportion of the fibrin ferment and a thrombase, the ligature helps in fixing the venom locally by producing thrombosis and thus greatly reducing the absorption rate of the venom. In case of lachesis, it was shown in Brazil that the ligature is not indicated as it produced gangrene at the site of the bite.

The method of application of a ligature. The binder should always be applied to the limb possessing a single bone, *e.g.*, the upper arm and the thigh and not on the forearm, calf, wrist or ankle which possess more than one bone and consequently the deeply seated interosseous blood vessels between them cannot be completely compressed by the help of a tight binder. The bandage should be applied within 10 minutes of the bite and it should be tight enough to obstruct the lymphatic and venous circulation, but it should not obliterate the arterial pulse. If a rubber tourniquet is not available a thick string, an elastic rubber tubing, belt, *dhoti* (loin cloth), turban or even a waist band may serve the purpose. The bandage can be tightened by inserting a piece of stick between the ligature and the limb, and twisting it on the ligature in a corkscrew manner; when the ligature is adequately tight the stick is kept in place by inserting one end underneath the ligature. It is loosened after about half an hour to allow the fresh blood to enter it and when the parts become pink the binder is tightened again. This procedure should be carried on every quarter of an hour so as to avoid serious damage to the tissues by prolonged local anoxæmia. After the first aid treatment, the ligature should be loosened more frequently and for longer intervals and if no cardiac symptoms appear it may be safely discarded.

The ligature is obviously made for delaying the passage of the venom into the circulation and thus extending the precious time for other active measures. *Effective ligature must remain the first and the foremost step in the treatment of snake bite.*

2. *Incision.* The second form of local treatment of value is the immediate and free incision into the site of the bite and its neighbourhood or after the application of the ligature in order

to let out the poison and to prevent the further absorption of the venom into the tissues. The skin and the subcutaneous tissues around the bitten area including the punctures of the fangs should be incised longitudinally along the muscle fibres and never across it. The incision is made in two stages:—

(a) The primary incision. It consists of cutting $\frac{1}{8}$ th to $\frac{1}{4}$ th of an inch, *i.e.*, as deep as the puncture of the fangs and is crucial in shape. Care should be taken to avoid big vessels or nerves. The effusion of the blood from the wound should be aided by squeezing the wound and by applying suction. (b) Secondary incision. After the primary incision and suction the wound may be further deepened to the subcutaneous tissues, *i.e.*, about $\frac{1}{4}$ to $\frac{1}{2}$ inch deep extending as far as the swollen margin. If the bitten part is a limb the incision should be circular, running all around the limb in the form of a 'bracelet'. Two such bracelet incisions about one inch apart should be made proximal to the wound. When the surface is flat as the back of the trunk, the incision should encircle the bitten and the swollen area. The secondary incision should be along the distal margin of the swelling and the suction should be continued for some time. If the swelling still increases, make another incision along the distal end of the fresh swelling and continue suction, for it is in the distal parts of the swollen area that the venom is more dilute and therefore is more likely to be absorbed into the circulation.

3. *Suction of the venom.* The sucking of the wound has been recommended by Celsus, but it should only be done by the mouth if there are no ulcers on the gums, palate, tongue, etc. The ligature and the incision must be supplemented by suction. The mouth is first rinsed with oil or warm *ghee* (clarified butter) and the wound sucked and spat out. The vacuum cups or suction apparatus have proved to be far more efficient than the suction by the mouth. A simple emergency suction apparatus can be improvised by attaching a rubber bulb to a glass funnel. The breast pump or cupping glasses also serve the purpose. Jackson and Dudley (1928) demonstrated experimentally that the venom can be removed from the tissues by the method of incision and suction. Experimental animals

after receiving as high as 4 M.L.D. of the venom could be saved by this method if suction was applied within an hour of the injection. The fluid sucked out contains the venom in solution and is highly toxic if reinjected into another animal and it can be neutralised with antivenom sera. The suction is repeated after half an hour. In the beginning the sucked out blood is thick, dark and semiclotting in condition, but subsequently it changes its appearance to a bright red colour due to hæmolysis and dilution with lymph.

4. *Burning and cauterisation of the bitten area.* This drastic procedure has sometimes been used. A burning coal or a red hot iron is applied immediately to the bitten area. Strong alkalis, acids such as nitric, sulphuric and carbolic, silver nitrate or crystals of potassium bichromate have also been used as escharotics. The disadvantage of this method is that as the burning only acts to a certain depth, absorption of the venom from the deeper layers cannot be prevented.

5. *Amputation.* This is another drastic treatment, but if done in proper time life may be saved. It is the best remedy, especially in viper bite. It is not indicated in cases of lachesis and echis bites where the mortality is very low, and its value is doubtful for cobra bite as the poison reaches the circulation within 8 to 10 minutes. It is useful in cases of bites of fingers and toes and when the patient is seen within ten minutes of the bite. Amputation is usually done by the patient himself as the cases are seen rather late for medical aid.

6. *Local venesection.* Kellaway (1920) demonstrated experimentally that venesection is of value in case of poisoning from the death adder and tiger snakes and can afford protection from a dose of one to one and a half times the lethal dose. It may be carried out within an hour or two of the bite before the ligature is removed. The idea is to wash out the parts with the patient's own blood. A second ligature, tight enough to obstruct the venous return, but not the arterial flow, is placed in position immediately distal to the arterial ligatures. An incision is made into one of the veins draining the bitten area and a succession of small blood-lettings from the vein is carried out by lifting the arterial ligature for a minute or two and

leaving the venous ligature in position. This treatment is quite useful, particularly where antivenene is not available. In an adult a pint and a half of the blood can be removed and if necessary replaced by transfusion or by giving an intravenous injection of a large quantity of gum in saline solution.

Neutralising and fixing the venom at the site of bite. It is clear that it is far more important and practical to destroy and neutralise the venom at the site of the bite before a lethal dose has been absorbed into the general circulation. Moreover, if less than a fatal dose has been absorbed before the patient comes under treatment, the destruction of the greater part of the remaining unabsorbed venom may turn the scale. The destruction of the venom locally is important in view of the uncertainty of the antivenene treatment, the amount of antivenene available to completely neutralise the large dose of the venom injected by a bite and the availability of an apparatus for intravenous injection. Cobra venom is absorbed quickly but in case of viper bite one ampoule of the serum should be injected locally at the site of the bite, and half an ampoule a little above the wound and below the ligature.

1. *Potassium or zinc permanganate.* About 200 chemical reagents have been tested, but their value in actual practice is limited. These remedies act by causing local coagulation and necrosis, thus destroying both the venom and tissues. The neutralising value of a chemical is greater when it comes in direct contact with large quantities of the venom and in high concentration. Chemicals are more suited for viperine than colubrine venoms.

Experiments by Brunton and Fayrer to prove that potassium permanganate oxidises the venom in the tissue were inconclusive, but Rogers (1914) showed that three to five times the lethal dose of venom of cobra or Russell's viper could be reduced to below the lethal limit by the application of the permanganate crystals treatment.

Acton and Knowles (1914) and Bannerman (1914) showed by *in vitro* and *in vivo* experiments that potassium permanganate has a marked action in destroying and fixing different venoms. The efficacy of this treatment depends upon the time and the mode of application. Wada (1917) showed that if potassium permanganate was injected within 7 hours of the bite, it neutralised the power of the venom by oxidising and fixing it locally. Unfortunately cases of snake bite usually occur in places where the victim is far from such aid and it was for such contingencies that Lauder Brunton devised his snake bite

lancet with a sharp blade at one end and a receptacle to contain potassium permanganate at the other end. The method advised was to cut open the bitten area and to rub in the crystals of the permanganate into the wound. After application of a ligature and the incision of the wound, a freshly prepared 1 to 2 per cent. solution of potassium permanganate should be forcibly injected with a Record syringe into and around the wound at various points until the solution begins to ooze out of the wound. The needle should penetrate at least $\frac{1}{4}$ inch deep into the tissues. The limb must be kept elevated and fomented with a hot and strong (3 to 5 per cent.) solution of potassium permanganate. The tourniquet should be kept in place as long as necessary, but not more than quarter of an hour so as to avoid necrosis of the area. Ten to twenty c.cm. of 1 per cent. solution can be injected into the bitten area. It is not always practicable to incise the parts with a lancet and rub the dry crystals of the potassium permanganate locally into the wound. The American authorities on the other hand do not recommend the local application of potassium permanganate, because they consider that it is toxic to the tissues and possesses no antidotal value.

2. *Gold chloride.* The use of gold chloride solution was suggested by Cunningham more than 3 decades ago, and later by Calmette and more recently Acton and Knowles advocated its use. One to five per cent. solution of this preparation can be injected subcutaneously around the site of the bite. Sealed ampoules of 15 gr. of gold chloride crystals are available in the market. The whole quantity should be dissolved in 20 c.cm. of sterile saline solution; this approximately gives a concentration of 5 per cent. The value of this treatment depends on the early administration and thorough diffusion of the bitten area before the venom is absorbed into the circulation. The salts of gold and permanganate should not be injected intravenously as they are both poisonous and ineffective by that method. Locally, extensive necrosis occurs after the injections. It has been observed that the use of ox-bile as a solvent improves the action of a weak solution of gold chloride and the permanganate. The local injection of gold chloride is considered superior to potassium permanganate but the former produces necrosis of the tissues.

3. *Dihydrochloride of palladium.* It is said to have proved more efficacious than gold chloride under experimental conditions.

4. *Calcium chloride.* A 2 per cent. solution can be injected locally and intravenously. It is said to be useful in preventing hæmolysis and aids the healing process; it is indicated in cases of *echis* and *lachesis* bites.

5. *Hydrogen peroxide.* It has been shown that injections of 1 c.cm. of hydrogen peroxide solution within 9 hours of the bite can oxidise about 5 mgm., i.e., 1.7 times the M. L. D. of the *Ancistrodon*

per kilo. weight of a rabbit. Its action is similar to that of potassium permanganate.

Artificial respiration. This is of value in colubrine poisoning if complete respiratory paralysis has not yet supervened. With the employment of artificial respiration, life has been prolonged as long as 30 hours after cobra bite. Artificial respiration should be kept up as long as the heart goes on beating. If the respiration fails, the administration of oxygen or carbon dioxide should be tried ; the latter gas can be given by making the patient breathe in and out of a bag thus increasing the carbon dioxide intake. In case of viperine poisoning, where death is due to cardiac failure and secondary hæmorrhages artificial respiration is useless.

Antivenene or specific therapy. The first scientific attempt to produce an artificial immunity was made by Sewell in 1887 in pigeons, when by small repeated injections he raised their resistance so high that they could resist 10 times the lethal dose of the venom of a crotaline snake. In 1892 Calmette showed that by repeated inoculation of venom heated to 80°C., a certain amount of resistance could be developed in animals. He also demonstrated that an antitoxic serum against cobra venom could be prepared by repeated injections of gradually increasing quantities of venom into horses and Fraser soon after independently arrived at a similar conclusion. Martin and Lamb showed that antivenene has a specific action against the venom employed for immunising the animal. Nuttall (1904) put forward the hypothesis that antivenene is of the nature of a precipitin serum and acts by forming a precipitate with the specific venom. Noguchi and Madsen succeeded in producing antisera by immunising horses with venom after the toxophorous group of the molecule has been destroyed, capable of neutralising the hæmorrhagin of the crotalus venom. The anticobra serum supplied by Calmette had some power of neutralising the venom of sea snakes, the king cobra and the common krait, but not that of banded krait, which has a partial viperine action. Kellaway (1931) believes that active immunity against snake venom is often not so exclusively specific as was once supposed, the high resistance of animals immunised to one

species of venom to other species of allied venoms being due to the similarity of venom in toxic constituents and to the close serological relation of the snakes.

Antivenene in India is prepared at Kasauli with the venoms collected at the Haffkine Institute, Bombay, in the form of Lamb's mixed cobra and Russell's viper antivenene. Experimental batches of pure echis antivenene have been prepared at the Haffkine Institute and at Kasauli and are effective. The former preparation is reported to be strictly specific for cobra and daboia venom but its efficacy also extends to the poisons of the closely allied species. The Pasteur Institute, Paris, prepares three antisera against the venoms of different snakes. These are (1) ER for European snakes, (2) AN for African snakes (*colubridæ* and *viperidæ*), (3) AO for West and Equatorial African snakes (*bitis* and *cepedon*), (4) C for the *Naja* snakes of India and Egypt. In Siam where cobras are particularly numerous, the Bangkok Pasteur Institute maintains a large establishment for manufacturing antivenene. The institute here is similar in its organisation and surroundings to the Butantan Institute of Serum Therapy in Sao Paulo maintained by the Brazilian government. This institute issues a univalent serum against the venom of the rattle snake and a multivalent serum against the bites by the central American snakes. The antivenene institute of South America has perfected a polyvalent serum for the bites of the rattle snake, copper head and moccasin. Monovalent, bivalent, or polyvalent antivenenes are now available for snake-bite cases in Europe, India, Africa, Japan, Java and Australia, as well as in the United States, Brazil, the Argentine and Central America.

The antivenene remains thermostable at 60°C. for five minutes, but is completely destroyed when the temperature is raised to 65°C. or above due to coagulation of proteins.

Detoxication of venom. The great toxicity of ophidian venoms has made the production of specific high titre antivenenes from horses a prolonged, hazardous and decidedly expensive affair so that any such process as detoxication of venom with simultaneous preservation of its antigenic properties becomes a matter of great practical importance to countries interested in the manufacture of antivenenes on a

large scale Grasset and Zontendyk (1933) of the South African Institute of Medical Research have done a good deal of work on the detoxication of snake venoms. Bile, solganal and formalin detoxicate the venom. The detoxicated venoms are subsequently used for immunisation experiments in animals. Maitra and Mallik (1932) observed that the contact of hepatic lipoids with daboia venom at 37°C attenuates its necrotic action on animal tissues but does not interfere with its immunising power. Horses are immunised by giving them weekly subcutaneous injections of gradually increasing doses of cobra venom, heated to 70°C for an hour; this precipitates the irritant toxins without injuring the neurotoxin.

Method of preparation The technique of production of antivenenes is a complicated one owing to the now generally accepted fact that the antigenic substances contained in snake venoms are on the whole highly specific. Horses are used for the production of the antivenenes. The immunising process must be carried out very cautiously owing to the great sensitivity of this animal to the venoms. The venom from a living snake is desiccated over sulphuric acid *in vacuo* and a weighed quantity is dissolved in sterile water and injected subcutaneously into horses selected for the purpose. In the preparation of anti-daboia serum, the venom is sometimes emulsified with sterile lung tissue before injection in order to fix the hæmorrhagin principles. The M.L.D. of cobra venom for the horse is 25 mgm and therefore the first immunising dose is much smaller than this. This is gradually increased until the animal is able to tolerate 1 to 2 gm of the dried venom at a single injection. This amount is equivalent to the entire yield of 20 average-sized snakes. Usually a period of 12 to 16 months is necessary to obtain a sufficiently powerful serum. At Kasauli the final dose of venom is very much smaller and the horses are brought up to the titre in about 4 months. In order to avoid the strong reaction produced by the injection of venom into horses various substances are added by different workers to neutralize or to reduce the toxicity of the venoms. Calmette uses the solution of hypochlorite of calcium; some workers combine a little antivenene or formaline, etc. These substances reduce the toxicity but do not alter the antigenic properties of the venom. Brazilian workers prefer to use the unaltered venom in the preparation of antivenomous sera. Twelve days after the final injection the horse is bled to the extent of 8 litres, and five days later 6 litres and another 6 litres five days later, till 20 litres are obtained. In some laboratories the animal is put under chloroform and the whole blood and plasma is removed, yielding in this way 50 to 60 litres of serum; this procedure is believed to be more economical. The serum is prepared in the usual way, standardised into units on rabbits, and supplied in hermetically sealed ampoules of 10 c.cm. each. Standardisation of antivenene in Kasauli is carried out in pigeons. The minimal standards for unconcentrated antivenene are that 1 c.cm. should

neutralise not less than 1 mg. of daboia venom and 0.5 mg. of cobra venom. Higher titres are usually obtained and 1 c.cm. may neutralise 3 to 5 mg. of daboia venom. The therapeutic efficacy of the serum is estimated by titrating it before filling it into ampoules. The methods used are the prophylactic test in which the serum is given an hour before a dose of the venom, or the simultaneous test which allows the neutralisation of the serum-venom mixture to take place *in vitro* before their injection into the animal, or by the curative test used by the American authorities. Here the venom is injected intramuscularly into rabbits and twenty minutes later the antivenene is given by the subcutaneous route.

Concentration of antivenene. In snake bite, the biting snake frequently remains unidentified, and in countries where numerous poisonous species abound, resort to polyvalent antivenene has proved necessary. Polyvalent antivenenes, however, are very bulky for intravenous and intramuscular routes, and in consequence some method of increasing their potency by concentration, such as has been successfully applied in the manufacture of antivenenes in Brazil, South America and the United States, becomes highly desirable. In 1929 a polyvalent antivenene was produced at the South African Institute of Medical Research utilizing the sodium sulphate process.

Considerable experimental work has been done by Acton and Knowles (1915), Caius, Iyengar and Anderson (1924) and Mallick and Maitra (1932). Maitra, Naidu and Ahuja (1933) produced a concentrated antivenene by the sodium sulphate method. The ammonium sulphate method for concentrating sera is now in routine use.

To the plasma of immunized horses are added, (a) 3 per cent. of a 4 per cent. solution of calcium chloride, (b) two volumes of tap-water, and (c) of the total volume so obtained about 18 per cent. of ammonium sulphate. The specific gravity of the mixture is adjusted to 1099 by adding more of the salt or the tap water; it is then filtered through chain cloth folded like a concertina along the border to fit a funnel, the filtrate being returned to the filtering cloth until it comes through clear. The precipitate on the cloth represents the fibrin and the euglobulin, and in the clear filtrate pass the pseudoglobulin and the albumin. The precipitate is rejected.

To the filtrate, after measurement, is added about 10 per cent. more of the ammonium sulphate and the specific gravity adjusted to 1133. The mixture is stirred, allowed to stand for half an hour, stirred again and filtered through another piece of chain cloth. The precipitate collected on the cloth represents the pseudoglobulin; in the filtrate which is rejected passes out the albumin.

The precipitate is scraped towards the middle of the cloth with an ivory spatula, the cloth being then folded in such a way over the precipitate as to leave no folds and dead spaces. It is then subjected to pressure in a hand press, the pressure being applied at first gradually

then increased quickly until dripping ceases. The hard-pressed precipitate is removed from the cloth as a cake.

The cake is weighed, broken up and put in bags of cellophane (No. 300), in quantities of about 100 gm. for each. The bags are suspended from a rod and allowed to dip in running cold water. In 12 hours the contents of the bags are found to be liquid, clear and increased in bulk. The bags are now gently squashed and allowed to sink further, to increase the surface for dialysis. In 24 hours the contents begin to turn turbid and the turbidity increases steadily and is at a maximum in 96 hours. By this time the ammonium sulphate is all dialysed out. The dialysate is collected into a bottle to which are added washings from the bags to bring the total quantity upto a convenient figure. The original volume of the plasma divided by the volume of the total dialysate gives the degree of concentration.

To the dialysate is now added 1 per cent. of sodium chloride which at once turns the turbid and viscid fluid into a clear, less viscid and translucent product of slightly greenish hue. The pH is generally found to be between 6.9 and 7.1 and is adjusted to 7.5 or 7.6 with sodium carbonate. A preservative, 0.7 per cent. of a mixture of equal parts of ether and tri-kresol, is next added and the bottle left undisturbed for two weeks. A whitish sediment, consisting mostly of euglobulin and fibres from the chain cloth, collects and clears the product further.

A sample is now tested for potency and toxicity. If the titre of protection is satisfactory and the product is not toxic it is passed through a Seitz filter and bottled. The unconcentrated serum prepared against cobra and Russell's viper venom protects pigeons against 25 to 100 M.L.D., while 0.25 c.cm. of the concentrated serum neutralises 1 mg. daboia venom and 0.5 mgm. of cobra venom. It is issued in doses of 10 c.cm. which replace the former dose of 40 c.cm. of unconcentrated serum.

The antivenomous principle can be concentrated up to 7½ times its original potency by using the methods of Pick and Boer, so that 1 c.cm. of this concentrated serum injected intraperitoneally can neutralise 1.2 mgm. of the venom as against the original serum where 1 c.cm. neutralised 0.16 mgm. intraperitoneally. According to some authorities a concentration upto 10 times is possible, but such concentrations will be of the consistency of gum and therefore unsuitable for administration. In actual practice four times the concentration is usually obtained.

The dosage and mode of administration. From the venom injected by different poisonous snakes, Calmette estimated that about 400 c.cm. of anti-cobra serum would be required to neutralise the amount of venom ejected by a cobra at a single bite or of the *Enhydryna*, which is one of the most deadly of the sea snakes. In the case of the common krait and the king cobra 600

to 800 c.cm. are required and then only if the sera are injected intravenously but Acton and Knowles considered it doubtful if a man can stand a dose of 400 c.cm. of antivenene intravenously. They estimated that in a man dying of cobra bite within two hours or less after the bite, over 700 c.cm. of the antivenene would be required to neutralise the venom, while 50 to 100 c.cm. may suffice to save patients who would take 2 to 6 hours to die after the bite. In view of the uncertainty regarding the dose of venoms which has been received, it is wiser to inject 100 c.cm. of the serum intravenously at once in all colubrine poisoning cases whenever possible. The subcutaneous and intramuscular injections of antivenene, except at the site of bite are of little value because its larger molecular weight makes absorption much slower than that of the venom. Fresh antivenene should be injected as early as possible, at least within 3 hours after the bite. With sera concentrated four times, a dose of 50 to 150 c.cm. should save every case. A rough guide for the dose is 1.25 to 2 c.cm. of the serum for each mgm. of the dried venom injected. The ratio of the neutralising power of antivenene injected by subcutaneous, intraperitoneal and intravenous methods is as 1 : 2 : 4, i.e., when tested in living animals, 1 c.cm. of the serum neutralised 0.1 mgm. of cobra venom when given subcutaneously, 0.2 mgm. is given intraperitoneally, and 0.4 mgm. when given intravenously. Russell's viper antivenene when given by these routes neutralises 0.3, 0.8 and 0.8 mgm. of the venom respectively.

The dose of antivenene to be given also depends on the rapidity of the onset of symptoms, age, site, and general condition of the bitten area, interval since the bite, season of the year and the size of the snake. The age and weight of the victim are important factors in determining the dosage; children require two or three times more than an adult because of their small volume of blood, which by itself contains a certain amount of neutralising power. Moreover the toxicity of the venom is universally proportional to the body weight of the patient. Antivenene in case of cobra bite is effective within two-third of

the death interval but Hutchison believes that it is never too late to give antivenene and that there is a chance of recovery however desperate the state of the patient may be.

There is no danger of over-dosage, rather the danger lies in not giving an adequate dose to neutralise the venom. A curative dose shows its effect almost at once or within a few hours of administration; pain is relieved rapidly and other symptoms completely disappear in 12 hours. The swelling is reduced within 24 hours. In the case of *Lachesis* the multiple hæmorrhages stop in 6 to 12 hours after the specific treatment. The patient should be kept in bed and allowed no exertion for at least 10 to 12 days after recovery. The most difficult of all are cases of Krait poisoning. Here the venom is 16 times as toxic as the cobra venom and antivenene is more or less useless. Fortunately, such cases are rare in occurrence in India.

Precautions in the use of antivenene. In desperate cases where time is of utmost importance, the possible risk of anaphylactic shock should be disregarded, and injection of antivenene by intravenous and intramuscular routes be given immediately without delay. If after this poisoning symptoms persist give another dose of 100 c cm intravenously, and a third dose later on if indicated; 400 c cm. of antivenene can thus be given safely to an average sized adult. In the case of concentrated sera 100 to 150 c cm. will be sufficient. Sometimes it happens that there is a flocculent deposit in the phials, which should be quickly filtered through a clean and sterile piece of linen before being filled into a syringe. Injections should be stopped for a short time if any untoward symptoms such as redness of the face, palpitation, reeling and embarrassed respiration appear. Keep 0.1 to 0.5 c.cm. of adrenalin hydrochloride (1 in 1,000) in readiness to be injected intramuscularly if anaphylactic symptoms occur.

Treatment of symptoms. Symptoms of shock usually develop in viperine poisoning due to destruction of the blood cells, vascular lining of the blood vessels, persistent hæmorrhage, destruction of the liver and the kidney cells, vasomotor depression, general sepsis, infection, œdema and septicæmia. Our

experimental work has shown that in such cases a dose of adrenalin chloride is the best drug and 1 c.cm. of (1 : 1,000) solution should be injected intramuscularly and repeated in an hour if necessary. Pituitrin is also useful. Blood transfusion, calcium injected intravenously, hæmoplastin, normal horse serum and adrenalin are indicated. A cup of hot black coffee is the best and the safest beverage. Aromatic spirit of ammonia may be necessary to revive the patient. Small doses of alcohol and strychnine may be given as stimulants, but the practice of giving enormous quantities of alcohol cannot be too strongly deprecated. Camphor in ether, and pituitrin may be given hypodermically as general and vascular stimulants. Rogers has advocated on physiological grounds the employment of adrenalin in viperine poisoning. In case of snake bites in which the toxins have a marked paralytic action upon the vasomotor centre, 1/16 gr. of strychnine intramuscularly has been advised to stimulate the spinal centres. Cocaine and morphine have been used locally and hypodermically to relieve pain. Sparteine 1/6 gr., digitalin 1/60 gr., pilocarpine 1/3 to 1/5 gr. and lobeline 1/6 to 1 gr. have all been tried to steady the pulse and stimulate the respiratory centre, but with no encouraging results. Five to ten c.cm. of calcium chloride (5 per cent. solution) have been given intravenously to increase the coagulation of the blood and to help the healing processes.

The fall of blood pressure and the rapid loss of blood due to hæmorrhages and extravasation lead to paralysis of the vasomotor centre. Effort should therefore be made to replace the blood by transfusion. Whole blood has been successfully injected into the peritoneal cavity or deeply into the gluteal muscles without typing or matching the blood. Intravenous injections of large doses of normal saline with 5 to 10 per cent. of glucose have given encouraging results. The dose is controlled by observing its effect on the blood pressure and pulse rate and repeated as frequently as necessary. Six hundred to eight hundred c.cm. of glucose saline can be safely injected, and a few drops of pituitrin or adrenalin may be added to keep the blood vessels in tone. Artificial respiration is of value in colubrine

poisoning as complete respiratory paralysis has not yet supervened.

RESUME OF THE ROUTINE TREATMENT OF SNAKE BITE

A. *The first aid or immediate treatment.* (1) The first aid treatment is used if the patient is seen within ten minutes of the bite. Secure absolute recumbancy. Fix a tight band immediately on the limb a few inches proximal to the bitten area and another ligature about 6 inches above. The ligature should be tight enough, but should not obliterate the arterial circulation. The part of limb having a single bone is the best site for ligature.

(2) If the bitten area is a finger or a toe apply a ligature above and amputate the bitten part within 10 to 15 minutes.

(3) If the bitten area is a flat surface or is very vascular, immediately incise it about $\frac{1}{8}$ to $\frac{1}{4}$ inch deep and $\frac{1}{2}$ inch long and forcibly express the blood and fluids as much as possible and apply suction cups or breast pump. Rub in crystals of potassium permanganate or swab well the incised parts with strong solutions of this salt.

(4) Cauterize the bitten area with strong acids, alkalies or burn it with live coal and keep the patient at perfect rest.

(5) Give stimulants like spirit of sal volatile (spt. ammon. aromat.) 10 to 15 drops in an ounce of water, coffee, etc. Keep the patient in bed.

(6) Reassure the patient that the danger of the snake bite is usually overrated and that 2/3rd of all the bites are usually from non-poisonous snakes and therefore there are more chances of recovery and less of serious consequences.

B. *Specific treatment.* (1) By the time the physician arrives there has usually been much delay, and hesitation, and indigenous remedies have been applied. His responsibility, therefore, is very great; life is in imminent danger and death may follow rapidly, he has therefore to decide quickly and act quickly. If the patient is seen early and if the bite was from a viper, he should examine the parts, tighten the ligature and excise the area.

(2) Infiltrate the bitten area with 5 to 10 c.cm. or more of the antivenene or if not available, 5 to 10 c.cm. of a 5 per cent.

solution of gold chloride or 1 to 5 per cent. solution of potassium permanganate with a syringe till the solution begins to ooze out from the wound.

(3) Inject specific antivenene as soon as possible after the bite. In cases of cobra or daboia bites, inject 80 to 100 c.cm. of antivenene intravenously within 20 to 30 minutes and give still larger doses if venom intoxication is coming on. With sera concentrated four times a dose of 50 to 150 c.cm. should save every case if given within $\frac{1}{2}$ to 1 hour of the bite. If intravenous administration is difficult, it may be given hypodermically into the sides of the abdominal wall.

(4) Inject antistreptococcal polyvalent serum as dental and oral sepsis is common in snakes. Inject intravenously 30 c.cm. of a 2 per cent. solution of calcium chloride thrice daily ; give a saline purge and ensure perfect rest.

SNAKE VENOMS IN THERAPY

Snakes and their venoms have been regarded as of great medicinal value in India. Snake venom is called *Sarpa visha* in Hindi and *Garala* in Sanskrit. The use of snake venom in Hindu medicine is of comparatively recent origin, as references to it are only met with in such modern works as *Ratnavali*, *Sarkaumudi*, etc. The Hindu practitioners obtain the poison by making the reptile bite a piece of wood, and the poison flowing out is collected on a plantain leaf. It is preserved by drying or by rubbing with a little mustard oil and spreading it on the leaf. Although the venoms of other snakes are mentioned, it is chiefly the venom of the Indian cobra which is used.

Almost all the parts of the body of a snake have been used in one or other incurable disease. Dutta (1932) has given a large list of animal products which have been used in the Hindu medicine, e.g., extracts of frogs, minced meat of lizards, skull bones of man, meat of sparrows, fat of bear and lion, feathers of the peacock, etc., have been used in different diseases. The use of cobra venom has also been advocated in the treatment of leprosy, incurable ulcers, bleeding, etc.

Ainslie (1826) wrote that the flesh as well as the skin of certain snakes were believed to possess medicinal properties in some Eastern countries. In *Ulfex Udwtieah* the flesh of snakes is described

as possessing 'hot' and 'dry' effects. The dried and powdered flesh of Jamool (an inoffensive hill snake), and the Malay Paumboo, has been advocated as a remedy against leprosy. The moult of snakes powdered and mixed with oil of *Dalbergia arborea*, when applied externally is said to be of value in epilepsy. The blood has also been used in Mahommedan medicine in the treatment of leucoderma. A preparation of arsenic and dead cobra is applied externally to leucoderma patches and syphilitic rashes in northern India. Wild tribes of North Burma and the Shan States eat the flesh of certain snakes. The venom has also been used in India as a drug of addiction, in the form of a pill. It is mixed with arsenic, opium and musk and is used as a tonic, aphrodisiac and as a prophylactic against many diseases. It has been used as a hepatic stimulant in ascites, cholera, collapse, etc.

Snake venom, particularly the venoms of *Naja naja* and *Lachesis trigonoccephalus* have been used in homœopathic medicine for the last 50 years. The venom next in importance is that of *Crotalus horridus*. Muire in South America used the venom of *Crotalus casavella*. Other venoms used are those of *Bothrops lanceolatus*, *Elaps*, *Apis mellifica* and *Trachinids*. The majority of diseases in which the venom of *Lachesis* is indicated in this system are abscesses, carbuncles, erysipelas, cancer, apoplexy, paralysis, meningitis, mental diseases, asthma, tuberculosis, syphilis, chorea, flushes, metrorrhagia, hæmophilia, hæmoptysis, skin diseases, and the diseases of the teeth. Cobra venom is indicated in diphtheria and malignant tumours.

In Western medicine Rattlesnake venom (Crotaline) has been used in a number of diseases. It is said to have been employed beneficially in the treatment of pulmonary tuberculosis, acute pneumonia, pulmonary gangrene, asthma, chronic spasmodic cough, hoarseness, neuralgia, chorea, epilepsy, hystero-epilepsy and hæmophilia. The use of the venom for respiratory and nervous affections has been discredited, but quite recently interest regarding its efficacy in epilepsy has been revived. Its use in therapeutics is based on its depressing properties on the nerve cells.

It is said that the pathological effects of any given venom on man vary with the dose injected. While large doses are lethal, small doses produce beneficial physiological effects.

The rationale of application of venom in therapy. The application of venom in medicine may be based on the presence of the following active principles: (a) neurotoxin, (b) cytolyisin and absorption of granulation tissues, (c) coagulative and hæmorrhagic enzymes, production of protein and histamine-like shock, and (c) protective properties against rabies and epilepsy.

Neurotoxin. The neurotoxin principle is present in all snake venoms though it preponderates more in cobra venom as compared to

the venom of vipers and other snakes. This principle has a strong depressant action on the higher centres. Its action is particularly marked on the vasomotor and the respiratory centres. In small doses it has an irritant action, but in large doses or on prolonged contact it produces paralysis of both the sensory and motor end-plates. The venom, therefore, in graduated doses may be used to depress the higher psychical centres and is useful in delirium, hallucination, aphasia, melancholia, etc. Improvement may occur in apoplexy, meningitis, hysteria and chorea. It may be used to depress the respiratory spasms of the asthmatic attack. In small doses it may be useful in early stages of hemiplegia and paraplegia. On account of its producing anaesthesia by paralysing the sensory nerve endings it has been used locally to stop the severe pains of inoperable carcinoma.

Cytolysin and tissue absorption. The venom produces necrosis by damaging the intima layer of the blood vessels when it is injected intravenously. Recently, it has been experimentally shown that, if in the thigh muscles of a rat an aseptic space be formed by an operation and then different substances are placed in it for a period of 5 to 10 days and then the section of the wound is taken and examined histologically new inflammatory cells are seen to collect around the foreign irritant substances to form granulation tissue. This tissue reaction occurs to protect the wound against the penetration of pyogenic organisms into the tissues. In the case of cobra venom no such protective granulation tissue was formed. On the other hand the tissue cells around the cobra venom were absorbed. This shows that cobra venom has the property of absorbing the granulation tissues and neoplastic protective cells formed in the tissues. This property has been utilised in the treatment of malignant growths with the idea of absorbing the neoplastic cells of the tumour. Laignel-Lavastine and Korossios (1933) have shown that in this way the growth of the neoplasm is retarded and even the distant metastases may disappear. It cannot be claimed however that a definite cure can thus be brought about.

Hæmorrhagin, thrombase and agglutinins. Cobra venom when injected intravenously produces intravascular clotting while the viper venom and crotalin venom produce excessive hæmorrhages. Fitzsimons (1929-30) stresses that the pathologic effects of any venom in man vary with the dose injected, while a large dose may be lethal a small dose may produce only a beneficial physiological result, the doctrine of *similia similibus curantur*. Small doses of ophidian venom have been used to cure the symptoms produced by the venom itself. The hæmorrhagic and neurotoxin principles in it have been used in the treatment of epilepsy, blackwater fever and hæmophilia, etc. 'Venene' a mixture of different venoms, has been used in the treatment of menorrhagia, metrorrhagia, bleeding piles, epistaxis, purpura, hæmophilia and flushes in females.

Protein and histamine desensitization. The author (1933-34) pointed out that viper venom produces a fall of blood pressure and symptoms of shock due to paralysis of the capillaries. The shock produced appears to be similar to that of histamine or protein. The venom in graduated doses may be also used to desensitize persons against protein sensitivity. This has been done in asthma, or as non-specific protein therapy against erysipelas, carbuncles, epilepsy, etc., and it acts by producing a protein shock or suppressing allergic symptoms. Frank Coke (1934) observed that persons bitten by honey bees were cured of the rheumatic complaints. Cases have also been recorded where persons after a single bite have ceased to get attacks of epilepsy for years. Similarly the bee venom has been used against rabies since both the bee venom and rabies virus have been shown to be allied in action.

USES OF SNAKE VENOMS IN CERTAIN DISEASES

Carcinoma. Cobra venom is said to afford a means of diagnosis of the presence of carcinoma. The test depends upon the activation by cobra venom of the hæmolytic action of the serum in the complement deviation test and it is asserted that the positive test is given only by the serum of persons suffering from malignant disease. The test is known as *Farmachidi's test*.

Cobra venom has also been used in the treatment of carcinoma. It is alleged that cobra venom has the property of destroying all the neoplastic cells and granulation tissues. In rats with spontaneously grafted adeno-carcinoma injections of cobra venom produced disintegration in a few days (Calmette and others 1933). Gosset reported on the experiments done at Hospital Sâl Petrière (Paris) for the Academy of Medicine on 115 cases of every stage of carcinoma injected with cobra venom ; Laignel-Lavastine and Korossios experimented on the algias of cancer patients. They found that injection of 0.001 mgm. of cobra venom relieved the pains in inoperable neoplasms in patients who otherwise had to use morphine injections daily. The injections needed repetition every 8th or 10th day.

Very small doses of venom which provoke neither suppuration nor general reaction, lead to relief of pain and cicatrization and produce other signs of healing. Epithelioma of the rectum has also been treated in this way. The distant metastases are said to have disappeared. Whatever else may have happened

the cobra venom is emphatically declared to be a good analgesic and promises a hopeful future in the symptomatic treatment of cancer.

Epilepsy and hysteria. It has been observed that in persons bitten by snakes epileptic attacks may cease for years. Spangler of the Philippines claimed that epilepsy can be cured by injections of snake venom. He used rattlesnake venom (Crotalin) till 1927 as a non-specific desensitizer in epilepsy, controlling the dosage by the degree of eosinophilia produced. A snake serum called contratoxin was also used in Texas. Claims were made by Mehnarto that by combining one type of reptilian plasma which produced haemolysis with another type which produced agglutination he could obtain a serum which produced lytic action on various micro-organisms. This serum was used in London just before the war with some apparent benefit in cases of tuberculosis, owing probably to its non-specific action in producing protein shock. Fitzsimons (1931) prepared 'venene' by blending of venoms of different species of snakes, which is said to make septic contamination impossible. This preparation has been widely used in South Africa. It is believed that alternate hypodermic and intramuscular injections of venene into the arm muscles are useful in hysteria and other nervous conditions such as neurasthenia, illusions, nervous exhaustion, asthenia, profuse and painful menstruation, chorea and paralysis. It has a lasting tonic effect on the cardiac muscles. It is said to accelerate the metabolism, soften the walls of the blood vessels and restore the circulation and nutritional processes to normal. It is believed to arrest premature senile decay. The venene treatment, however, still requires further investigation to establish its claims in therapy.

Mackenzie Wallis, W. D. Nichol, N. Craig and others have suggested the presence of an allergic element in a certain proportion of cases of epilepsy and the benefit of such as has resulted from venom treatment may well have been due to desensitization produced by its injections. In the treatment of epilepsy the venom is given in doses of 1/200 gr. by hypodermic injection, 3 to 5 injections being given at 8 days' intervals; after-

wards two more doses of 1/75 gr. are given at 14 days' intervals. If the symptoms do not disappear, another dose of 1/25 gr. is recommended. It has been advised that during treatment the administration of bromides should be discontinued. The dose and the interval of administration are to be varied according to the age of the patient and the nature of the injury. Fitzsimons pointed out that this method of treatment is not free from danger unless the venom is properly prepared by skilled hands

Asthma. Spangler (1925) used intramuscular injections of the proteins of the venom of the rattlesnake (crotalin), which contains a peptone and a globulin, for non-specific desensitization therapy in allergic asthma. An increase in the percentage of eosinophil cells, lengthening of the clotting time of the blood, increasing the permeability of the vessel walls and production of general cell and glandular stimulation are all recognised factors in the mechanism of non-specific protein reaction. He took the degree of eosinophilia produced, as a guide to dosage and frequency of administration of the proteins. Usually the highest rise in the percentage of eosinophiles following venom protein injection in doses of 1/400 to 1/50 gr. occurs by the second or third day. Within 5 to 7 days after injection, the eosinophiles will usually have dropped to 4 per cent. or less, and then the patient may be given another injection. The strength of the dose is not increased if a given strength produces an increase of 8 to 10 per cent. of eosinophiles by the second or third day after an injection. By continuing the injections the rise of eosinophiles gradually becomes less and finally does not exceed the normal limits. The patient is then non-specifically desensitized.

Uterine hæmorrhages. Peck and Goldberger (1933) treated patients suffering from functional bleeding. The venom of *Ancistrodon piscivorus* in solution of 1 in 3,000 in normal saline was used and 1 in 10,000 merthiolate was added. It is given intradermally in doses of 0.2 c.cm. and subsequent doses of 0.4 c.cm. bi-weekly; improvement occurred within 5 days to 2 to 3 weeks. In some cases six injections were given during a period of 2 to 3 weeks with the control of bleeding

anæmia also considerably improved. The treatment should be continued at least for 3 months even after the clinical improvement has manifested itself. During the first 5 to 6 injections care should be taken that the sites of injections are separated by at least 10 c.cm. ; the left arm and right thigh can be used alternately. If hypersensitivity occurs it is better to reduce the concentration of the solution to 1 in 10,000 and to continue the dose until 0.4 c.cm. of 1 in 3,000 is reached. The plan of injections to be followed is given below :—

1st injection	0.1 c.cm. of 1 in 10,000
2nd "	0.4 c.cm. of 1 in 10,000
3rd "	0.2 c.cm. of 1 in 6,000
4th "	0.3 c.cm. of 1 in 6,000
5th "	0.1 c.cm. of 1 in 3,000
6th "	0.4 c.cm. of 1 in 3,000

Antivenene also has been used by Stockton and Franklin (1931) in case of hæmorrhagic diseases. In severe cases of bleeding, where almost every kind of treatment has failed, the patient was desensitized by giving small intracutaneous injections of antivenene in doses of 0.1 to 0.2 c.cm. every half hour and when desensitization to anaphylaxis has occurred 10 c.cm. of antivenene were injected subcutaneously on the inner surface of the thigh. The bleeding is said to have stopped almost immediately.

Hæmophilia. The coagulant action of different venoms has been suggested by various workers and has been experimented on with normal human blood and citrated plasma both *in vivo* and *in vitro*. The application of this coagulant property present in snake venoms and its use in hæmophilia was suggested by Hartridge. It has been noticed that neither coagulant nor anticoagulant action is common to any large zoological group of snakes. In allied genera the venoms of some quite nearly-related species are markedly opposite in action. The only large genus in which the venom is consistently coagulant is that of vipers. The Indian daboia venom (*Vipera russellii*) was found to be by far the most powerful coagulant agent against hæmorrhages. In the case of hæmophilia it was noticed that once the coagulation started with this venom the process

of fibrin formation was completed rapidly. The clot produced was tough and elastic, in marked contradistinction to the soft slowly forming ineffective clot characteristic of hæmorrhagic diathesis. Experimentally one drop of the Russell's viper venom in concentration of 1 in 1,000 when added to 10 drops of hæmophilic blood clotted in 17 seconds, whereas the blood from the same patient clotted spontaneously in 35 minutes. In dilutions of 1 in 100,000 the coagulation time was sufficiently short, i.e., about 60 seconds and its effect was not lost even in dilutions of 1 in 10^{18} , i.e., one in million million^{million} dilution.

These dilutions or sub-minimum lethal doses, as reported by Macfarlane (1934) produced no local effects in the form of œdema, hæmorrhages, ulceration or destruction of tissues in rabbits, guinea pigs and mice when injected subcutaneously. When applied locally to the wounds in sterile solution, they did not lead to supuration.

The coagulating property rapidly deteriorates when the venom is stored in solutions even at 0°C. or when it comes in contact with carbon dioxide. The solution is best sterilised by passing it through a Berkfield filter which does not influence its activity. Use of venom as an hæmostatic agent is indicated in, (1) dental extractions, tonsillectomy and capillary oozing in abdominal operations and (2) in hæmophilia to control epistaxis and hæmorrhages from wounds. In all cases local application of 1 in 10,000 solution was without any ill effects.

Enough data are not yet available to substantiate the therapeutic claims but the clinical trials in the above diseases have been quite encouraging.

Rheumatism. Persons suffering from chronic rheumatism are said to derive great benefit after being stung by bees. Forster prepared an ointment containing bee venom for local application in this condition. Salicylic ointment is at first applied to the skin to render it more absorbent and then the ointment containing the bee venom is used. This writer treated cases of acute and chronic articular rheumatism, sciatica and neuralgia by such applications with good results. The ointment is to be applied for 8 days, the dose of the venom being gradually increased; the treatment is then stopped for 4

days and can be continued for a longer period if necessary. The action of bees' venom is increased by producing local hyperæmia. Nowotony (1933) reports that an injectable preparation of the venom under the name of *Immenin* has been prepared and has been found very useful in chronic inflammatory processes.

OTHER VENOMOUS ANIMALS

There is a large class of other lower animals which possess glands and stings and secrete toxic chemical substances which are injurious to man and higher animals. The poisonous substances are either defensive or protective measures and play an important rôle in the metabolism and growth of the individual. Even in the vegetable kingdom these defensive and protective measures are in existence.

The animal kingdom as a whole is directly or indirectly parasitic upon the plant kingdom and, therefore, plants often fall victim to the ravages of various classes of animals, particularly the herbivorous animals which live exclusively on a vegetable diet. The defence in plants is manifest in the form of thorns, spines, prickles and bristles. These are sharp-pointed structures especially developed to ward off the herbivorous animals (e.g., in the acacia and thistle). Thorns are modifications of branches which originate from the deeper tissues of the plant. They are straight and hard and pierce the body. Some plants secrete poisonous and irritant substances in form of latex, others have stinging hairs over the leaves and stems. These hairs are tipped by glands which secrete a kind of poison. When they pierce the body the hairs break at the tip just below the gland which remains in the tissues and begins to secrete the poison and causes irritation and inflammation. Other protective measures are repulsive smell, bitter taste, mimicry, etc. which are found extensively in plants.

Among the lower animals, besides snakes, scorpions, centipedes, sea anemones, insects, bees, hornets, etc., often poison man and they are described here.

1. Sea anemones. These include sea anemones, jelly fishes (*Rhizotoma pulini* and *R. cuvieri*) of European and Mediterranean waters. All these varieties possess certain specialised cells called *cnidoblasts*, i.e., little sacs which contain a spirally-coiled filament surrounded by poisonous fluid. When stimulated these cysts explode, the filament is ejected and pierces the skin and in this way introduces the poison. These sharp and fine filaments have been called stings.

Symptoms. The stings from anemones cause itching and an intense burning sensation which are the first symptoms ; rashes and even skin eruptions follow later. A papule appears at the site of contact, followed by a red, blue and then a black coloration. This may slough or an ulcer may form.

The exact nature of the chemical substance of the venom is not yet clearly worked out. Two poisonous principles named *thalassin* and *congestin* have been isolated. The latter is very toxic, whilst the former is less toxic and only locally irritant. The jelly fishes of the tropics also produce severe local reaction, e.g., redness, swelling and urticarial eruptions may occur.

The treatment consists in application of alkalies such as diluted ammonia to the affected area and giving analgesic drugs to relieve the local agonising pain. Collapse if present should be combated in the usual way.

2. Helminths. Next in zoological order come the intestinal worms, as *Dibothriocephalus latus* and *Tænia saginata*, *Ankylostoma duodenale*, *Ascaris lumbricoides* and *Tænia echinococcus*. All these secrete a form of poison which is absorbed from the gut of man and produces profound anæmia and cardiac symptoms. The treatment consists in getting rid of the helminths from the body.

3. Toads. The venom of *Bufo marinus* in whatever way it is introduced produces the same toxic effects. There is an initial phase of excitation followed by convulsions and then depression, paralysis and gradual failure of the heart and respiration. If introduced locally it produces a localised œdema and foetid gangrene. In the mucous membrane of the eyes and the nose, it produces ischæmia and anæsthesia followed by dolorous congestion and hypersecretion and even leads to panophthalmitis. The venom has a cumulative effect. If death has been quick the post-mortem examinations show visceral hæmorrhages, cardiac infarcts and pulmonary œdema.

4. Arthropoda. This class consist of scorpions, spiders, centipedes, etc.

(a) **Scorpions** These belong to the class of *Arachnida* characterised by a stout tail armed at the end with a sting. They vary a good deal in size and in their poisonous properties. The large scorpions met with in India belong to the genera *Buthus* or *Palamnæus*. The poisons of different kinds of scorpions differ quantitatively and qualitatively. The method of striking is to bring the tail which consists of the last 5 segments forward over the body so that the curved spine in its last segment of the tail penetrates into the skin of the victim. Two poison glands are situated in the last segment, and open through a duct on either side of the curved spine which is used in stinging.

The body of the scorpion is divided into a cephalothorax (*prosoma*), the broader portion of the abdomen (*mesosoma*), next followed by smaller

five segments (*metasoma*) popularly called a tail. The terminal post-anal segment (*telson*) is armed with a barb or a sting. The appendages consist of a three-jointed 'chelicerae' which are used for holding the prey, a pair of large six-jointed 'pedipalpi' for seizing the prey and four pairs of seven-jointed legs. The scorpion holds the prey with two pairs of forelimbs brings it near its mouth and if necessary stings it by inserting the tip of the telson into the animal. The scorpion's venom is a thick, oily, clear or faintly yellow coloured fluid having a specific gravity of 1.092. It is faintly acid in reaction and contains no cellular elements. It contains 28 per cent. of solid matter and on drying forms crystals. The maximum amount of venom in the glands of *Buthus tumulus* is 5.2 mgm.

It is believed by various workers that the active principle is in the form of a nucleo-protein, acid albumin or a primary protease. The poisonous action resembles that of the neurotoxin of snake venom and the hæmolytic principle is like that of viper venom. Calmette has shown that the venom of *B. occitanus* can be neutralised by cobra venom. Lecithin and cholesterin are also present in the scorpion venom, and it can be digested by pepsin and trypsin and can be oxidised by permanganate of potash and calcium hypochlorite.

The M. L. D. of the venom for white mice of average size is 0.05 mgm. and for rabbits 0.5 mgm. The dog, the rabbit and the guinea-pig are more sensitive than the mouse or birds. The frog is more resistant than mammals. The palamænus venom is far less toxic than *buthus* venom.

The venom in the scorpion is not only a means of defence, but is also used to kill its prey. The venom is only toxic when injected subcutaneously or intravenously and has no ill effects if taken by the mouth. The scorpion venom is said to resemble closely the snake venom in action. The venom paralyses the nervous system and death in animals is due to the curare-like action on the nerve end-plates especially of the muscles of the respiratory system. It produces coagulation of blood, hæmorrhages due to injury of the capillary walls and leads to formation of emboli due to agglutination of the red blood corpuscles. It increases the lachrymal, nasal, salivary, laryngeal and tracheal secretions due to its action on the vagal and spinal centres. On the intestines it acts like pilocarpine and by increasing peristalsis it produces vomiting and purging. The venom is rarely fatal in man and is not any more dangerous than the bee or wasp venom.

In man the symptoms of the bite are redness, swelling, intense burning pain radiating from the site. This is followed by weak pulse, quick and hurried respiration, convulsions, mental disturbances, hallucinations, marked salivation and lachrymation, and profuse sweating and polyuria; abortion may occur in pregnant women. The nervous system becomes highly irritable, reflexes are increased,

tremors, muscular twitchings and spasmodic movements later followed by paresis or paralysis of the individual muscles may occur. There may be a locomotor paralysis, nystagmus and blindness. The sting is rarely fatal in adults, but it is not infrequently fatal to children. The sting of *B. quinquestriatus* is fatal in 60 per cent. of children under five years of age.

TREATMENT. The principles that guide the treatment of snake bite apply in general to that of scorpion sting. A proximal ligature, incision of the wound and sucking out of the venom and application of potassium permanganate are useful as in the case of snake bite. If possible immediate injection of immune horse serum will be very efficacious. Washing and bathing of the part with weak solution of ammonia or borax, and local injection of colloidal manganese may be tried. Five to ten min. of a 5 per cent. solution of cocaine subcutaneously in adults and 1 to 5 min. in children around the site of the wound help in relieving the pain. Eucain and stovaine may be conveniently substituted. Tyrosin and juice of dahlia are said to have a neutralising action on the venom. Buchmann considers local injections of 1 per cent solution of tocain in 2 cm doses, given subcutaneously, to be a good remedy.

Antiscorpion serum. Metchnikoff (1901) observed that the blood of the scorpion is distinctly antitoxic against the scorpion venom. Todd (1909) prepared an antiserum from the Egyptian scorpion and showed that it acted both prophylactically and curatively in animals and in man. Employed curatively it relieved the intense pain of scorpion bite. Antivenene against scorpion sting is prepared at the Butantan Institute in Brazil, in the Pasteur Institute in Algiers, the Lister Institute, Elstree, England and the Behring Institute in Germany. The scorpion serum is not prepared in India for there appears to be no necessity for it. The antivenene prepared at Kasauli (India) against cobra and daboia venom imparts a certain amount of protection in rabbits and dogs which have received a lethal dose of the venom of *B. tumulus* and *Palamnaeus swammerdami*. None of the Indian plants recommended for the treatment of scorpion sting in indigenous medicine was found by Cain and Mhaskar to have any preventive or antidotal effect. Lately, Sergeant and Sergeant (1934) have noticed that the venom of Algerian bees (*Apis mellifica*) has some immunising power against the scorpion venom (*Buteus occitanus*).

(b) **Spiders.** This group is called *Aranea*. The spiders are found all over the world, but by far the largest ones are met with in the tropics. The species having the spinning organ just in front of the anus and having no tegral plates visible are interesting from our point of view. This variety is called *Opisthothelae*. These are further divided into two tribes as *Megalomorphae* and *Arachnomorphae* depending on the site of the spinning organs. There is a great deal of misconception regarding the bites of spiders. The common spiders usually do not bite

but when they do bite the bites amount to no more than a pinprick. In California, Brazil, South Russia and Australia toxic and even lethal effects in man and animals from the bites of poisonous spiders have been recorded.

Medical text books devote very little attention to the spider bites. But the bite of the 'black widow' (*Latrodectus mactans*) is quite serious and may even prove fatal. The venom of the venomous spiders resembles that of the scorpion in appearance and action. It is a thick, oily, translucent, lemon-yellow coloured fluid, slightly acid in reaction and is bitter in taste. It dries at 37°C. forming a light yellow powder. Kobert and Sachs have found a *haemolysin* and an *arachnolysin* in the several types of spiders. The *arachnolysin* acts upon the erythrocytes in man, rabbits, ox, mouse and goose, but not on those of the horse, dog, sheep and guinea-pig; 0.5 mgm. of the venom when given intravenously causes death in guinea-pigs of 600 gm. weight in less than two hours. Bogen succeeded in immunising rabbits by the administration of graduated doses of the venom. The venom has injurious effects on the isolated heart of the frog, and the capillaries are injured; this leads to marked transudation of fluid and oedema. The venom acts on the central nervous system producing cramps and convulsions. Locally, inflammation is followed by dry necrosis of the skin. There is severe pain at the site of the bite followed by radiating pain and swelling in the whole limb; sweating, palpitation and rise of temperature are present. In the case of Corsican scorpions (*L. tridectinguttalus*) erection of the penis and anuria occur very frequently. Later, an eruption may occur which consists of a general invasion by red lenticular spots, non-confluent and not disappearing on pressure. Bronchial constriction plays an important part in determining the fatal issue.

TREATMENT. The main effort should be to prevent the absorption of the poison by application of a ligature and to open the wound and wash it with a solution of permanganate of potash, or an alkaline solution such as a weak solution of ammonia or carbonate of potassium may be used. If the bite is not of a serious type the parts may be kept covered with a dressing soaked in a solution of ammonia and water or with permanganate of potash. In the case of the bite of Bengal spiders, Fink recommends the exposure of the bitten area to the smoke evolved from lumps of mustard oil cakes, burned on a charcoal fire and dropped into a basin of cold water. De Asis Cesareo (1934) has used intravenous injection of a 25 per cent. magnesium sulphate solution with marked benefit in the case of the 'Red back' spider of the Philippines, which is sometimes fatal. This venom has a special predilection for the peripheral nerves and nerve end-organs. Other symptoms produced are elevated blood pressure, weak pulse, general weakness and numbness, muscular pain and paralysis of the lower limbs. Brazil and Vellard have prepared a bivalent antivenene by immunising sheep and have demonstrated its therapeutic efficacy in man; rapid improvement follows its use. The

spider antivenene, in common with those derived from snakes and scorpions, is highly specific.

(c) *Ticks (Acarina)*. These are well known to cause severe symptoms by their bites apart from the introduction of parasites such as *Piroplasma* or *Spirochæta*. The ticks pierce the skin by means of their teeth on the digits of their chelicerae. The bite causes itching or severe pain, fever, lassitude, even delirium and convulsion. Death occurs in rare cases.

The properties of the venom are comparable with those of other arachnid venoms. When introduced into the dog, rabbit, guinea-pig, rat and mouse, it produces progressive motor paralysis. It is important not to remove the tick forcibly, as the mouth parts are thus broken off and remain in the skin. If in removing the tick, the parts of the jaw remain in the skin, there is a possibility of infection which may lead to sloughing of the surrounding tissues. The first thing therefore to do is to detach the tick which is by no means easy as the curved teeth hold on the wound very firmly. The best plan is to rub any bland oil on the ventral surface of the tick. This interferes with its respiration *stigmata* and compels the tick to loosen its hold and it drops off in a minute or two, or it may be removed by excising a small piece of skin at the site of its attachment.

The bitten area should be bathed with very hot water, and then a concentrated solution of bicarbonate of soda may be applied. A 1 to 2 per cent. ointment of menthol may be rubbed in locally to allay the intense itching. Huts infected with ticks should be burnt down or fumigated with sulphur, carbon disulphide or sprayed with kerosene oil and hot water. The feet of beds should be placed in cups containing water and kerosene oil, and the coverings of the bed may be dusted with pyrethrum powder or camphor powder.

(d) *Centipedes (Chilopoda)*. Centipedes are common all over the world, but the tropical species are much larger than those found in the temperate zone. The poison apparatus is formed by the appendages of the first trunk segment, which is modified to form a large pair of jaws and at the base of this the poison gland is placed. The duct of this gland opens on the apex of the claw and there are two jaws; a centipede bite will show two minute punctures or drops of blood. As the legs have no poison glands it is difficult to account for the frequently reported cases in which the centipede in travelling over the skin has left an urticarial trail. It is possible that some of these cases have been cases of caterpillar sting.

The venom resembles scorpion venom and is primarily intended to kill the prey which consists of small insects and larvæ. It is an opalescent liquid, acid in reaction, and miscible with water. A solution injected into the rabbit's ear vein produces immediate paralysis and coagulation of blood.

The symptoms are those of itching, intense pain extending along the whole limb followed by lymphangitis and lymph adenitis. The

bitten spot becomes red and swollen and finally black. There may be great mental anxiety, vomiting, irregular pulse, dizziness and headache.

Treatment is the same as in the case of other poisonous insects. The swelling may be reduced by applying an ice bag. It may be necessary to inject morphia to relieve pain.

(c) **Bees (*Apidae*)**. Stinging from bees is not infrequent in man, and in the tropics people are often severely bitten by bees and suffer very much, though occurrence of death is rare. Bees belong to the order of *Hymenoptera* which also includes wasps, hornets and ants. Bees are very common in India particularly the hive bee (*Apis mellifica*); the wasp (*Vespa vulgaris*) and the hornet (*V. orientalis* or *V. crabo*) are also met with everywhere.

The venom of bees has been studied by Brandt and Ratzeburg (1839), Paul Bert (1865), Carlet (1884), Josef and Langer (1897) and Phisalix (1904) and others. The body of the bee is divided into head, thorax and abdomen from the posterior end of the last of which projects the sting in the form of a chitinous sheath, narrow posteriorly and wide anteriorly. There are two, sometimes three, poison glands in the abdomen which open into a sheath round about the sting. The sting consists of a central shaft and a pair of barbed darts.

The bee venom is a transparent acid fluid, bitter in taste, aromatic in smell and has a specific gravity of 1.1313. The acid reaction is due to formic acid, but it is not the active principle, and the properties of the venom, as was formerly believed, do not depend upon it. The venom resembles cobra venom in containing substances which produce local inflammation, substances which act on the nervous system and substances which produce hæmolysis. Intravenous injections of the venom into dogs and rabbits produce tremors, convulsions, nystagmus, emprosthotonos and death from respiratory failure. The action of the venom is probably both on the nervous system due to neurotoxin, and also on the blood as it produces marked hæmorrhages in the visceral organs. Injected into human skin it causes a reaction identical with that caused by diluted rattle snake venom and by histamine. A case is on record when a girl of 7 bitten by a bee developed a violent explosion of hay fever which was controlled by ephedrine. The child had otherwise no susceptibility to hay fever.

The symptoms from the bite are pain, redness and swelling of the area which disappear after a few hours. Suppuration and blood poisoning are rare complications. In weak and old people there may be constitutional symptoms such as nausea, faintness, vomiting, difficulty in breathing and eruption on the skin. In cases of multiple stings or in stings of some of the hornets there may be considerable constitutional disturbances amounting even to collapse. Later, there may be slight fever, cedema, urticaria or macular eruptions on different parts of the body. It may lead to partial loss of consciousness. There

may be cold and clammy sweating, irregular and weak hardly perceptible pulse and signs of shock. All the apidae may cause severe symptoms if the bites are extensive and particularly on spots like the eyes, ears, and lips or in very old people and young children.

Treatment. In the case of the honey bee, the sting, with the poison glands attached, is frequently left in the wound, but in the case of other bees, wasps and hornets, the sting is not left in the wound. If the sting is left in the wound it should be removed by lifting it out with a knife so as to avoid squeezing out any more venom into the wound. Hot applications are of great value. The usual applications of alkalis, solution of ammonia, carbolic acid (1 in 20 or 1 in 10) if applied immediately on the stings, bring satisfactory results. Potassium permanganate may be tried. Calcium hypochlorite (1 in 60), ice compresses or ice bags are also useful.

Insects, wasps, beetles, etc., also give troublesome pain. The treatment in all these cases is almost the same as mentioned above.

(f) *Ants (Formicidae).* In the tropics the bites of some of the large ants are very painful and may cause faintness, shivering and at times temporary paralysis. Ordinarily the bite of an ant amounts to no more than a sharp stinging possibly with the development of a wheal at the site of bite. The venom contains formic acid, but from the severe effects of the bites of some of the tropical species it appears that the venom must contain other toxic substances as well. The treatment consists of bathing the bitten parts with dilute solution of ammonia. Ants can be kept out of beds by placing the legs of the bed in cans filled with water with a layer of oil on the top (to prevent mosquito breeding) or by sprinkling powdered camphor between the sheets.

CHAPTER V

DRUG ADDICTION AND ITS TREATMENT

From time immemorial mankind has tried to attain degrees of emotional intensity and duration, which are otherwise unknown to the brain. It took recourse to consuming substances of no nutritive value, solely for the purpose of exciting the function of brain centres which transmit agreeable sensations and to maintain for sometime the consciousness of experienced emotion. The habitual use of alcoholic beverages and certain vegetable substances for stimulative and restorative purposes has thus gained a strong foot-hold in the daily life of human beings all the world over. The earliest records available show that opium and certain other narcotic drugs, *e.g.*, mandragora, hyoscyamus, hemlock and others are amongst those commonly used.

Addiction to drugs is met with all over the world. The inducements which bring about the first recourse to the use of a narcotic drug are varied. Some take them out of curiosity while others from a deliberate intention to experience a pleasant though temporary change in the mental state. It has been stated that prolonged use of certain drugs taken during illness as medicines has also claimed its victim in certain cases. Such patients, overcome by their influence, become habitual drug takers. The drugs used vary in their action, some of them being stimulating, others depressing ; each of them gives to its devotees a certain measure of comfort and pleasure tending in a curious and inexplicable way to create a craving for more of the drug and in a greater or less degree gives rise to drug habit. With many there are no ill-effects, but the habitual use of opium, morphine, alcohol, cocaine, etc., leads to grave moral and physical degradation and the difficulty of breaking the habit has to be faced. Addicts are recognised as persons who, not requiring continued use of a drug for relief of symptoms of organic diseases, have acquired, as a result of repeated administrations, an overpowering desire for its continuance and in whom with-

drawal of the drug leads to definite symptoms of mental or physical distress or disorder. Addiction thus becomes a disease which necessitates proper treatment.

Influence of the climate and other factors lead to habitual use of drugs in the tropics and in countries like India the physician has often to face the problem of treating drug addicts. It was, therefore, thought necessary to introduce the subject in this work.

Drug addiction in India. The problem of drug addiction in India presents many features which are widely different from those met with in the Western countries and about which a great deal of misapprehension exists in Europe and America. The habitual use of drugs of a stimulative and restorative character was prevalent in India probably long before it was in any of the other countries of the modern world. The juice of the *Soma* plant was a favourite drink of the Aryan settlers and was regularly taken by them many centuries before the Christian era. What exactly was the *Soma* plant is not known, though a number of plants such as *Cannabis sativa*, *Ephedra vulgaris*, *Asclepias acida*, have been implicated. During the Hindu period, i.e., up to the 8th or 9th century A. D., alcoholic beverages were used by the people as well as the preparations made from hemp drugs. These produced not only a sedative effect, but also brought about euphoria in the form of pleasant dreams, forgetfulness and, it would also appear from the writings of that period, voluptuous satisfaction. Opium and poppy were introduced on the west coast about the 9th century A. D. by the advent of the Mohammedan traders, and opiates soon came into use. A study of records shows that during the period of the Moghul Empire, alcoholic beverages, opiates and hemp drugs were freely used. A decoction made from poppy capsules known as 'koknar' was extensively used all over India, and is used to the present day in parts of the Punjab. A beverage containing wine, opium, Indian hemp and poppy capsules, known as 'charbargha' (four-leaved) was drunk by the well-to-do classes in the time of Akbar (1556 to 1605) and later. Opium on account of its stronger effects appears to have taken a great hold of the people and poppy was extensively cultivated all over the country during this period and was indulged in by all classes.

Opium. *Opium eating and smoking.* Most of the raw opium sold in this country is used for addiction purposes in one form or another. It is generally consumed in the form of a pill or solution in water. Opium smoking although not common is still practised by the lower strata of the society in many parts of the country. It is common in Assam and in certain parts of the Central Provinces and Berar. The proportion of opium smokers to opium eaters in Assam has been variously estimated from one third to one half of the total addicts but our recent enquiries

show that the number has now come down to a quarter. The government of India and all the provincial governments have adopted the policy of checking opium smoking by diminishing the facilities for the practice of the habit through legislation. These measures have succeeded to a great extent and as a result of this the habit has greatly declined.

Although opium is habitually used by large sections of the population at the present time, the indulgence is not so widely prevalent as might be imagined from some of the recent publications on the subject. The Government of India have strictly adhered to their promise to the League of Nations and have progressively reduced both the production and consumption of opium. It has been shown that although if the country is taken as a whole the consumption of opium is low, in certain parts it is very high. For example, in Bengal Presidency taken as a whole, the consumption per 10,000 of population is 8 seers per annum, instead of 6 seers as required for the medical and scientific needs. In the town of Calcutta it is 58 seers, in Hooghly district 21 seers, Howrah 16 seers and 24 Perganas 15 seers. In the Madras Presidency as a whole it is 8 seers, but for East Godavari and West Godavari it is 37 and 22 seers respectively. For the Punjab as a whole it is 12 seers, but for Ferozepore district 33 seers, Lahore 34 seers, Ludhiana 25 seers, Amritsar 30 seers. In the whole of the Central Provinces and Berar it is 9.0 seers, but in Amraoti it is 40 seers, Akola 50 seers and in Balaghat 30 seers. In Assam as a whole it is 19 seers, but in Lakhimpore it is 70, Sibsagar 45, Nowgong 27, Darrang 22 and Kamrup 8.9 seers. The highest consumption recorded in India is in Sadya frontier tract, being 94 seers. The higher figures are due to smoking of the drug, which necessitates a much higher consumption per head. On the other hand, there are extensive areas in all provinces where consumption is very low, i.e., 1 to 5 seers per 10,000 of population per annum. Such areas are now on the increase. In Assam, Goalpara and Sylhet are examples of such places. In the Punjab there are 20 out of 29 districts where the consumption is below the standard laid down by the League of Nations, as being necessary for purely medical and scientific needs of the population, i.e., 6 seers or 12 pounds per 10,000 of population per annum.

It will thus be seen that the habit is not widely disseminated among the population, its incidence among various classes is very irregular and although there are admittedly certain areas and certain classes of population which are badly affected, there is evidence to show that in many parts of India the consumption of opium is below the standard laid down by the League of Nations. These areas with high consumption rate are being investigated with a view to determining the causes which have led to increased consumption and steps are being taken to put down excessive use. This is evident from the following table.

Year.	Consumption of opium in seers in British India (excluding Indian States).			
1912-13	5,06,664
1930-31	2,41,211
1931-32	2,13,000

N.B.—1 seer is approximately equal to 2 pounds.

The average dose taken in the writer's recent series of over a thousand cases was roughly 10 gr. daily per addict as compared with 20 gr. worked out by the Opium Commission of 1895. The problem of addiction to opiates in this country, although it is still very extensive, does not appear to exist in such intense and pernicious form as it does in the West with morphine and other alkaloids of opium. It may be stated here that in old days, when opium was cheap, addicts were undoubtedly found who took 180 to 500 grains of the drug daily. The writer in recent years has met with only a few individuals who took more than 50 gr. daily; many of the old addicts however take more than 15 gr. daily. The chief reason for smaller dosage is that the price of opium has risen enormously. Whereas during the pre-British period, in the Punjab, opium used to sell at 2 to 3 annas (2 or 3 pence) per 'tola' (180 gr. or 12 gm.), in 1901-02 it cost 8 annas for the same amount and in 1929-30 Re. 1-12-0 (2 shillings).

Administration of opium to infants. Habitual administration of opium to infants at certain periods of their life has been prevalent in India for many centuries. The habit appears to have been started because of the drug's power of allaying diarrhoea and vomiting, relieving cough and pain, and producing sleep. The custom, although it is still met with in almost every part of India, has greatly declined during the last two or three decades. The drug, however, is still extensively employed in the Central Provinces and Berar and in the industrial areas in all parts of India. In Berar it is stated that 75 per cent. of the infants are doped with opium and 25 per cent. of the total opium consumed goes to infants. The consumption is still higher in the cotton-growing areas where children account for 40 per cent. of the total consumption. The main reason for administering the drug is economic, the drug being given to keep the children quiet so as to allow the mother to carry out her work, whether in the factory or the field, unhampered. The practice is begun during the first few weeks of the infant's life, the earliest time to commence being 3 weeks and the latest period 3 months. The drug is usually discontinued when the child attains the age of 2 or 3 years, that is when it begins to play about and can live on ordinary food. The dose varies from one eighth to three grains daily. The drug affects the child's health adversely and hinders growth. The children receiving opium have an emaciated, unhealthy and toxæmic appearance.

They are more liable to catch infections and attacks of epidemic diseases and the mortality rate among them is comparatively high. Although deaths from overdosage are not frequent they do occur. Non-fatal overdosage is not uncommon.

Addiction to 'post' (unlanced capsules of *Papaver somniferum*). The poppy capsules are known to have been used for their soporific properties by the ancient Egyptians, Greeks and Romans. For many centuries they have been used in the Chinese, Hindu and Mohammedan medicine as sedative in inflammatory diseases of the alimentary and respiratory tracts. During the 16th, 17th and 18th centuries when the Moghuls were in power in India, the capsules were extensively used to prepare a beverage which had soothing and euphoric effects and which was almost universally indulged in. The habitual use of poppy capsules for euphoric purposes has considerably decreased during the last three decades but the addiction is still prevalent in certain districts of the Punjab, and in many parts of the Rajputana states, especially Jaipur. The present writer after a careful study of over 500 addicts has come to the conclusion that habitual use of poppy heads produces physical, mental and moral degeneration in the habitue. As compared with the opium habits its effects on the individual are much more pronounced.

Addiction to opium alkaloids. Habitual use of morphine has considerably increased in India during recent years, the increase at present being confined to Northern India. There appears to be grave danger of rapid extension of this habit to other parts if steps are not taken to check it. Morphine addiction among Indians is usually met with in young persons between the ages of 20 and 25 years. The habit is not started for the sedative and analgesic effects of the drug as in Western countries, but for its euphoric effects and because of its supposed aphrodisiac properties. Formerly the alkaloid was taken almost exclusively by the mouth, but recently the injection method is coming into use. By this latter method, the effects produced by the drug on Indians are very similar to those produced by cocaine. The habit produces a state of chronic toxæmia and detrimentally affects all tissues of the body particularly the nervous tissues. In morphine habitues the physical, mental and moral deterioration sets in much more rapidly than in opium addicts. Addiction to other alkaloids of opium, e.g., codeine, heroine, is very rarely met with in this country.

Indian hemp. It grows wild in the montane and submontane tracts over the whole of north-eastern and north-western parts of India and three of its preparations, i.e., *bhang* (dried leaves), *charas* (resinous exudate) and *ganja* (flowering tops) were largely used by the poorer classes on account of their very low cost. Even to the present day hemp drugs are the narcotics extensively employed by the poorer classes throughout the country. Extensive work in the field has enabled the writer to estimate approximately the prevalence of hemp drug addiction in India.

and taking the country as a whole the incidence of addiction in British India ranges between 0.4 to 0.8 per cent. of the population. In Southern India, where the spontaneous growth of *Cannabis sativa* does not occur, hemp was and is still cultivated for use as a drug of addiction. The physical effects produced by these drug habits are not so marked as those of opium but they undoubtedly lead to physical, mental and moral degeneration. When under the effect of these drugs, the addicts appear to lose all idea of correlation of time and space. They forget their environments and do not know what they are doing. *Ganja* and *charas* are much more potent in this respect than *bhanga* and their excessive consumption, especially of the latter, gives rise to insanity and leads to crime. This was one of the points discussed by the Hemp Drugs Commission, but no definite conclusions could be arrived at.

Alcohol. The use of distilled alcoholic liquors has extended during the early part of this century but has reduced lately. In old days distilled liquors were used to a very limited extent; wines were largely used. The aboriginal races of India made a beverage by fermenting rice—*pachwai*—and by fermenting palm juice—*tari*. Both these are extensively used in many parts of India to the present day. The main fluid that is habitually drunk by the Nagas of Assam Hills (Manipur State) is a weak country beer called *zu*. It has been shown that the alcoholic content of the majority of the crude beers used in India is low and their nutritive value is very high. Some of these beers are rich in vitamins which are often poor in the dietary of the people who drink them. The areas where such beers are consumed are remarkably free from deficiency diseases. Distilled country liquors and foreign liquors are used by the richer classes to a comparatively lesser extent. The drinking of youth and the social drinking in the endeavour to mitigate the wear and tear of life and to get relief from its annoying factors, as it exists in the West, is not commonly found among Indians. Extensive habitual use of alcohol is uncommon and the harmful effects produced by it are rarely encountered. The problem of alcoholism has not up to the present time assumed a serious aspect in this country. It may however be pointed out that the use of distilled country liquors is increasing in certain areas and in many parts of India drunkenness is being more frequently met with among the masses. This is due to the fact that while restrictions are being imposed on the sale of opium and hemp drugs their price has risen owing to increase of excise duty, but in spite of the high excise duty a bottle of distilled liquor can be purchased for a few annas. Country liquors in many parts are taking the place of opium and hemp drugs.

Cocaine. The present writer (1931) has shown that cocaine came into use quite accidentally about 50 years ago. In spite of all the restrictions imposed on the import, possession and sale of the drug, the

habit has spread from Calcutta to large towns along the two main railway routes through the Central Provinces into the Punjab and the North-West Frontier Province. From Bombay it spread to some of the large towns in that presidency. Cocaine is not manufactured in India but is smuggled into the country in large quantities. For some time past the Far East has driven the European and American manufactured product out of the market. The drug is illicitly brought by crews of ships running between Calcutta and the Far East and is heavily adulterated before it is sold. Cocaine is usually taken in the form of an injection or as a snuff in Western countries, but at present practically the only method of taking the drug in India is by the mouth. It is commonly consumed by putting it in *pan* or betel leaf and for that reason addiction to this alkaloid is prevalent among the betel-leaf chewing population of North-West India, Bengal, Bihar, the United Provinces and the Punjab. The habit not only exists among the well-to-do people but a large number of the artisan class in large towns are also addicted to it. It has been calculated by competent authorities that over 200,000 ounces of cocaine were smuggled into India in 1929 and that the consumers paid between Rs. 270 lakhs and Rs. 648 lakhs to the retailers for their doses of the drug. The symptoms and effects produced by it were studied in 200 cases (1931).

New drug habits. During the last few years chloral hydrate as a drug of addiction has also made its appearance in Northern India. It has come into use since the price of spirituous drinks has gone up considerably on account of the increased excise duty. Many of those that drink alcohol habitually in India do not take it merely to obtain mild excitement or sedative effects, as is usually the case in the West, but to obtain intoxicating effects. Owing to increase in the price of liquor they cannot afford to buy sufficient quantities for this purpose and the ingenious idea of potentiating the effects by adding small quantities of chloral hydrate (0.5 to 1.0 gm.) has occurred to them. The drug is sometimes mixed with tea and is habitually consumed by some people. Chloral habit has thus sprung up though fortunately a very limited area is affected at present. The drug is powerful and toxic and several fatalities have been reported from accidental overdoses. Chloral hydrate is a cheap product selling at about Re. 1-12-0 per pound, and as there are no restrictions to its sale at the present time it can be bought by any one in any quantity from the chemists shop. Half to one gramme or a little more added to an alcoholic drink produces symptoms of intoxication followed by sleep. The habit is harmful and dangerous. It is much more liable to produce pathological changes in the organs and immediate fatal results than any other drug of addiction in this country. The mental, moral and physical effects produced by this addiction are more pronounced than any other drug habit. The drug is cheap and is easily procurable as there is no control over its sale and these factors are largely responsible

for the spread of its use among the population in certain localities. There is a danger in the use of chloral hydrate for adulteration of alcoholic beverages (toddy, rice-beer, etc.) being extended and of the further spread of chloral habit.

Barbituric acid derivatives. A number of fatalities resulting from indiscriminate therapeutic use and self medication with these drugs have occurred and a few cases of addiction have also been observed among the educated classes in India. The fact that besides the toxic effects produced by massive doses, the barbiturates also produce dangerous cumulative effects and a tendency to habit formation has not been sufficiently appreciated by the medical practitioners in this country. A warning is therefore necessary. The need for bringing the sale of drugs like chloral hydrate, butyl chloral, paraldehyde, sulphonal, bromural and barbituric acid derivatives under a more strict control is very urgent.

Briefly then the principal habit-forming drugs used in India are :—

I. Opium is still extensively used both by adults and infants. *Post* or *koknar* (unlanced capsules of *Papaver somniferum*) were largely used at one time, but owing to restrictions in the cultivation of the poppy, that use is now limited to a small area in Northern India. The use of morphine, though uncommon, is gradually increasing.

II. Hemp drugs. *Bhang* (dried leaves), *charas* (oleo-resinous exudation) and *ganja* (dried flowering tops coated with resin) are extensively used all over the country by the lower strata of society on account of their very low cost.

III. Alcohol. *Pachwai* (fermented rice) and *tari* (fermented palm juice) are largely used by poorer classes. Distilled country spirit and imported liquors are used by the richer classes.

IV. Cocaine was introduced fifty years ago; its use is spreading in Northern India.

V. Chloral hydrate has been introduced during the last 10 years; barbituric acid derivatives are being tried. The use of these drugs at present is limited; but there is danger of their extension for adulteration of alcoholic beverages.

Ætiological factors. It will be observed from the fore-going that the first three groups of drugs which are commonly used in India, are mostly raw and crude products. In many cases they have to be prepared by the addict himself before use, which in itself limits their excessive consumption. Further by the use of crude products the addicts absorb comparatively smaller quantities of the active principles which are responsible for producing the toxic effects. In Western countries almost all the drugs used for addiction purposes are highly purified products such as morphine, heroin and cocaine. Moreover many of these drugs in the West are taken in the form of injections. This method brings about the action more quickly and more intensely. At the same time the action is not so lasting as when the drug is taken by the mouth. All these factors lead to a greater desire or craving on the part of the

addict for more frequent repetition of the dose and the habit is liable to be carried to excess and the addict to become a danger not only to himself but to the society. In India most of the common drugs of addiction are taken by the mouth and being crude products never produce such intense effects as are observed in Western countries. A large number of addicts from the lower strata of society are so poor that they have not the means to carry the indulgence of even the crude and cheap drugs to an excess; the upper classes are temperamentally moderate. Besides India is pre-eminently an agricultural country which makes it possible for the majority of its inhabitants to lead a comparatively free and easy existence. The strain and stress of life which drive people to the habitual use of sedative drugs are not so great as in the West.

In spite of all these factors the problem of drug addiction is of very great importance from its extensiveness. The magnitude of the problem can be judged by the fact that whereas in most of the countries in Europe and America the addiction rate of the population is from 0.1 to 0.2 per cent. or even less, in many parts of India the rate is 1 to 3 per cent. or even more. These drug habits are responsible not only for much economic loss but also lead to physical and mental deterioration and are of very great importance from a health point of view.

Another noteworthy feature of drug addiction in India, especially so far as opium and hemp drugs are concerned, is the religious and social aspects of the problem. Indulgence in opium, on account of age-long usage and custom, is sometimes compulsory on such occasions as marriages, deaths and social gatherings among certain classes. Hemp drugs are considered to be food of the gods and are offered in temples on religious festivals and ceremonial occasions. Some religious sects take these drugs under the belief that they help the individuals indulging in them in freeing his mind from the worldly attractions and in this way concentrate on the deity. This is the reason why in places of religious worship like Benares, Muthra, Puri, etc., there is an enormous consumption of these drugs. Such use of these drugs is, however, rapidly decreasing.

The medical and semi-medical uses of opium and hemp drugs are other important factors. In a vast country like India, where the facilities of medical relief are poor, the majority of the population do not get the benefit of Western medical science. The sedative drugs such as opium and hemp preparations are largely used as household remedies and habits are often formed from such use. The doping of infants with opium can partly be attributed to this. It is still firmly believed by the masses of ignorant classes that opium is a wonderful tonic to the child, it stimulates his growth and prevents the child getting sick. The writer has fully discussed elsewhere the medical and semi-medical uses of opium and the large variety of conditions for which it is used as a household remedy. Almost all the diseases for the relief of which opium and hemp

drugs are used are of minor character. Often the drugs are taken to dry secretions from the conjunctiva and the respiratory tract. Many people suffer from toxæmias of focal sepsis, pains of rheumatic and neuralgic type, mental depression, irritability and hypersensitiveness of the nervous system. These drugs in small doses give them relief and lead to the drug habit.

Treatment of Drug Addiction

The importance of prophylactic measures in preventing drug addiction is appreciated by the medical profession and habit-producing drugs are used with great care. Every physician who treats drug addiction should keep in view that prevention is better than cure. Restriction on the production and sale of the narcotics by the State authorities will not suffice and efforts directed merely towards the suppression of the demand for narcotics are apt to fail. Medical men have been unwittingly responsible in starting addiction in a large number of cases. Every practitioner should see that nobody becomes an addict through his fault and great care should be exercised when selecting hypnotic and analgesic drugs.

It is possible that the abuses of narcotic drugs may be avoided or prevented by giving consideration to the possibility of substituting non-habit-forming drugs whenever possible. When the use of habit-forming drugs is essential, however, care should be taken not to give larger and more frequent doses than are absolutely necessary to achieve the desired end. Patients requiring daily administration of habit-forming drugs should be frequently seen by the practitioner and the amount of drugs ordered or supplied should not exceed that required by the patient. The changes in treatment should be in writing and administration on the part of nurses and other hospital staff should be limited. The patients should not be informed of the name or dose of the drug administered and hypodermic injections should be avoided as far as possible and never self-administered. The use of these drugs should be discontinued immediately when no longer required and if craving has resulted close supervision and appropriate treatment should be maintained until patient is rendered free from the desire.

Treatment of established habit. The true nature of drug addiction and the rationale of its treatment should be thoroughly understood by the physician in charge of the case. The personality of the physician is very important and the patient should be handled very cautiously. The physician should consider an addict as a sick person and not a vicious person with bad morals. Drug addiction is a disease and must be treated as a disease. There is however no specific treatment for drug addiction that will miraculously operate to rid the addicts of their malady. Every possible detail should be studied about the patient's habit so that he may be more accessible to physical and psychotherapeutic treatment. It should be impressed on the patient that he can readily overcome the disease by resolution, patience and self-control. The harsher methods generally fail. The necessity of rest in bed, proper action of the bowels and stimulation of the functions of the kidney and skin are some of the important factors which should not be forgotten before starting the treatment even at the expense of some delay. In addition to the poisonous effect of the drug every addict has to contend with an alimentary toxæmia (of endogenous nature) which is the result of his disordered metabolism. In cases where the treatment is compulsory and in the case of jail patients care should be taken that the addict does not get a secret supply by some underhand means. Other important points to be remembered while treating a drug addict are that the name and dose of the narcotic, if administered out of necessity, should be kept secret. The word 'cure' should not imply merely getting the patient rid of the drug temporarily or permanently by gradual or sudden deprivation of the drug but it should imply his return as far as possible to somatic and psychic integrity, and this desirable state of health is difficult to obtain.

The treatment of drug addiction and especially addiction to opiates can be divided into two phases, involving first the detoxication or physical rehabilitation stage, secondly the emotional stabilisation and re-educational phase.

Detoxication or physical rehabilitation stage. By detoxication or physical rehabilitation is meant the withdrawal

of the drug either suddenly or gradually followed by measures to improve his general health. Various methods to effect detoxication have been discussed by Adams in his review on the treatment of drug addiction. The following methods of withdrawal are in vogue.

I. *The Ambulatory method* is most suitable from the ordinary practitioner's point of view. The patient is free to go about but receives from the doctor or under his instructions such quantities of the drug as are absolutely necessary. The object is to gradually reduce the amount of the drug so that it can either be reduced to a minimum or be completely withdrawn without the least possible discomfort. This method is very popular in India and is often self-practised by the wiser class of opium and alcohol addicts.

II. *Sudden withdrawal method* was at first tried in Germany by Levinstein in 1875. The method consists of withdrawing the drugs from the beginning. The procedure is a very severe and drastic one and has been mostly given up, but it has still some advocates in the United States and in Europe, who favour it with the argument that there is a large psychic element in addition to the physical conditions in the production of the withdrawal symptoms. If the patient is made confident that he is not going to have any more of the drug he will not suffer from such severe symptoms as anticipated. Hence they consider this method quite safe. Scalesh and Kuh (1934) treated 5,000 cases in U. S. A. by this method without any serious withdrawal or asthenic symptoms and had no death.

The Ministry of Health of Great Britain, Departmental Committee on morphine and heroine addiction (1926) after going through all the different methods came to the conclusion that the sudden and rapid withdrawal methods were not satisfactory on the whole because they were only applicable in the case of young and healthy addicts and those who had not been addicts for long periods. They were sometimes dangerous and the permanent results of the sudden method were bad and there was a strong tendency to relapse.

(a) *Sudden withdrawal without special measures.* In its simplest form it means complete cessation of the addicts's ration from the beginning and confinement of the patient to bed under the care of a

skilful nurse. The bowels should be working properly but drastic purgatives should be avoided. Diarrhoea and sickness are treated on general lines. In-omnia is met by simple hypnotics like bromides and paraldehyde. For collapse cardiac tonics like strychnine, digitalin and cardiazol are given. In cases where there is actual danger to the life of the patient give small doses of morphine. For detailed information of this method the reader is referred to the work of Richards, Nelaes and Massee.

(b) *Sudden withdrawal under the influence of hypnotic drugs.* The idea of using hypnotic drugs is to hide the withdrawal symptoms by means of sleep. A large list of hypnotic drugs have been employed by the exponents of this method the most common being paraldehyde, somnifen, luminal-sodium, pernocton, and other barbiturates. The use of these drugs is no doubt attended with some danger. A modification of the 'sleep method' has been described by Meuberger. He employs a light chloroform anæsthesia in the same way as in midwifery cases. The paroxysms of craving are treated in the same way as the pains of child birth and whiffs of the anæsthetic are given from time to time to secure narcosis. The chloroform may be administered from a drop bottle over a compress and administered whenever the patient is under a strong spell of the craving. This method requires close attention by the doctor and the nurse.

(c) *Sudden withdrawal by the aid of drugs of the atropine series.* Scopolamine or hyoscine hydrobromide and atropine are the drugs used in this method. Scopolamine treatment has been tried by Light and Torrance in Philadelphia General Hospital. The patient is at first prepared by being placed on liquid diet for 24 hours. He is given a mild dose of calomel at night to be followed next morning by a saline purgative. He is then given three doses of scopolamine hydrobromide 1/200 gr. hypodermically at 4-hourly intervals and with each dose is given 1/40 gr. of strychnine. A few more injections of scopolamine may be given, the dose being gradually raised to 1/100 gr. and at the end of 36 hours the drug is stopped. When the patient begins to get out of the influence of scopolamine, large doses of phenobarbital are given and if the withdrawal symptoms are still severe and troublesome, a single dose of $\frac{1}{4}$ gr. of morphine may be given. Any further treatment of the case is symptomatic.

(d) *Sudden withdrawal with the aid of specific drugs like narcosan.* Narcosan was first used by Lambert and Tinly in 1926. It is stated to be a solution of lipoids, proteins and water-soluble vitamins. The lipoids are obtained from soya beans and cotton seeds, the proteins from alfalfa seeds or Hungarian millet and vitamins from various plant seeds. The advocates of this drug believe that narcotics such as morphine call forth in the body certain protective substances to neutralize them and when they are suddenly withdrawn these neutralizing substances are themselves toxic to the body and produce with-

drawal symptoms. The lipoids in narcosan are believed to neutralize the toxic substances in place of narcotics. Some of the authorities do not believe that alkaloids can act as antigen. Martin and Williams believe that certain non-specific vegetable proteins in narcosan may stimulate endocrine function. These authors used a preparation from alfalfa proteins combined with ovarian hormone with gratifying results. Recently they have supplemented their protein and sex hormone preparation with adrenal cortex preparations.

(e) *The blister serum treatment of Modinos.* This is another specific treatment which has recently come into vogue. Properly speaking this should be termed as rapid and not sudden withdrawal. The method is very simple; cantharides cerate plaster to a size of 8 sq. cm. and 1 mm. in thickness is applied to the patients' chest or abdomen, and after 16 hours serum varying from 2 to 8 c.cm. is taken and reinjected into the upper part of the arm or leg. The operation is repeated on the 3rd or 4th day, and the 3rd injection is given 4 to 6 days after the second injection. The dose of the narcotic is rapidly reduced and may be completely cut off within 3 to 7 days. It is believed that antibodies are formed which create a distaste for the drug but this view is not universally accepted and the distaste for the drug is attributed to the production of hypersensibility. Other authorities, like Noordhock, consider that the so-called hypersensibility is not specific but is merely psychological and may be obtained by merely injecting common salt solution. He further states that relapses after the treatment are as common as with other methods. Before starting the treatment the urine should be examined for albumin as cantharides may cause injury to the kidneys.

(f) *Sudden withdrawal aided by special drugs like euphyllin, insulin, etc.* Euphyllin and insulin have been credited with the power of alleviating a certain amount of the distressing withdrawal symptoms. Euphyllin has been used on the presumption that morphine withdrawal induces hydration of the blood and probably of the tissues in general. The drug is a powerful diuretic and may be given intramuscularly or intravenously twice a day in 0.48 gm. doses. The injections are given for 3 to 10 days according to the severity of the symptoms.

Insulin treatment. Insulin alone or with grape sugar has also of late been tried on the Continent. Sakel (1930) used insulin alone in doses up to 80 units in 24 hours, to combat withdrawal symptoms in cases where morphine was cut off abruptly with satisfactory results. Braun administered bigger doses of the drug and in addition employed soporifics like luminal. The results of these authors are very encouraging.

III. *Rapid withdrawal cure.* Rapid withdrawal consists in completely withdrawing the drug in a fortnight. It can be accomplished in the following ways:—

(a) *By the injection of auto-serum* (already described under sudden withdrawal).

(b) *Aided by drugs of the opium series.* Heroine, codeine, cocaine have been tried from time to time especially by the lay people but have invariably resulted in the substitution of a habit of a worst kind. The only drug worth the name is codeine which can be administered during abstinence symptoms in doses of 1 to 3 gr. at 2 to 3 hourly intervals. Lambert also advocates this treatment but he reduces the dose by one tenth every day for 10 days. Codeine is begun on the second day and the dose rises with the decrease of morphine. The initial doses are $\frac{1}{2}$ gr. every 4 hours rising the next day to 1 gr., 3rd day 4 gr. and 5 gr. on the 5th day. The drug is administered in the form of codeine phosphate through the same syringe as morphine. By this plan of giving the drugs together the patient does not know when morphine is stopped and he is getting codeine only. Codeine is then gradually tapered off and saline injections substituted until the withdrawal symptoms are over. The patient does not suffer at all under this method and is quite safe.

(c) *Aided by endocrine preparations.* Liver extract, adrenalin and other glandular products have been employed. Rojas and Belby first tried this method in the Argentine and hence it is known as 'Argentine method.' The dose of morphine is reduced to 10 mgm. within the first 4 to 5 days, then $\frac{1}{2}$ to $\frac{1}{2}$ c.cm. of adrenalin solution (1 in 1,000) is substituted for the drug and it is stated that the patient cannot detect the change. Ephetonin, a therapeutically allied drug to adrenalin has also been tried with success by Bernhardt. These drugs however, should not be used in sympathetico-tonic patients.

(d) *Aided by drugs of the atropine series.* Lambert and Towns used a mixture of belladonna, hyoscyamus and xanthoxylum in the proportion of 2 parts of a 15 per cent. tincture of belladonna and one part each of a fluid extract of hyoscyamus and xanthoxylum. In the beginning 2 drops of this mixture were given at hourly intervals, the dose being gradually increased to the point of tolerance for belladonna. Simultaneously the drug was withdrawn as the condition of the patient permitted. Free action of the bowels was maintained by means of blue pill followed by salines. Post-withdrawal insomnia was combated with a large dose of luminal.

Scopolamine in conjunction with hypnotics is employed by Hahn and others. Twilight sleep methods have been used in Germany.

IV. *Gradual withdrawal.* This method is suitable for countries like India and has been recommended by the departmental committee in Great Britain. The following are some of the important modifications.

(a) *Without any drug.* It has been already described under the ambulatory treatment.

(b) *With the aid of drugs.* The author has often used with success drugs like belladonna, bromides, nux vomica, etc. These drugs are substituted for opium and administered in the form of a pill and in this way the dose of opium is reduced to nil. In opium smokers the smoking is first replaced by opium by mouth and then the drug is gradually withdrawn with the help of the above mentioned drugs.

(c) *Conditional reflex method.* Charles Rubenstein at Los Angeles sanitarium has recently devised an interesting method. In every case hypodermic injection of morphia was accompanied by the ringing of a bell, but later on massage of the dorsum of the fore-arm for one minute after each injection was substituted. In another case a tuning fork held close to the ear until the vibrations ceased was used as the conditioning stimulus. In each case, after the reflex had been established, injection of sterile physiological saline or water replaced the morphine injection. In both cases it was found that the treatment was rapid and effective and did not produce the so-called withdrawal symptoms.

Emotional stabilisation or re-educational and social re-placement stage. This constitutes a rebuilding of a personality after the drug has been withdrawn because if the character is not rebuilt there will be a relapse. A wise physician will study the causes which led to the addiction and if possible remove them. The patient's general health should be built up both by physical and medical measures. Outdoor life, occupational and diversion therapy and engagement in a hobby are important. Physical and mental fatigue and lassitude should be avoided as they are very often the cause of relapse. Psychotherapeutics are important. In the rebuilding of the personality lies the hope of preventing relapse.

Treatment of Drug Addiction with Special Reference to India

Although in India drug addiction has existed on a more extensive scale than any other country in the world with the exception perhaps of China, little is known regarding the problem. Two commissions were appointed to go into the matter in the end of the last century; a Royal Commission was appointed in 1893 to enquire into the prevalence of opium habit and a commission to go into the question of hemp drugs was appointed by the Government of India in 1895. Both these commissions collected important information regarding the prevalence and effects of these drug habits in a general way, but unfortunately the medical and scientific aspects of these addictions were not inquired into fully at that time. Nearly forty years have elapsed since these com-

missions did their work. Considerable changes have occurred and new drug habits have come into being, yet a perusal of the literature shows that very little work has been done on this important subject. The information available even with regard to the present-day incidence of the drug addictions is meagre. The temperance and anti-opium societies have published some data, but these are biased and often inaccurate and misleading. Even such an important subject as infantile administration of opium, which is still so prevalent, is doing an enormous amount of harm and is probably the cause of the high infantile mortality in this country, has not been systematically investigated. Opium eating is very prevalent in many parts and opium smoking is indulged in freely in Assam and other areas. The hemp drugs are used to an enormous extent. No systematic work has been done to determine the ill-effects produced by these drug habits.

It is not therefore surprising that the medical profession in this country is very ill-informed on the subject of drug habits and their treatment. During the course of his investigations in different parts of the country, the writer has not come across many medical men who had any considerable knowledge regarding the treatment of drug addictions or of the phenomena which accompany abstinence. The general impression appears to be 'once a drug addict always a drug addict'; he is incurable and that is the end of him. Ordinary hospitals generally refuse to admit addicts; mental hospitals are not suitable for many reasons. There are no institutions established anywhere in India and the institutional treatment under expert guidance is unknown. It would certainly be advantageous if a few specialised institutions of the type of abstinence sanatoria were established in areas where the incidence of addiction is very high so that treatment could be carried out on scientific lines. There is no doubt that the public would take advantage of them. The writer's experience so far as the treatment of addictions is concerned is, therefore, limited to the non-institutional methods. From the point of view of treatment, the drug addicts in this country are divisible into three main groups :

I. There is a large group who use opium or hemp drugs in small or very moderate quantities. The majority of these have started the drug after the middle period of their life, generally for some minor disease or ailment. They usually start with a small dose and do not increase it. The narcotic and the euphoric effects of the drug have no attraction for them; indeed these are not produced in this group at all. The *habitués* thus have no temptation to increase the dose, in fact, they fully appreciate the evil effects which would result from it. Most of them are good and successful citizens and carry on their daily work quite efficiently. The writer has known numerous persons who have taken small doses of opium or hemp drugs for 20 or 30 years without any apparent harm. As a matter of fact it would appear that the drug was doing them good as its stoppage made them ill and prevented them from

carrying on their daily vocations of life. It stands to reason that when a person can lead an active and useful life on fixed and unchanging doses, there could hardly be any mental or moral deterioration. Treatment in this large group would appear to be quite unnecessary. Some of this group, however, gradually increase their doses and suffer from the toxic effects of the drug. In such cases only treatment is desirable and is wanted.

II. The next and a very large group consists of those who owe their entry into the paths of addiction to the association with and example of other addicts and to no other reason. Some of these are normal individuals who are anxious to be treated and they respond quite well to treatment. A proportion, however, start the habit from idle and vicious seeking after new sensations; they take the drug for its pleasure-giving effects and for sexual stimulation, and are generally found in large towns. Many of them have a defect of character and their mental make-up and appear to be engrossed in furthering their indulgence and increasing the dose. They also have a tendency to indulge in more than one drug at the same time, *e.g.*, alcohol and opium, alcohol and cocaine; alcohol, opium and hemp drugs. This class of vicious addicts are the most difficult from the point of view of treatment. Fortunately this type, which is more in evidence in Western countries, is not commonly met with in India. The few that exist belong generally to the rich and indolent classes. They do not seek treatment and nothing short of forced confinement in a special institution and prolonged training and reconstruction of character will restore them.

III. There is the third smaller group of *habitués* who have started using the drug in an attempt to tide over a period of special strain or gross over-work and fatigue. This class of addict is the product of large towns and their percentage is not nearly so high in India as in the West. This is the class who are anxious to get rid of the habit, are easily amenable to treatment and do very well even under non-institutional treatment.

Prophylaxis. The importance of prophylactic measures in preventing drug addiction is appreciated by the medical profession in India and habit-producing drugs are used with great care. While an analysis of the histories of drug addicts in Western countries shows that the medical man has been unwittingly responsible in starting addiction in a large number of cases, in India the writer has not come across a single case in which addiction to opiates or hemp drugs could be attributed to their use by the medical practitioners in the first instance. With cocaine and morphine addiction, however, this has occurred quite frequently. In India, where addiction to crude drugs is in vogue and the alkaloid addiction so far as opium derivatives are concerned is uncommon, the importance of prophylaxis by the doctor does not play such an important part as in Western countries. The stringent restrictions imposed by the Government on the distribution and sale of narcotic drugs (opium and

its derivatives and cocaine and its derivatives) have to a very great extent safeguarded the spread of alkaloid addictions. Such drugs are not allowed to be sold except when prescribed by a qualified medical practitioner; the dispensing chemist has to keep a careful account of every grain of the drug sold in books kept for the purpose which are frequently scrutinised by the authorities.

Treatment of Opium Addicts

Sudden and gradual withdrawal. The withdrawal of the drug by the 'sudden method' advocated by Bonhoeffer has been recognised to be scientifically the best method of treatment in many countries. In spite of the success achieved with it in Europe and America it has not been possible to carry it out in India. The writer has tried the method, but has met with little success. The reason is that the conditions under which the cases were treated were far from ideal. There are no specially equipped institutions in this country where addicts undergoing this form of treatment could be housed and could have all the facilities to take them through the critical period of abstinence symptoms. The post-withdrawal insomnia and the digestive and other troubles are extremely distressing and need efficient handling. Some of the writer's cases had to be treated in the wards of an ordinary hospital. Some were treated in their own homes where the success of such a treatment was doubtful from the beginning. The writer's experience, therefore, with regard to the sudden withdrawal method is limited and unsatisfactory from every point of view. Although he has no personal experience of such treatment in special institutions, he has no hesitation in saying that so far as Indian addicts are concerned, the sudden withdrawal would imply a period of frightful physical and mental suffering and trial which the majority of them would be unable to bear. The shock of sudden withdrawal would be too much for many of the addicts and even those with strong will-power and determined to get rid of the habit will stand it with difficulty. It would make the most willing and determined of them lose confidence and they would end by refusing to go through the treatment. Their sufferings would make them lose their faith in the treating physician, and they would become distrustful and hostile so that it would become difficult to establish friendly relations or to inspire confidence in them. The writer has often heard inveterate opium eaters remark that they would rather endure hell than the abstinence symptoms. Experience in India is in accord with those of many authorities in the West who consider that the patients subjected to harsher methods of treatment, such as locking them up and letting them 'suffer it out' are the very ones that are more likely to relapse and go back to the habit. The above remarks apply to the opium addicts only. In the case of hemp drugs, cocaine, alcohol and chloral hydrate, sudden withdrawal can be carried out under non-institutional conditions without any great difficulty.

The writer has met with a great deal of success with the slow or gradual withdrawal method. There is no doubt that whether the process of withdrawal is gradual or sudden, a great deal of suffering has to be gone through by the patient. Administration of no amount of drugs will completely eliminate the distressing symptoms of abstinence. With the gradual method, however, the pain and discomfort of actual withdrawal are reduced to a minimum. If due attention is paid to the psychological side of the treatment, the patient is made to believe that the physician thoroughly understands his trouble and is doing his best to relieve him of his sufferings, the chances of a permanent cure are greatly enhanced. The patient may even carry not unpleasant memories of his restoration period. Another advantage is that the post-withdrawal insomnia, which is an extremely distressing condition, is much less frequent. Moreover under conditions existing in India, it appears to be the method of choice. If the withdrawal is affected with reasonable celerity and with as little discomfort to the patient as possible, it will encourage other sufferers to seek the treatment and those who have relapsed may also return. While it cannot be said how long it will take an Indian patient to be cured if he were to undergo treatment in an institution with the sudden withdrawal method, the experience of many European institutions is that at least three months' stay is necessary. The adoption of such a treatment will, therefore, be very expensive for a country like India. The writer's experience is that with the slow withdrawal method it takes three to six weeks to effect a cure in most of the Indian addicts who are going to be cured. The decrease in dosage is carried out very gradually at first so that it is imperceptible. After a few days it can be effected more rapidly especially if some pill such as that containing *nux vomica*, gentian and black pepper is given as a substitute. The substitution is started with the morning dose at first, leaving the evening dose untouched, this procedure prevents insomnia. Minor symptoms such as diarrhoea, epigastric pain, nausea may be met by giving ordinary alkaline mixtures. Usually in three to four weeks the drug can be entirely stopped.

It cannot be denied that in spite of all precautions a large number of failures result. In many cases when it was hoped that all was going well, it was suddenly discovered that the patient was secretly obtaining a supply of the drug. The ingenuity shown by the addicts in this connection and the extraordinary way in which they evade those on guard, is amazing. The chances of the treatment being prematurely suspended are also great. Even by the slow method the withdrawal cannot be effected except by exercising a good deal of compulsion. Most of the patients start with good resolutions but give in about the second or third day when the symptoms are very acute. To keep control over such patients under ordinary hospital or home condition is very difficult indeed. With full knowledge of all these difficulties the gradual method has been tried under non-institutional conditions with a fair degree of

success, especially in addicts of short duration. Considerable care and attention have to be exercised in the selection of cases. Before starting the treatment the patient must be thoroughly examined and any physical condition which may have led to addiction, *e.g.*, septic foci, etc., must be treated. The duration of addiction is an important factor, cases under 5 to 7 years taking 10 to 15 gr. daily are generally amenable to treatment. In many persons taking over 20 gr. daily for prolonged periods, circulatory disturbances leading to collapse are likely to supervene if the drug is suddenly withdrawn. Sudden withdrawal is successful and is recommended with addicts taking under 5 gr. daily.

The gradual withdrawal method is also suitable for mass treatment of opium addicts. During the Great War in the East African campaign the writer was in medical charge of a Sikh Company of sappers and miners, about 200 strong, from a State from Northern India. Most of the Indian officers and men of this unit were heavily addicted to opium, many taking as much as 100 gr. daily and some over 200 gr. The unit in the beginning brought a certain supply of opium with it, but this was soon exhausted and men had to fall back on the Commissariat supply of 5 to 6 gr. daily. With the help of the Officer Commanding of the Company, the writer had no difficulty in cutting down the dose to a few grains a day, in a month's time, without any of the men showing signs of distress. They gladly went through the cure and some of them gave up the habit entirely. As there were no towns near, the chances of any one obtaining local supplies were completely eliminated.

The writer has shown that there is a predominant psychic element in opium addiction and the production of abstinence symptoms. He has come across cases of persons addicted to large doses of opium (20 to 100 gr. a day) who have been sent to a jail for some criminal offence and their supply was inevitably stopped, they did not however suffer from very marked symptoms of abstinence. Even in severe cases of morphine addiction many of the mental symptoms such as agitation, anxiety, persecutory ideas, psycho-sensory disorders, mania, even hysteriform or epileptiform attacks, present all the features of an acute psychosis. During the treatment of addicts to rid them of opium habit, the drug can be largely or totally replaced by substances such as gentian or nuxvomica in pill form without the patient realising it. Further if the patient is not aware that he is taking opium, the drug can be effectively given for weeks or months for its therapeutic effects, without producing addiction or abstinence symptoms. A great deal can be done by getting the co-operation of the patient and proper attention to the psychological side of the treatment ensures success in many cases.

Infantile administration of opium. The habit in infants and children is not difficult to break. In the usual course of events the parents continue to give the drug up to the age of two or three years and then when the child can take care of itself it is stopped. Both the gradual and sudden methods of withdrawal have been tried with equal degree

of success, but it is better to adopt the sudden method. The psychological element plays a very minor part in children and as a rule there is little discomfort. The withdrawal symptoms met with are looseness of the bowels and irritability of temper, and in severe cases loss of appetite, nausea and abdominal pains also occur. Diarrhoea can be easily controlled by powders containing sodium bicarbonate, bismuth carbonate and aromatic chalk. In severe cases with mental irritability a bromide mixture with a few minims of tincture of belladonna may help to quieten the patient. The child gets quite well in a few days and a cure is effected, no after-treatment is, as a rule, necessary. Even the worst cases with marasmus and emaciation begin to put on weight soon after they are rid of the habit.

Opium-smoking. The experience in India is that opium-smoking is more difficult to cure than opium-eating. Fortunately, owing to very strict regulations the habit of smoking opium is now rapidly disappearing from many parts though it is still prevalent in Assam. The writer's experience of its treatment is very limited, but there appears to be little doubt that an opium smoker is much more attached to the drug than an opium eater. It would appear that although smaller quantities of the alkaloids are absorbed (most of them must be destroyed by heat), the absorption is very rapid from the large surface of the capillaries of the lungs and the respiratory tract, and the effects are sudden and more intense resembling an injection of morphine. The treatment of opium-smoking has not been properly worked out in India. Some authorities allow the patient the drug by the mouth and gradually cut down smoking. Once eating is successfully substituted for smoking the addict becomes more amenable to treatment.

Addiction to 'post' (unlanced capsules of P. somniferum). The common belief among the addicts is that *post* does less harm than opium. The writer's experience, however, is not in accord with this view. A person addicted to poppy heads requires comparatively much larger doses of opium to produce a similar effect; moreover the physical and mental effects produced by ordinary doses of *post* are much more marked than with moderate doses of opium. This, in all probability, is due to the potentiating effects the constituent alkaloids of poppy capsules have for one another. It is more difficult to get rid of this habit than the opium habit. The sudden method is rarely practicable in these cases, the gradual method being the only one which meets with success. The dose is gradually reduced by half a capsule till a fourth of the original dose is reached and then it is stopped entirely.

Auxiliary treatments. Atropine and hyoscine have been tried in the earlier stages of withdrawal of opium and strychnine in the later stages with good results. The belladonna hyoscyamus mixture recommended by Lambert is useful in that it lessens the shock, decreases diarrhoea and relieves insomnia. Gastrogenous phenomena are not marked in the treatment of the opium habit as they are with morphine, and alkaline and

acid treatments are not necessary. Adrenalin and ephedrine have been tried for mitigating the withdrawal symptoms in a few cases with good results. It is rarely necessary in this country to use sedative drugs such as cocaine, narcosan, luminal, sodium amytal, pernocton, etc., in the gradual withdrawal treatment of opium eaters and the writer has no experience of the use of these drugs. He has used insulin with success in a number of opium and morphine addicts. So far as opium eating is concerned he has carefully tested the effects of the drug on the blood sugar of both diabetics and normal Indians. Small and moderate doses of opium have little or no effect on the blood sugar of individuals who are not suffering from disturbances in carbohydrate metabolism. In persons whose blood sugar content is abnormally low, opium may raise it. The blood sugar in the early and mild types of diabetes may be reduced and it is only in the severe forms of the disease that the blood sugar is actually raised. In some patients opium does no more than raise the renal threshold of excretion. The writer's findings with regard to opium agree with those of Simenauer, Pulfer and Anton who found that in human beings as opposed to animals, morphine produces little or no disturbance of the carbohydrate metabolism.

The utility of diuretics such as novasurol and ephyllin in slow withdrawal method is doubtful. The writer's observations show that in addicts taking moderate and large doses of opium there is retention of fluid in the blood; in those taking small doses, however, the output of urine is actually increased and the blood fluid is not altered. When the kidneys are damaged and there is albuminuria the administration of 1 to 9 gr. of opium daily produces an appreciable decrease in the quantity of urine passed and in none of the cases were there indications of added damage to the kidneys which the drug is reputed to do in such cases.

Vesicatory serum therapy in opium addiction. Although the writer's own experience with this form of treatment is limited, but the method is being tried in the treatment of opium addicts in Burma jails. Opinion among the medical officers trying the treatment is unanimous on one point, namely that one or more injections of the autoserum from a blister make the addict sensitive to opium. The patients say that they do not wish to take opium any more, not because they do not like it, but because the consumption of the drug even in large quantities does not produce the pleasure or exhilaration that it used to produce before. On the contrary the effects produced by a dose are unpleasant, and heaviness of the head, nausea, vomiting, etc., are produced. A distaste for the drug is thus developed and as euphoric effects are not produced opium is not wanted. A control experiment was also tried in the following manner. Some addicts were blistered in the usual way and the fluid from the blister was removed. Instead of the fluid from the blister being injected, in a number of cases injections of normal saline were given. It was found that the addicts who had normal saline did not respond in the same

way as those in whom actual serum was injected. In other words, mere blistering did not do any good so long as the serum was not reabsorbed, nor were the effects due merely to the psychological effects of the injection. It is at present difficult to say how long the sensitiveness to the drug of addiction will last, but investigations on this subject are being carried on. It must be remembered, however, that most of the addicts were prisoners under prison discipline and living under conditions in which temptations by way of easy access to opium did not exist. In one of the jails the treatment was tried on two warders who were free to go about and could easily obtain opium if they so desired. In both cases the injections of serum produced the same effects as in the prisoners.

Whether the treatment will eventually produce a permanent cure or not is difficult to say in the present state of investigation but the results so far obtained are certainly striking. The patients gained in weight after the treatment, the appetite returned and the general health improved in a remarkable manner. The following provisional conclusions can be drawn from the data so far obtained:—

- (1) That the treatment with vesicatory serum injections is a valuable measure in the treatment of opium addicts.
- (2) That probably addicts who have any will-power left will be completely and permanently cured of the habit through its agency.
- (3) That probably those who have no will-power left, although they may be temporarily benefited, will relapse as soon as they have the opportunity.

It is believed that about 50 per cent. of addicts could be cured by this method.

Lecithin treatment. Lecithin treatment of opium addicts has been mentioned by Ma (1932) and is being tried in India by the author. From certain observations made on the physical properties of the blood sera of such addicts, it has been found that the protein contents, specially the neuro-proteins, are lacking or deficient, particularly during the withdrawal period. Ma (1931) from a cytopathological study of chronic morphinism in albino rats found that the withdrawal of the drug in the addicted animals leads to severe pathological conditions of the Golgi apparatus in the cells of various organs. Without treatment these conditions are overcome in 10 to 12 days. Feeding with lecithin, on the other hand, for a period of six days before and for some days after prevented Golgi apparatus from becoming abnormally reduced and was accompanied by a condition of general well-being of the animal which was absent in those receiving no lecithin. The treatment has been tried in China on 143 opium-smokers. In addition to their ordinary diet the patients are given 6 to 9 eggs per day to enrich the diet in lecithin. The bouts of craving are overcome by the administration of tincture of opium in small doses. The lecithin given is

prepared from eggs and made into pill with glycyrrhiza powder, the usual daily dose being 4 to 6 gm. Lecithin obtained from soya-bean has been used in China in the treatment of addiction to opium. It is administered by the mouth in doses of 60 to 90 gr. daily and said to produce a spontaneous and gradual discontinuity in the use of the drug by the addict. The administration of lecithin is discontinued a few days after the complete stoppage of opium. No discomfort is noticed and no abstinence symptoms are produced.

Hemp drugs. The treatment of hemp drug habit is not at all difficult, though it is easier to cure the eating habit than the smoking habit. The withdrawal symptoms as they are met with in case of opium addicts are hardly ever seen, indeed the patients find no difficulty in giving up the habit of their own accord. In Northern India many people indulge in 'bhang' drinking in the hot weather on account of its cooling and refreshing effects and give it up in the winter quite suddenly. Hemp preparations when taken habitually by the mouth can be suddenly withdrawn without any marked untoward symptoms. Temporary loss of appetite, constipation lasting for a few days and rarely palpitation and restlessness may occur, all these can be easily dealt with.

Charas and ganja. These are stronger preparations and as these are generally indulged in by smoking, their effects on the system and particularly on the nervous system are more pronounced. The will-power of the smoker is weakened and without the physician's help he is not able to give up the habit. Treatment in special institutions with facilities for forcible withdrawal is likely to give the best results. The psychological and mental treatment and training and education of the addict are as important in case of hemp drug smokers as opium addicts, in spite of the fact that considerable physical pain accompanying withdrawal is absent.

Cocaine. The habit of eating cocaine is easier to cure than that of injecting cocaine. Removal of the addict from the environments in which he has learnt the habit and from associates in whose company he indulges in the drug, preferably to a place where he cannot get it, often effects a cure. The writer knows of many instances where the individuals from one part of the country went for a few months to another part where they were unable to get the drug and where there were no associates; they were able to conquer the craving for many months at a time without difficulty. When, however, they returned to their old surroundings they again succumbed to the temptation. Similar facts have been observed in addicts who have been kept confined in prisons. They are able to give up the habit during confinement and go for years without the drug; they generally take it up again after discharge. The writer is convinced that cocaine eating is comparatively a much milder form of indulgence than cocaine injecting.

Psychotherapy and mental training are important; the psychological rearrangement of the personality by finding some innocent emotional

compensation will often help the habitue to give up the habit. The drug must be withdrawn all at once and symptomatic treatment given for the withdrawal symptoms. Next to the opium habit, the cocaine habit is the most difficult drug habit to cure in India.

After treatment. The importance of psychological aspects of the treatment of drug addicts has already been stressed. The responsibility of the physician does not end after the drug is withdrawn. The period following the withdrawal is most critical and dangerous and unless great care is taken relapses will occur. The whole of the nervous system has been strained and a thorough reconstruction and rehabilitation of the personality and the character of the addict are imperative if a permanent cure is desired. The physician can do much by way of encouraging the patient and making him believe that by his will-power and firmness he will get rid of the habit. A common belief among Indian addicts is that elimination of the drug habit will leave them sexually impotent. There is no basis for such a belief and the patient should be fully assured that the loss of sexual desire which they observe after giving up the drug is a temporary phenomenon and is a part of the general loss of tone of the organs. It passes off in 4 to 8 weeks but rarely it may last for several months. During the period following withdrawal a good tonic in form of iron, arsenic and strychnine is very helpful. Occupation therapy is also very important. As soon as possible the patient should start doing some work so that his attention is diverted in other directions. He must lead a quiet life and avoid excesses of all kinds for a year or more after withdrawal has been successfully effected.

PART VI

DISEASES OF THE SKIN

Anatomy and Physiology of the Skin. The skin or integument is an integral part of the body and is in close relationship with the subjacent structures through its connective tissues, blood vessels and nerves. It can be considered as an elastic covering of complex structure with certain independent physiological functions and bearing specialised appendages, namely, the hairs and nails. Structurally, the skin consists of three principal layers, the epidermis or cuticle, the dermis or corium which is the true skin and the subcutaneous tissue.

The *epidermis* or *cuticle* is the outer superficial layer which is waterproof and protects the underlying delicate structures like fine blood vessels and nerves from external injuries. It is composed entirely of epithelial cells of squamous and cuboidal type and is devoid of blood vessels or capillaries. Depending on the situation and thickness, the epidermis is formed by three to five layers of cells which are termed from above downwards, *stratum corneum*, *stratum lucidum*, *stratum granulosum*, *stratum Malpighii* or the *rete mucosum* and the *stratum germinativum* or basal cell layer. It is from the basal layer that all the other layers originate.

The *stratum corneum* or horny layer is the outermost and varies in thickness in different parts of the body. It is thickest on the palms and soles, intermediate on the scalp and thinnest on the eyelids, face, prepuce, webs of the fingers, flexor aspects of the elbows, groins and sides of the tendo achillis. The cells in this layer do not possess nuclei and are flattened and dry near the surface. These cells are keratinised and are partially impervious to water owing to the presence of a waxy substance. The *stratum lucidum* occurs immediately beneath the horny layer and is seen in microsections as a thin, even, colourless, translucent band. It is composed of one or two layers of irregular distended cells with vestigial nuclei. The *stratum granulosum* is the next deeper layer and is composed of one or more flattened coarsely granular cells with shrunken nuclei lying in vacuole-like spaces. This layer is very thin or absent in the fine skin at the webs of the fingers etc. The *stratum Malpighii* or the rete is also known as the prickle cell layer and comprises of a varying number of polygonal cells distributed in a 'mosaic pattern.' The cytoplasm is spongy and the cells, all of which show definite nuclei, are united to each other by delicate protoplasmic processes—the prickles. In the upper regions these polygonal cells are more or less flattened and in the neighbourhood of the basal layer they are somewhat elongated. The *stratum germinativum*

or basal layer consists of a single row of cuboidal cells arranged vertically to the basement membrane separating the epidermis from the corium. The nuclei are large, oval and centrally situated and show mitosis. These cells contain melanin pigment to which the colouration of the skin is due.

Although the entire surface of the skin appears to be smooth and regular, it is in reality traversed by numerous ridges and furrows distributed according to the folding and stretching to which the skin is subjected during movement. Fine lines exist over the entire surface of the body. On the flexor aspects of the fingers and toes the distribution is more regular and of a pattern characteristic to the individual. The epidermis is anchored to the dermis by means of fine fibrils originating from the corium.

The *corium* or *dermis* is the true skin which, like the epidermis, also varies in thickness in different situations, being thickest on the palms and soles, and thinnest on the eyelids, webs of the fingers and toes, etc. It is anatomically considered as being composed of two strata, namely, the *pars papillaris* and the *pars reticularis* and is richly supplied with blood vessels, nerves and lymphatics. The *pars papillaris* or the superficial stratum consists of round or oval cone-like projections resting on an irregular ridge-like formation in the connective tissue and extends from the basal layer of the epidermis to the level of the sebaceous glands. The *pars reticularis* or the deeper stratum which is composed of interlacing bundles of dense fibrous tissue, commences at the level of the sebaceous glands and merges into the superficial fascia of the subcutaneous tissue. Strands of voluntary and involuntary muscle fibres are found in the *pars reticularis*; of these, the striped muscles occur only in the face and neck while unstriped muscles are more numerous in the scrotal and perineal regions, in the areola of the nipple and on the scalp. Arrector pili muscles originate from the inner sheath of the hair roots, and run obliquely to be inserted at the base of the *pars papillaris*.

The corium is supplied with *blood vessels* situated at four different levels where they form plexuses. The deepest of these plexuses is formed in the subcutaneous tissues. The arterial side comprises of a richly anastomosing irregular network of tortuous vessels which send off branches to form the second plexus about the level of the sweat glands. Extremely fine twigs of arterioles are sent off from the second plexus to form arborising networks in the upper portion of the dermis especially around the sebaceous glands and hair follicles. Some of these fine vessels pass upwards and form the subpapillary plexus with regular oblique meshes from which fine capillaries pass into the tips of the papillae. These capillaries do not anastomose. The walls of the papillary capillaries and the arterioles of the subpapillary plexus consist of a single layer of endothelial cells. The venous return is from a single papillary venous capillary to the subpapillary venous plexus which lies just below the papillae, and anastomosing freely, forms a regular network of

even-sized vessels. Two more venous plexuses are seen, one in the cutis and the other in the subcutis, and are composed of large veins supplied with valves. Control of the capillaries depends on the activity of the suprarenals and the pars posterior of the pituitary, and the permeability of the endothelial wall varies directly with the calcium content of the blood. These plexuses respond to external and internal stimuli in various ways and the resulting clinical phenomena depend on three factors, namely, (a) dilatation or (b) constriction of the capillaries, arterioles or venules with (c) increased permeability of the capillary endothelium or the endothelium of the subpapillary plexus. For example, the first effect of cold is pallor which is due to constriction of the capillaries but dilatation of the deep arteries. During the second stage, the arteries and arterioles contract and the veins dilate giving rise to blueness of the skin. In the third stage there is occlusion of the arteries and stasis in the veins with erythrorrhæxis resulting in gangrene. If recovery takes place in the second stage, there is dilatation of the papillary capillaries with exudation of serum into the prickle cell layer and consequent formation of blisters.

In the epidermis there are no *lymphatic vessels* with distinct endothelial wall but numerous intercellular spaces are seen between the cells of the different strata. In the papillary portion of the corium a plexus of fine lymphatic vessels accompanies the blood vessels and drains the lymphatic spaces of the epidermis. A large number of lymphatic spaces also occur in the corium, so much so, that the connective tissue bundles, muscle fibres and the coil glands seem to 'float in distended lymphatic spaces.' A second coarse plexus of lymphatics is found in the deeper portions of the pars reticularis of the corium where the distribution follows the deep blood vascular plexuses. Anastomosing branches are sent off from both these lymphatic plexuses which supply and drain all the structures in the corium.

The *sensory nerve fibres* of the skin are of both medullated and nonmedullated kind. The medullated fibres pass upwards through the subcutaneous tissues along with the blood vessels. The medullary sheath is generally lost at the level of the pars papillaris where the fibrils form irregular network and send off extremely fine twigs upwards between the cells of the epidermis as far as the stratum lucidum. A large number of medullated fibres terminate in the tactile corpuscles, end bulbs and Paccinian corpuscles which are situated on the tips of papillæ just below the epidermis. The connective tissue coats of the hair follicles are also supplied by fibrils of medullated nerves. The non-medullated fibres which are derived from the sympathetic ganglia supply the voluntary and involuntary muscles of the skin.

The subcutaneous tissue varies in thickness and density in different parts of the body and is composed mainly of irregular lobules of fat distributed in a fibrous network which supports the blood vessels and

nerves. The superficial fascia forms a resilient base for the whole thickness of the skin to rest upon.

The entire thickness of the skin is pierced by the ducts of the sweat glands and by hair follicles. Both the sweat glands and the hair follicles are placed deep in the subcutaneous tissue, the sebaceous glands which accompany the hair shafts occur in the deeper portion of the *pars papillaris*.

The *sebaceous glands* vary somewhat in structure from a simple saccular to a multiple racemose gland. Their size bears no relationship to the size of the hair follicles with which they are connected, the smallest glands are found in the scalp and the largest in the *mons veneris*, scrotum, nose and external ear. Meibomian glands in the eyelids and Tysonian glands on the glans penis are modified forms of sebaceous glands. Sebaceous glands are found in the corium on all parts of the body except the palms and soles and the terminal phalanges.

The *sweat glands* are situated in the superficial portion of the subcutaneous tissue and consist of a single tube of almost uniform calibre wound into a globular mass. They are found on all parts of the body except at the margins of the lips, on the glans penis and on the inner side of the prepuce. Largest number of sweat glands occur on the palms and soles and fewest on the back and buttocks. The circum-anal, ciliary and ceruminous glands are modified forms of sweat glands. The duct passes upwards spirally through the corium but at the interpapillary portion of the rete this regular spiral appearance is lost. The corkscrew-like course is again resumed at the level of the stratum granulosum and its termination on the surface is marked by a minute funnel-shaped depression in the skin.

The hair. These are horny, pigmented, cylindrical outgrowths derived from the epidermis and having their roots firmly fixed to pouch-like depressions in the deeper portions of the corium. They occur on all parts of the body except the palms and soles, the terminal phalanges and the penis. Three kinds of hair are found on the human body, namely, (i) soft or lanugo hairs which have thin minute shafts and grow on the forehead, limbs, trunk and ear; (ii) long hairs occurring on the scalp, beard and moustache areas, pubes and axillæ; (iii) stiff bristly hairs of the eyebrows and eyelashes. Straight hairs are cylindrical while curly hairs are somewhat flat and ribbon-like and are oval in transverse section. The root is enclosed in the hair follicle which has three layers. The external and middle coats are formed by fibrous connective tissue and are supplied with blood vessels and nerves. The inner coat is structureless and homogeneous and does not contain any blood vessels and nerves.

The nails. These are flat horny outgrowths of the surface epithelium covering the dorsal surface of the terminal phalanges of the fingers and toes. The body or visible portion consists of flat translucent horny cells growing from the subcutaneous rete and resting on the nail bed in the corium. The root is firmly embedded in a pocket-like recess formed

by an infolding of the epidermis. The proximal white portion is the germinating matrix, the intermediate pink portion is the nail proper and the distal yellow portion is the dead area which is pared off periodically. The rate of growth varies with age and the season of the year being most rapid in young adults and during the summer months. The finger nails grow faster than the toe nails.

Functions of the skin. (1) *Protective.* The horny layer being keratinised and impervious to water acts as a barrier to bacterial infection of the subjacent structures. This function is subsidised by secretion of the sebaceous glands which keeps the surface epithelium in a pliable condition. Protection against mechanical injury is afforded by the firmness and elasticity of the corium and the fatty cushion-like structure of the superficial fascia on which they are resting. The vulnerable points in the skin are the pilosebaceous orifices through which bacteria gain access to the deeper tissues.

(2) *Sensory.* The entire body is kept cognisant of its change of environments through the sensory nerves of the skin. The special end-organs transmit sensation of heat, cold, pain, pressure and tactile discrimination. The hair follicles are liberally supplied with sensory fibres and hence they also function as effective tactile organ.

(3) *Regulation of heat.* This is done by radiation and evaporation from the entire surface of the skin through the activity of the sweat glands and dilatation and contraction of the blood vessels. Heat or cold may act either directly on the involuntary muscle fibres of the vessels or indirectly through the vasomotor system. Heat produces dilatation and thereby more heat is radiated owing to a brisk circulation. Cold produces contraction of these vessels and radiation from the body is less owing to retarded circulation.

(4) *Secretory.* (a) *Sweat.* A fair amount of water is constantly lost from the body as insensible perspiration which keeps the skin soft and moist. The activity of the sweat glands is under control of the central nervous system and is influenced by atmospheric conditions such as temperature and humidity and various physical states such as emotion, exercise and nausea. The sweat glands are not much influenced by changes in the chemical state of the blood as the kidneys are. Sweat proper is an important factor in the regulation of the body temperature, especially in bringing down the temperature of febrile or other toxic conditions. Excretion of nitrogenous and other waste products is negligibly small as sweat proper consists of about 99 per cent. of water with certain amount of sodium chloride, phosphates etc., in solution or suspension. The composition and consistency vary according to the region and duration of sweating, the secretion of the axillary and circumanal glands being thick and oily. The reaction is always acid and thus affords a protection against multiplication of bacteria on the skin.

(b) *Sebum*. It consists of an oily semi-fluid material composed of fat, fatty acids, salts, cholesterin, albuminoid substances and water. A certain amount of fatty degenerated cellular debris is mixed with it. The secretion varies in quantity according to the situation, being most abundant on the face, sides of the nose, scrotum and the areolæ of the nipples. The production of sebum is slow and continuous and is affected to a certain extent by the vascularity of the skin but the activity of the glands is controlled by the gonads. The principal function of sebum is to lubricate the hair shafts and prevent them from becoming too hard and brittle or too easily saturated with moisture. It also prevents too rapid and undue loss of heat from evaporation by forming a thin spreading film of oily substance on the skin.

(5) *Absorptive*. The horny layer is totally impervious to water or alcohol but fatty substances are absorbed to a certain extent. The degree of absorption depends on the volatile property of these fats or oils at the low temperature of the body heat. Absorption can take place readily through the papillæ if the skin is abraded.

(6) *Nutritive*. The fatty subcutaneous tissue of the skin acts as a store of nutrition in case of emergency and need. Nearly one fifth of this lipid substance is present as free cholesterol which is activated by ultraviolet light and thereby exerts its antirachitic effect.

(7) *Respiratory*. A certain amount of carbon dioxide and a fairly large quantity of water is exhaled from the surface of the skin.

(8) *Melanin pigment*. The colour of the human skin is due to the concentration of melanin pigment in the basal layer of the epidermis. There are certain specialised cells called melanoblasts situated in the upper layer of the corium, which elaborate melanin from the end products of digestion of vegetable proteins especially those derived from the leguminous plants. Under normal conditions the colouring matter is secreted by the melanoblasts as an achromatic substance, and during its drift upwards towards the surface, it is oxidised and stored in the basal layer as the dark russet-brown melanin. Here its principal function is that of a light filter to protect the fine capillaries anastomosing in the papillæ from the injurious effects of strong sunlight. The activity of these melanoblasts is controlled by the internal secretion of the suprarenals and anterior pituitary and hence the basic factor in the colouration of the skin is racial or hereditary. The colour of the hair and iris is also a racial character for the same reason. The essential difference between a dark negroid and a very light Caucasian type of skin is not so much due to the numerical distribution of the melanoblasts (in fact, the negroid skin may show as many melanoblasts in a given area in a microsection as a Caucasian skin) but to the relative capacity of the basal cells to completely oxidise and store the precursor of melanin substance derived from the melanoblasts.

Diseases of the skin may be produced by purely external causes acting on the surface of the integument, or the cause may be internal, the manifestation on the skin being only a reflection of the internal disease. The external causes can be considered under the following heads: (A) Parasitic, (i) animal parasites, (ii) vegetable parasites. (B) Physical agents.

External Diseases Produced by Animal Parasites

SCABIES OR THE ITCH. This disease is caused by the gravid female '*Acarus scabiei*,' burrowing into the epithelial layer of the skin where it consists of two layers only, namely in the webs of the fingers, at the wrists, around the navel and the nipples, on the penis, buttocks, folds of the axilla and between the toes. In very young children, the lesions may be generalised affecting the palms, soles, face and the scalp owing to the skin being thin and tender all over the body. The tunnel produced by the burrowing parasite is utilised for laying eggs and the larvæ which are hatched leave the tunnel by tearing through the roof, thus keeping up the infection by invasion of fresh areas. There is violent itching—hence the name 'the itch'—which is worse at night. The abrasions produced by scratching are very often infected secondarily with pyogenic cocci and the entire clinical picture may be changed thereby. This is especially noticed in the case of babies. The infection is transmitted by direct contagion and is almost always associated with lack of personal hygiene. The disease is often found among the inmates of boarding houses and schools. Instances of infection in people of very cleanly habits are occasionally seen.

Treatment. Sulphur in all forms is the specific. Where there is extensive secondary infection, it should be treated first with cooling lotions, *e.g.*, calamine lotion or weak antiseptic lotions, *e.g.*, acriflavin lotion (1 in 3000), etc. When the inflammation has subsided, intensive sulphur treatment should be given. In straightforward cases treatment consists of scrubbing with a hard nail brush, soap and hot water in the morning to open up the burrows, followed by sulphur ointment (B. P.) which should be rubbed in and kept on for at least 4 to 6 hours. The scrubbing and application of ointment is to be repeated before retiring at night. All clothes next to the skin, bed sheets, pillow cases, counterpanes, etc., should be sterilised by boiling every day; if this is not feasible, the patient is kept without a bath and his clothes, linen, etc., are not changed for 3 days and on the 4th day everything is sterilised by boiling for one hour. The patient is given a good bath with soap and hot water. Some people are intolerant to sulphur and begin to show signs of sulphur dermatitis early in the course of treatment. β -naphthol ointment (10 gr. to 1 oz.) or balsam of Peru ($\frac{1}{2}$ to 1 dr. to 1 oz.) are two of the best substitutes in such cases, but the latter, if used in too concentrated solution for a long time, produces

general toxic symptoms. Sometimes sulphur dermatitis is brought about by the specific treatment being prolonged unnecessarily by the patients themselves as they think that the irritability of the skin caused by the sulphur is due to persistence of the infection. The patients and their relatives should therefore always be warned not to continue the intensive treatment after the 4th day. Growing children may develop allergic dermatitis and this condition should be carefully differentiated from actual scabies and treated accordingly. Prophylaxis is of great importance in preventing a relapse. As a rule more than one member of a family is affected, and unless all of them are treated at the same time, a complete cure cannot be established. Sulphur and camphor dusting powder (sulphur ppt. 2 dr., camphor 2 dr., zinc oxide 1 dr., boric acid $\frac{1}{2}$ dr., starch 3 oz.) sprinkled lightly on the body after bath and on the bed linen at night, is a very good prophylactic agent.

Danish method of treating scabies. The patient is stripped, his clothes are fumigated and Vlemminckx's solution is painted on with a brush. The patient is given a bath with soap and hot water after two hours. This solution is prepared as follows: quicklime 1 oz., sulphur ppt. 2 oz., water 15 oz., boil in earthenware vessel till reduced to 10 oz.; let it stand for some time and decant off the clear sherry-coloured supernatant fluid.

PEDICULOSIS (Lousiness). Three types of the parasite are met with, namely, *P. capitis*, *P. vestimenti*, and *P. pubis* (crab louse).

P. capitis affects the scalp and is spread by direct contagion in schools and boarding houses and from the use of infected hair brush or sleeping with an infected bed fellow. The adult louse causes a good deal of irritation of the scalp and is often associated with *seborrhœa oleosa* of the skin. Secondary infection of the nature of impetigo is not uncommon, and a certain amount of matting and falling of the hair is always noticed, especially in girls who wear their hair long. In persons of cleanly habits it is a transient infection, but in people in whom a head-bath or shampoo is only a luxury it may go on for years and produce actual alopecia. *P. capitis* in long standing cases may invade the body hairs as well. The eggs are laid on the hair shafts and are called nits. For the adult lice, kerosine oil acts more or less like a specific. The hair should be soaked well with kerosine oil, kept on for half an hour and then washed off with soap and warm water. This treatment should be given twice a week, and in the interval, antiseptic hair lotions—resorcin 30 gr. to 1 oz. or β -naphthol 20 gr. to 1 oz.—should be applied night and morning to destroy the nits. All matted hair should be clipped off.

P. vestimenti or the body louse lives on the clothes and only draws its food supply from the human host by sucking his blood. The only way to a radical cure is thorough disinfection of all clothing by steam and hot ironing and strict personal hygiene. It is spread by direct contact.

The parasite is considered by entomologists to belong to the same species as *P. capitis*.

P. pubis affects the pubic hair in both sexes and in men may sometimes affect the hair on the abdomen, chest, axilla, even the eyebrows and eye-lashes. The bite causes intense itching and the parts affected become almost eczematous owing to the abrasion and drying up of serous exudate. It is usually transmitted by intercourse although in rare instances the infection has been picked up from a closet seat. The treatment consists of shaving all the affected parts and burning the hair, a 10 per cent. calomel ointment or β -naphthol ointment, 10 gr. to 1 oz. being applied afterwards. On the eyebrows and eyelashes (which the sufferer usually refuses to shave or clip off) 0.5 per cent. yellow ointment (ung. hydrarg. oxidi flavi) is used.

CREeping ERUPTION. It is caused by larvæ of insects or nematodes burrowing under the skin and producing lesions which are raised above the general surface, linear or gyrate in character, and may be either continuous or broken with bead-like vesicles. The commonest type of lesion is a slightly raised thread-like erythema which is pronounced at its extending part and fading away at the older part traversed by the larvæ. Creeping eruption due to hookworms is seen amongst labourers in plantations and gardens where the hookworm larvæ are rather plentiful in the soil and gain entrance through the unprotected skin of the feet, the commonest sites being between the toes, the thin skin by the sides of the tendo achilles or less commonly on the dorsum of the foot. The larva migrates mostly at night and causes good deal of irritation; scratching opens up the burrows which become infected with pyogenic cocci giving rise to secondary impetigo or weeping eczemas.

Treatment. Cleaning up the sores with fomentations or baths in weak lysol (15 to 20 drops to a pint), and application of calamine lotion or ammoniated mercury ointment as the nature of the secondary infection requires. In uncomplicated cases without secondary infection best results are obtained by cauterising the area around or just beyond the advancing part with carbolic acid and dressing with weak perchloride of mercury lotion (1 in 8000). Another effective method is freezing with an ethyl-chloride spray.

External Diseases due to Vegetable Parasites

RINGWORM OR DERMATOPHYTES. Two varieties are recognised, viz., (1) those that affect the hair and hairy areas alone; and (2) those that affect the smooth skin. In the first group are included:

I. Genus *Achorion* (species *schoenleinii* and *actoni*) which causes favus. II. Genus *Microsporum* (species *audouinii*) which gives rise to ordinary scaly ringworm of the scalp. III. Genus *Trichophyton*, ectothryx and endothryx varieties. The ectothrices cause suppurative lesions of hair follicles, and infect the outer side of the hair shaft; the

endothrices, on the other hand, infect the medulla of the hair shafts which break off flush with the level of the skin with slight scaling of the epidermis.

Ringworm of the scalp. Infection with fungi of the *Achorion* group causes *favus*. The lesions are characterised by multiple, sulphur-yellow cup-shaped crusts, called *scutula*, each of which is pierced by a hair shaft and emanating a characteristic mousy odour. They vary in size from a pin's head to a large coin and are sometimes imperfectly formed, appearing as grayish or yellow specks scattered throughout the scalp. Contiguous *scutula* often coalesce at the margins and give rise to fairly extensive patches with thick yellowish adherent scales. The disease may spread on the glabrous skin of the body where the lesions are of fairly large size, discoid in shape and covered with thick yellow crusts. The nails may also be affected. The hairs of the affected area become dry, wiry and lustreless and ultimately fall off. Suppuration occurs in most cases followed by scarring of the skin and consequent permanent alopecia. The scars are white and depressed and the skin appears smooth, thin and glossy. Subjective symptoms are trivial or entirely absent. The disease is contagious and is spread by direct contact in schools and boarding houses. The infection may sometimes be picked up from a barber's shop and no age is exempted.

Ordinary *scaly ringworm* of the scalp, caused by infection with fungi of the *Microsporum* group, is a disease of childhood and is rarely seen after puberty. Both male and female children are almost equally affected. The lesions which are always multiple, begin as small, red, scaly papules, perforated by the hair shafts which become loose, dry, lustreless and break off just above the surface of the skin. The spread of the disease is slow with a tendency to involution in the centre and extension at the margins giving rise to patchy areas of partial baldness with reddened hyperæmic bases and covered with whitish or grayish scales. Typical cases present 'picket' area appearance of the scalp. The lesions do not suppurate as a rule and the alopecia induced by the infection is never complete.

The ectothryx variety of *Trichophyton* produces fairly deep-seated infection of the hair follicles and is accompanied with suppuration and inflammatory changes in the corium. The distended follicles stand out as small, red, tumour-like beads bearing the loose hair shafts which drop off very soon, leaving dilated gaping orifices discharging pus or seropurulent fluid. Several contiguous lesions may coalesce to form fairly large masses—the *kerions*—which are characterised by rounded, boggy, carbuncle-like tumours of fairly large size with numerous sieve-like openings through which pus can be squeezed out. There is intense inflammatory change in the subcutaneous tissues. The lesions are extremely sensitive to pressure and sometimes cause good deal of pain.

Infection of the medulla of the hair shafts with *Trichophyton endothrix* produces what is known as 'black dot ringworm' of the scalp. The

lesions occur as multiple dry, scaly patches with the hair shafts broken off flush with the surface of the skin. The follicles are not affected at first but undergo sclerosis and atrophy late in the disease when the hair shafts are destroyed by the fungus. They produce complete alopecia.

The beard and moustache are sometimes attacked by the ectothryx variety of *Trichophyton* (*T. violaceum*) giving rise to pustular folliculitis and kerion.

TREATMENT. Local application of antiseptic lotions, paints and ointments are of little value. A cure can only be established by complete epilation of the infected hair shafts for which exposure to unfiltered X-rays is best. If there are suppurative lesions, calamine lotion, acriflavin lotion, or 5 per cent. solution of gentian violet in 20 per cent. alcohol should be used first. Sometimes kerion occurs owing to abnormal tissue reactions and this condition requires palliative treatment with starch poultices, carbolic or boric acid compress, as a preliminary to X-ray therapy. Careful prophylaxis is essential to prevent relapses, especially in boarding schools and dormitories. Weak antiseptic hair washes with perchloride of mercury, 1 in 2000, should be used once a week. Thallium acetate has been used orally to make the hair fall off, but owing to the toxic nature of this compound, its use is very risky.

Ringworms affecting the smooth skin. These belong to the genus *Epidermophyton* and give rise to eczema-like lesions which may be dry and scaly, or moist and inflamed, depending on the situation of the lesion as well as the friction of clothes, etc., producing maceration of the skin. In the moist areas, like the groin or axilla, the lesions are extremely irritable and vary in colour a good deal, the margin is usually squamous, sometimes vesico-pustular and weeping. This is popularly called Dhobie's itch and may sometimes spread over the entire surface of the body, palms, soles, nail and even the hair of the scalp. It is very resistant to treatment and relapses occur almost every rainy season. The diagnosis is not difficult in uncomplicated cases, but when there is secondary infection with pyogenic organisms, the true nature of the lesion may be overlooked. Definite diagnosis in straightforward cases or of a single patch can be made by scraping off the dry scales from the margin and examining under the microscope with suitable stains or other reagents, when the segmented mycelia of the *Epidermophyton* can be seen.

TREATMENT in such cases is fairly simple, and painting the affected area with tincture of iodine for three or four days usually effects a cure. Sulphur-camphor dusting powder sprinkled lightly on moist areas after bath is a very good and reliable prophylactic agent.

In chronic cases, various complications require special treatment which, in the beginning, has to be mainly symptomatic. The eczematous weeping areas should first be fomented thoroughly with weak lysol lotion (15 min. to 1 pint) at about 104°F. and kept moist with calamine

or other soothing lotions during the day. The intractable irritation often yields to salving with camphor and coconut oil (5 to 10 gr. to 1 oz.). The coconut oil itself possesses a certain amount of fungistatic properties. When the eczematous condition is better, specific treatment with resorcin, salicylic acid, benzoic acid, etc., can be commenced either as ointments or suspended in traumaticin.

The following prescriptions offer a good combination of remedial drugs which have been tested at the School of Tropical Medicine, Calcutta, and found efficacious:—

(1) Modified Whitfield's ointment. Salicylic acid 15 gr., benzoic acid 15 gr., vaseline 1 oz. Modifications with carbolic acid 3 gr. to 1 oz. or resorcin 10 gr. to 1 oz. are also of value.

(2) Resorcin $\frac{1}{2}$ dr., tincture benzoin compound 1 oz. painted once at night and removed with spirits the next day. This is useful in dry squamous ringworms, 3 to 4 days' treatment effecting a cure.

(3) Chrysarobin 5 to 10 gr., gutta percha 1 dr., chloroform 1 oz., to be dispensed in air-tight glass stoppered bottles, and painted on with small brush. This is also useful for dry types, one application sufficing.

(4) Cignolin (chrysarobin derivative) 1 to 3 gr., acetone pure 1 oz. This is also to be kept in air-tight glass stoppered bottle and painted with a fine brush. One application usually cures.

In using chrysarobin and its derivatives great care should be taken to guard against inflammatory reactions, especially if the patient is a hypersensitive subject.

Chronic irritation sometimes produces hypertrophy of the deeper layers of the epidermis which is responsible for persistence of the itching even after the ringworm is cured. Such cases require adequate thyroid medication and keratolytic ointments like salicylic acid in fairly large doses— $\frac{1}{2}$ to 1 dr. to an ounce in lanolin base.

On the hard skin of the palms or soles this disease is very often associated with allergic states—*cheiropompholyx*, a condition which does not yield to vigorous and systematic local treatment. Under such conditions the cause of the allergy should be carefully investigated and removed, and then the local treatment will take effect.

In people who sweat rather profusely on their feet, a nidus of ringworm infection can almost always be found in the cleft between the fourth and fifth toes; the skin looks sodden and dead and starts itching as soon as it gets dry. Breach of surface epithelium favours secondary infection with pyogenic cocci, and inflammatory reactions and cellulitis are not uncommon complications which require special treatment as the merit of the cases demands. Uncomplicated cases are best treated mainly on prophylactic lines; the clefts between toes should be dried carefully after the bath and sprinkled lightly with sulphur-camphor dusting powder before putting on socks or stockings. Oozing of serum should be treated with 20 per cent. silver nitrate solution painted on at night

and repeated for four consecutive nights. Painting with resorcin $\frac{1}{2}$ dr. in an ounce of compound benzoin tincture for the subsequent 3 or 4 days effects a complete cure.

All other types of dry scaly ringworms of the body can be treated on these general lines and the importance of prophylaxis should be impressed upon the patient (1) Camphor and coconut oil (5 to 10 gr. to 1 oz.) to be rubbed well in before bath. (2) Lysol fomentation (15 to 20 drops to a pint of warm water) for naturally moist areas like the groin, scrotum and axilla, night and morning. (3) Ointments containing salicylic acid, resorcin and benzoic acid, applied twice daily. (4) Sulphur-camphor dusting powder when the irritative lesions are cured.

Ringworm of the nails. Two clinical varieties are commonly met with, namely, (a) *The hypertrophic form*: where the fungi affect the bed of the nail causing thickening and black discolouration of the matrix, which becomes very dry and brittle. The lesions can sometimes be seen as parallel lines along the long axes of the nails, and this gives it an appearance of 'worm-eaten wood'; the cuticle generally remains unaffected. Secondary infection may occur giving rise to paronychia when the soft tissues of the terminal phalanges become swollen and very painful so that hot fomentations, antiseptic baths or even surgical interference become necessary. Even the uncomplicated cases are difficult to treat owing to the fact that fresh nails growing on the beds at once become infected, and unless the whole nail is removed and the bed treated thoroughly, radical cure is not effected. Best results are however obtained by scraping the nail thin with a nail file or knife after softening with 5 per cent. solution of caustic soda and then painting with either 3 per cent. solution of copper sulphate or a paint consisting of perchloride of mercury 2 gr., tincture of iodine 1 dr., chrysarobin 10 gr., water 1 oz. It stains the nails rather badly. The scrapings should be done every day for about 6 months, which is the time taken by the nail to grow from the cuticle to the tip. Care should be taken not to injure the cuticle or any part of the soft tissues around the nails when scraping, otherwise the ringworm paint may produce intense irritation, or even drug dermatitis. For rapid shedding of the nail X-rays may be used, but certainly not as a routine measure. Prophylaxis is very important—especially for infection of toe nails; socks and stockings should be boiled every day, and the insole of shoes and slippers wiped with lysol lotion (1 in 20) every other day. Sulphur-camphor dusting powder should be used on the feet lightly sprinkled on the toes and between clefts before putting on socks or stockings.

• (b) *The atrophic form*: the fungus attacks the surface of the nail matrix which becomes very thin, friable and discolored. Growth of the nail is markedly hindered, and the cuticle at the base of the nail is sometimes raised up owing to the accumulation of dead keratin substances underneath. The horny skin tissues around the nails are some-

times infected especially in the toes. Treatment in such cases is not very difficult because all local applications can reach the site of infection which is more superficial than in the hypertrophic form. The same line of treatment and prophylaxis applies for both the hypertrophic and atrophic forms and it is necessary to continue with remedial measures for about 6 months.

Infection with Organisms of the Genus *Malassezia*. Two types of infection are met with:—(1) In the scalp, dry or oily type of seborrhœa, caused by *Malassezia ovalis*. (2) On the face, neck and body, fine furfuraceous, scaly, pigmented or depigmented lesions caused by *Malassezia furfur* and known as pityriasis versicolor or 'chuli'. It is not yet definitely known whether *Malassezia ovale* and *Malassezia furfur* are different species of the genus *Malassezia* or are the same organism undergoing morphological and cultural changes owing to difference in the substrate in which they are growing.

SEBORRHŒA. It is a mild inflammatory condition of the scalp and body due to infection by the fungus *Malassezia ovalis* or bottle bacillus of Unna. The primary infection is always on the scalp and later on, spreads on the face and the upper part of back and chest. On the face it causes acne and on the body, seborrhœic dermatitis. The predisposing factors are individual susceptibility and heredity, of which the latter determines the numerical distribution of the sebaceous glands in a particular area of the skin. The clinical character of the disease varies with the age. In infants, the 'vernix caseosa' becomes infected with bottle bacilli and forms what is called the 'milk crust' which produces irritation, inflammation and desquamation of the surface epithelium. A few weeks or months later, the clinical picture may be completely changed to one of infantile eczema owing to an acquired hypersensitiveness, generally to milk, which renders the skin very irritable, and this allergic state augments the inflammatory changes induced by the primary fungous infection. The lesions are mostly confined to the scalp, cheeks and legs, but may spread all over the body. As an acute or subacute condition, it produces severe irritation and scratching; the resulting breach of surface favours secondary infection with streptococci and staphylococci causing impetigo and boils.

TREATMENT. Remove the vernix caseosa by soaking well with olive oil and then apply mild soothing liniment, such as liniment calamine. For the impetigo, ammoniated mercury ointment 5 gr. to an ounce, or an ointment containing zinc oxide 10 gr., ammoniated mercury 2 gr., in one ounce of vaseline are used.

The disease usually remains quiescent between 5 and 15 years and reappears at puberty. In the scalp the dry type of seborrhœa is called dandruff or scurf and in subjects with hyperactive sebaceous glands, it produces seborrhœa oleosa. The scalp is full of white or greyish scales which may be dry and powdery in the dry type, or wet and clay like in

the oily type. The scales are formed by rapid desquamation of the horny layer consequent on the inflammation set up by the fungus. The degree and extent of the disease varies a good deal. On removing the scales red and inflamed areas are left on the scalp. The lesions may spread to the adjacent areas on the forehead, face, neck; the back of the ears is also a very common site of affection. In the early stages of the disease the mild irritation stimulates the growth of the hair but later on causes loss of hair and baldness.

TREATMENT. Remove the scales by soaking well with olive oil for one or two hours; shampoo the hair with spirit soap consisting of soft soap 1 oz., rectified spirit 2 oz., or green soap 1 oz., ether 1 oz., rectified spirit 1 oz., and then apply resorcin lotion containing resorcin—30 to 40 gr., spirit of ether 1 dr., spirit of rosemary 1 dr., castor oil 10 min., rose water up to 1 oz. For people with light coloured or grey hair, euresol should be substituted to avoid staining of the hair. If the disease does not yield to this treatment, apply an ointment containing acid salicylic 10 to 15 gr., sulphur precipitate $\frac{1}{2}$ oz., lanoline 2 dr., vaseline up to 1 oz. or mercury oleate ointment (10 per cent.) at night. In the morning remove the ointment with olive oil and apply the resorcin lotion after bath. Seborrhœa of the scalp is very persistent and requires prolonged treatment. When the acute conditions have subsided the application of the ointment at night is discontinued; the spirit soap shampoo is given twice weekly and the resorcin lotion is used as hair dressing every day. In severe cases the hair should be cropped short.

SEBORRHŒA CORPORIS. When the infection of the fungus spreads to the body, a mild inflammatory reaction of the skin of the neck and upper part of the trunk—commonly called flannel rash—is induced. The skin is covered with fine furfuraceous scales. Later on the skin may be thickened and lichenoid, the hair follicles may also be affected causing peri-follicular hyperkeratosis—seborrhœic folliculitis. On the face the follicles stand out prominently and are hard and shotty to the feel. Extension may occur to the trunk and extensor surfaces of the arms and forearms, and sometimes the whole body as far down as the lower extremities may be involved. The condition is very distressing when a large area is affected; it causes great irritation and the patient is seen scratching almost all the time.

Treatment. Sulphur is the sheet anchor of treatment in this disease. Any of the sulphur lotions, of which the following are used more commonly, can be applied after bath. *Yellow sulphur* lotion consists of precipitated sulphur 30 gr., glycerine 10 min., absolute alcohol 2 dr., lime water 2 dr., and water 1 oz. The *compound sulphur* lotion consists of precipitated sulphur 1 dr., rectified spirit 2 dr., salicylic acid 10 gr., tragacanth powder 5 gr., and water 1 oz. The sulphur lotion should be rubbed well on the affected area which is then dusted with a powder

containing precipitated sulphur 1 dr., camphor $\frac{1}{2}$ dr., acid benzoic 2 dr., starch powder $5\frac{1}{2}$ dr. When rapid desquamation is required *white sulphur lotion* consisting of sulphuretted potash 15 gr., zinc sulphate 15 gr., tragacanth powder 4 gr., water 1 oz. can be used.

ACNE VULGARIS. It is an inflammatory condition of the sebaceous glands caused by *Malassezia ovalis*. The predisposing causes are, (i) age—it occurs during puberty when the sebaceous glands undergo full and rapid development along with the attainment of functional maturity of the gonads, (ii) constitutional disorder, e.g., anæmia, (iii) constipation and (iv) too highly fatty food or excess of carbohydrate in the diet. The determining cause is infection by the fungus and the contributory cause, a secondary staphylococcal infection leading to suppuration. The excessive secretion of the sebaceous glands favours the growth of the fungus which obstructs the gland mouths and thereby sets up local irritation. The plug obstructing the mouth of the glands is called the comedo and consists of the desquamated horny epithelial cells and a mass of fungi. The obstruction causes a condition of partial anærobiasis which favours the growth of the acne bacillus. The commonest sites of this affection are the face and forehead, but the upper part of the back and front of the chest are also affected.

Treatment. (i) General. Correction of constipation, dyspepsia or anæmia and improvement of the general health are very important. Diet should be light and easily digestible. (ii) Seborrhœa should be effectively treated. (iii) Local. The comedones should be pressed out with an extractor and not by means of the finger nails. The face should be washed in hot water—as hot as the patient can bear—and sulphur or spirit soap, and then one of the sulphur lotions applied locally. When suppuration has taken place, the boils should be lanced and antiseptic compresses applied. Staphylococcal vaccines are sometimes useful in suppurative cases. In severe and intractable cases X-rays improve the condition.

PITYRIASIS VERSICOLOR. (Bengali—*Chull*). The lesions, in this condition consist of yellow or yellowish brown, slightly scaly, macular patches, mostly on the trunk, face, neck and sometimes on the upper extremities. As a rule it does not extend to lower extremities. Except for causing discolouration of the skin and slight itching it does not produce any subjective symptoms. The disease is commonly seen during summer and the rainy seasons.

Treatment. Hot bath with sulphur soap for toilet and then application of one of the sulphur lotions. The sulphur-camphor dusting powder should be used as a prophylactic for some time after the cure is effected and in the beginning of every summer and rainy seasons.

It should be explained to the patient that the nidus of infection is in the roots of hair and regular treatment of the scalp with shampoo and resorcin or euresol hair lotion is essential. Mustard oil has a

certain amount of inhibitory action on *Malassczia ovale* and can be used with advantage. European patients, however, do not like the greasy feel in the hair. Beta naphthol 20 gr., dissolved in an ounce of cocoanut or olive oil can be used for soaking into hair overnight which can be washed off with spirit soap shampoo the next morning. For extensive cases involving the face and body, separate towels for drying the head, and the face and body is recommended. Swabbing the forehead, back of the neck, ears, axillæ and groins with rectified spirit every day after bath prevents spread of the infection on the body.

ACTINOMYCOTIC LESIONS OF THE SKIN AND NAILS. The causative organism, *Actinomyces keratolytica*, affects the horny skin of the soles of feet, the nail beds in the toes and the hard skin at the bases of the balls of the toes. Clinically, three types of lesions are met with, viz., 'laja' or sodden skin, 'phata' or cracked foot and 'chaluni' or sieve-like condition of the soles. The toe nails, when affected, appear thinned out 'worm eaten' and almost black in colour. The palms of the hands are affected in a small percentage of cases. In all cases there is an associated hypertrophy of the horny layer with areas of keratolysis distributed in lines—'phata'—or around small circumscribed pits—'chaluni'—going as deep as the true skin and which makes walking extremely painful. Secondary infection and abscesses are not uncommon complications from mechanical injury from thorns or gravel.

Treatment. Treatment consists of cleansing up the cracks and pits thoroughly and painting with commercial formalin lotion (15 to 30 min. to 1 oz. of water or glycerin). Prophylaxis in the way of protection with shoes or sandals is very important.

External Diseases due to Bacteria

STAPHYLOCOCCI. Infection of the skin by these organisms may be divided into three main groups : (a) superficial infection of the hair follicles causing suppurative folliculitis (sycosis); (b) infection of the sebaceous glands and the adjacent tissues causing a certain amount of tissue necrosis and formation of limiting barriers—boils and abscesses; (c) infection of deeper structures, such as sebaceous glands and sweat glands, with extensive tissue necrosis and tendency to rapid extension—carbuncles. Staphylococci are universally present on cutaneous and mucous surfaces which are in contact or in communication with the external air. So long as there is no breach of surface from external injuries, chemical or mechanical, staphylococci can be harboured for an indefinite period without causing any lesions. The organisms can sometimes gain entrance into the deeper structures by lymphatic permeation. The most important portals of entry are the dilated mouths of sebaceous, sweat or mucous glands, even though the surface of the skin or mucous membrane may remain intact. Depending on the vitality of the tissues invaded and the toxicity of the strain

of staphylococcus, there may be produced simple boils involving only the hair follicles, abscesses with a certain amount of necrosis of tissues and formation of limiting barriers to the inflammatory process or carbuncles with extensive sloughing of the tissues tending to spread fairly rapidly in all directions. The primary lesions are not very difficult to diagnose and in all the lesions, whether superficial or deep, the four important signs and symptoms are always present, namely, pain, heat, redness and swelling.

Superficial infection. The hair follicles of the moustache and beard areas, front part of the legs, front and outer sides of the thighs, and the pubic region are sometimes infected by staphylococci giving rise to a condition called sycosis (barber's itch or coccogenic folliculitis). Each hair shaft is surrounded by an inflammatory pustule, the follicles are distended, painful and irritable, the skin between affected follicles being erythematous and painful. There is always a tendency towards cicatrization on healing so that the hair is completely destroyed and the skin badly scarred. In men, it is a particularly intractable disease in the shaving area and usually cure is prevented by infection of fresh follicles by the razor blade. In India, friction of the border of the 'dhoti' or 'sari' keeps up the disease in the shin areas. In rare instances, all the follicles of the body hairs, including those of the eyebrows and eyelashes, may be affected.

Treatment. Patients should be advised to give up shaving for sometime. The skin should be cleansed with warm olive oil and gentle friction with a piece of soft muslin or gauze followed by swabbing with weak antiseptic lotion, e.g., 1 per cent. carbolic lotion. Hot boric compress is useful in cases with acute inflammatory reaction in markedly hirsute subjects. Manual epilation of all loosened hairs should be done morning and night. A very useful and reliable remedy is 5 per cent. gentian violet lotion in 20 per cent. alcohol,—(gentian violet 20 gr., absolute alcohol 1½ dr. and water 1 oz.)—painted on morning and night. The only objection is the staining of the skin which is rather difficult to wash off. Other aniline dyes have been tried with fairly good results but the same objection holds for all the remedies in this group. Vaccine therapy yields very indifferent results. Successful epilation of the affected area definitely establishes a cure, for which X-rays have been very effective. It is not advisable to expose large areas over a long period as it may produce X-ray dermatitis or burns.

Prophylaxis has to be carried out by the patient with meticulous care. The razor blade should be washed thoroughly with soap and water and wiped down with 20 per cent. formalin solution immediately after shaving; the brush should be kept soaking in 20 per cent. formalin lotion for half an hour and washed thoroughly in water immediately before use. All cuts and abrasions during shaving are to be touched with absolute alcohol which can also be used for swabbing the beard and moustache area after the shave. If the skin feels too harsh and irritable,

salving with liquid paraffin at night has a very soothing effect and ensures an easier shave the next morning. Too frequent washing with soap and water is decidedly harmful.

BOILS AND CARBUNCLES. In the initial stage when the boil is just coming up, the best treatment is to apply cold compresses to reduce the hyperæmia and relieve the tension on the soft tissues. Weak antiseptic lotions, e.g., acriflavin 1 in 5000, carbolic acid 1 in 100, or plain calamine lotion can be used with advantage, and this line of treatment may abort the formation of a boil or an abscess in a certain percentage of cases. Exposure to ultraviolet light is very beneficial at this stage and sometimes prevents formation of the abscess. There should be no surgical interference unless and until pus has formed and the abscess is walled off from the surrounding tissues by a barrier of granulation tissue. After lancing, a hot compress, changed every 4 hours, is recommended to dislodge the adherent slough. The hot compress sometimes infects fresh sebaceous gland mouths in hairy areas like the axilla or pubis. The surrounding skin should be well swabbed with absolute alcohol morning and night with a view to sterilizing and hardening the skin, thus making it more resistant to infection. When the cavity is nearly filled up, it should be dressed with borovaseline ointment. Staphylococcal vaccine is not of any great curative value but it is a good prophylactic for people susceptible to 'mango boils' which recur with almost unvarying regularity every summer and rainy season. Usually, such people are subject to active seborrhœa of the scalp and treatment should be directed towards this important focus in order to prevent relapses. Recurrences and resistance to treatment are, in a small percentage of cases, due to lowered defensive power of the tissues—local kataphylaxia; such cases require internal administration of calcium, manganese or tin salts to restore normal tissue metabolism. Prophylaxis is adopted on the same lines as for seborrhœa. For carbuncles, hot boric compress and exposure to ultraviolet light are useful in the initial stage. When there is marked œdema of tissues or extensive sloughing, the affected area should be incised and dressed aseptically. Vaccines are useful at this stage and local packing with gauze soaked in antiviral lotions are effective.

Staphylococcal infection of the deeper tissues sometimes produces granulomatous nodules growing above and out of the general skin surface. The condition is called *granuloma pyogenicum* or *botryomycosis*.

PRICKLY HEAT. The affection begins in people who sweat rather profusely during summer months in the tropics and are in the habit of wearing too many tight-fitting clothes. The mouths of the sweat glands are obstructed owing to a sodden condition of the epithelium due to excessive perspiration and this produces sudamina vesicles on the body and desquamation on the palms. These sudamina are tiny

vesicles filled with clear fluid, the lesions being mostly found in the axillæ, bends of the elbows, on the chest, and in children usually on the back. Individual lesions are surrounded by a red inflammatory areola and are called prickly heat. They are extremely irritable and when abraded may develop into pustules which eventually lead to the formation of boils and abscesses. When these vesicles are infected secondarily with staphylococci, they appear white, like sago grains. In the axillæ these pustules generally attain fairly large size and are called *Pyosis mansonii*. Persons subject to seborrhœa are more susceptible to prickly heat because the primary infection with the fungus causes obstruction of the mouths of the sweat glands and consequent irritation favours secondary infection with staphylococci.

Treatment. The most important measures to check this excessive sweating are curtailing of vigorous physical exertions, avoidance of heavy tight-fitting clothes and hot, spiced foods. Intense irritation is best controlled by swabbing with calamine lotion or ammonia solution (1 dr. of Scrubb's ammonia to a pint of cold water) and sprinkling with sulphur-camphor dusting powder. Talcum powder is recommended for sensitive skins because they tend to develop sulphur dermatitis. The scalp must be treated with resorcin lotion at the same time as otherwise the local treatment of the skin will only give temporary relief. *Prophylaxis.* The precautionary measures should be commenced before the humid pre-monsoon season has set in and carried on until the rainy season is almost over.

STREPTOCOCCI. Streptococcal infection of the skin is superficial in character and produces a good deal of induration of the tissues with accompanying lymphangitis and a certain amount of constitutional disturbance. These organisms are present in healthy tonsils, teeth, intestines and other mucus surfaces but are hardly ever found on the surface of the skin. The extent of damage to the tissues depends, as in the case of staphylococci, on the susceptibility of the patient and toxicity of the infective strain. Streptococcal infection of the skin may be divided into (a) acute infection of the skin spreading rapidly through the lymphatics—*erysipelas*, (b) sub-acute superficial infection—*impetigo contagiosa*, and (c) chronic infection which is mostly localised—*ecthyma*.

ERYSIPELAS. The skin and subcutaneous tissues are acutely inflamed and there is induration of the deeper tissues. Clinically, the appearance varies from a transient hyperæmia to intense inflammation, vesiculation or even sloughing. There is localised swelling, redness and heat, the border is raised, brawny and indurated and the infection advances rapidly along the lymphatics. The centre of the lesion is paler than the margin and here the skin shows early degeneration. The onset is generally preceded by malaise and depression and is accompanied by severe constitutional symptoms. The fever which is often

preceded by a fairly prolonged rigor may rise as high as 105°C. All the symptoms of severe intoxication, namely headache, vomiting, anorexia, and joint pains are present; there is marked leucocytosis. In the worst types of cases, bronchopneumonia, hæmaturia, cutaneous petechiae, septic embolism or meningitis may supervene within two or three days of the onset. Such cases end fatally, especially in the two extremes of life. Cases of moderate severity, however, run an acute course lasting for about a week or 10 days after which the cutaneous inflammatory reaction subsides, the advance is arrested, the temperature comes down by lysis and general toxic symptoms gradually clear up. The affected area may remain hyperæsthetic for a considerable time after cure and show impaired capillary circulation, alopecia, thrombo-phlebitis or telangiectasis. Recurrent types of erysipelas have been described which are consequent on an active septic focus in the bowels, teeth, tonsils or throat and nose; the clinical picture is that of an acute lymphangitis and lymphœdema with access of fairly high temperature preceded by rigor. The duration is short, lasting about 3 to 5 days, and constitutional disturbances and toxæmia are not very severe. Any part of the body may be affected and repeated attacks at the same place result in a good deal of thickening of the subcutaneous tissues—a condition commonly known as *elephantiasis nostras*. The first attack is usually the most severe. Erysipelas of the facial area consequent on scratching an acne lesion is not only fairly common but is often fatal, especially in diabetic subjects.

Treatment. Palliative treatment is given during the acute stage. The patient should be strictly confined to bed with an ice cap if the temperature is above 102.4°F. Diuresis should be encouraged by frequent iced drinks; ice should be given to suck to control vomiting. Bowels should be opened with small enemata; rectal saline with glucose may be given if persistent vomiting interferes with the intake of nourishment. Alkaline mixtures are useful in so far as they help elimination to a great extent. Tinct. perchloride of iron in 15 min. doses can be given with advantage when the irritability of the stomach has abated. Liquid diet, e.g., barley water, gruel, diluted milk (if tolerated), glucose, raisin, tea, etc., should be given in small quantities and at frequent intervals; feeds should be iced to guard against recurrence of vomiting. *Local.* Iced compress of weak antiseptic lotions, e.g., acriflavin (1 in 5000) or boric acid 5 per cent. are very useful; lotio ichthyl 10 per cent. has also been found useful. The inflamed skin should be dusted with talcum powder and the area just beyond and all around the advancing edge painted thickly with surgeon's collodion or tincture perchloride of iron. All vesicles and pustules are carefully punctured with strict aseptic precautions and covered with dry dressings; surgical interference is necessary only when an abscess has formed. When the acute stage has subsided the parts should be dressed with 25 per cent. ichthyl ointment. *Specific.* Opinion is still divided on the use of anti-toxin or antiserum. Streptococci have very little of exotoxin and hence

it is believed that specific antisera are of hardly any curative value. Recently, polyvalent antistreptococcal specific sera have been produced by firms of repute and the results of treatment with these sera are very encouraging. Twenty c.cm. of the serum should be given subcutaneously as early in the disease as possible, all precautions being duly taken to guard against anaphylaxis in sensitive subjects. Injections are given every other day, the total quantity required to effect a cure hardly exceeds 150 c.cm. Calcium lactate 15 gr. is given per os three times a day during the course of injections. Oral administration of serum is of very doubtful efficacy. In children blood transfusion has good effects. *Curative and prophylactic.* To prevent recurrences a thorough investigation should be made to locate any latent septic focus or any other latent concurrent disease. With this object in view the clinician should combine with the laboratory worker so that both may work hand in hand for the benefit of the patient. It should be borne in mind that a single negative laboratory finding is of no significance at all; it is only after careful repeated examinations that one can definitely affirm or deny the presence of latent septic foci. Autogenous vaccines are of great value in this particular field. General tonics, e.g., iron, arsenic, calcium, and nourishing food and change to a salubrious climate constitute the three important adjuncts on which cure and prophylaxis are based.

IMPETIGO CONTAGIOSA. The commonest superficial lesion of the skin due to streptococci is *impetigo contagiosa* which is characterised by shallow ulcers surrounded by a halo of light erythema—(only seen in fair subjects) and covered with a light yellowish crust. There is slight oozing of serum which is charged with streptococci. The disease is auto-inoculable and contagious to others. The patient usually inoculates himself over various places from the exudate by unconscious picking and scratching and in schools and boarding houses it may occasionally spread in epidemic form. Children are more susceptible than adults owing to the skin being very fine in texture and it is a common experience to find babies in arms picking up the infection from other children or even their ayahs and nurses and then passing it on to the mother. The ulcers involve only the superficial layers of the epidermis and do not leave any scar on healing. As a rule they are not very painful but somewhat tender on pressure. There is always a certain amount of hyperpigmentation at the periphery of the healed area, but this gradually fades out provided the lesions are not of very long standing.

Treatment. Ammoniated mercury, 5 to 10 gr. to an ounce of lanoline or vaseline base, acts as a specific. Cure is established in 3 to 5 days. The superficial crusts should be softened with olive oil and gently removed before a thin smear of the ointment is applied night and morning. Induration and weeping which accompany some cases are best controlled with cold compresses of weak acriflavin lotion (1 in 3 to

5 thousands) or continuous application of calamine lotion. Repeated attacks at the same site produce tissue kataphylaxia, which condition requires general treatment with iron and arsenic tonics or cod liver oil. Vaccine therapy is hardly ever necessary except in long standing cases in adults where lowered vitality retards healing. The deep or veldt sore type of impetigo which is often found on the hands and feet does not respond to treatment with ammoniated mercury; the lesions are deeper, crateriform with good deal of sanious discharge and are often confused with Naga sore. Cold compresses with 1 in 3,000 acriflavin lotion clear up the lesions in about a week or 10 days. Auto-vaccine is of proved curative value.

ECTHYMA. This condition is very similar to impetigo but the infection extends more deeply in the skin and involves the corium. It usually begins as a vesicle or vesico-pustule which enlarges fairly rapidly and ulcerates with formation of a thick crust adherent at its edges to the skin. Lesions are usually multiple and in some instances are ushered in with fever and malaise. There may be a good deal of pain and tenderness owing to its deeper situation and the induration of the tissues. When the crust is removed a saucer-shaped ulcer with a raw base and elevated edges is revealed. These ulcers are auto-inoculable and leave pigmented or depigmented scars on healing.

Treatment. The crusts should be removed by soaking with warm olive oil, no soap and water should be used subsequently. Locally, cold compress with 1 in 3000 acriflavin lotion during the day, weak ammoniated mercury ointment (5 gr. to 1 oz.) or borovaseline at night yield the best results. In extensive cases the patient should be kept in bed and treated with iron and arsenic tonics or calcium lactate 10 gr. and parathyroid 1/10 gr. twice daily on an empty stomach. Every attention should be paid to improve the general health especially in growing children who respond well to cod-liver oil, malt or ostelin. Sunlight and ultra-violet radiation are valuable adjuvants in delicate subjects. Autogenous vaccine is of proved curative value but disappointing results are inevitable if too much faith is pinned on the injections alone. All focal infections should be carefully sought for and treated thoroughly.

DIPHTHERIA. Infection of the skin by *Corynebacterium diphtheriae* occurs as an acute primary condition or as a secondary infection on pre-existing sores and abrasion of the skin. The cutaneous involvement may be independent of infection of the mucous membranes. The characteristic lesions shew ulcers with swollen edges and a false membrane of a greyish colour covering the base. Constitutional symptoms are fairly severe and out of proportion to the number of ulcers which are rarely multiple especially in the primary type of cases. The disease is highly contagious and usually more than one inmate is affected in boarding schools or army barracks. Impairment of the

cardiac function sets in early and the case often terminates fatally if specific treatment is delayed too long.

Treatment. Injection of the antitoxin in full doses (50,000 units) near the lesion gives uniformly successful results. Local dressing with lint soaked with the antitoxin is also indicated. The injections should be repeated till constitutional symptoms disappear. Segregation and quarantine are essential for preventing an epidemic in boarding schools, etc.

ANTHRAX (Malignant pustule). The disease is caused by a spore forming bacillus, *Bacillus anthracis*, and is commonly seen in people dealing in hides, cattle farmers, wool sorters, tanners, butchers and stable grooms. A few cases have been reported to have occurred from the use of cheap pony-hair shaving brushes. It is an acute and generally fatal disease with accompanying suppurative adenitis and grave constitutional symptoms, septicæmia and metastatic abscesses. A typical lesion is generally seen as an inflammatory papule within a few hours after the infection. The inflammation spreads rapidly and a blister appears surrounded by intense infiltration and oedema. Spontaneous rupture of the vesicle occurs early, exposing a dark brown eschar surrounded by small vesicles and pustules resting on a red, swollen and indurated base. The discharge is purulent or sanguineous and is full of *B. anthracis*. The inflammatory signs increase, oedema of the tissues spreads, other bullæ develop accompanied by high temperature and grave constitutional symptoms. The regional lymph glands suppurate, and septicæmia with metastatic abscesses in vital organs precipitate a fatal termination. In milder cases, the constitutional symptoms are slight and the gangrenous tissue sloughs out leaving a clean ulcer which heals by formation of granulation tissue.

Treatment. Immediate and wide excision is urgently indicated. When the face is involved multiple incisions and cauterising with phenol or tincture of iodine may be substituted for wide excision which causes marked disfigurement. Antianthrax serum should be given early with an initial dose of 100 c.cm. The dose is repeated till the fever subsides. Injection of the serum at the site of the lesion is recommended and sometimes yields good results. Normal bovine serum, which has a certain amount of antibodies against anthrax normally present may also be used when antianthrax serum is not available.

All linen, clothes and utensils should be sterilised every day in the autoclave at a temperature of 120°C. The soiled dressings should be burnt at once.

GLANDERS (Equinia, Farcy). The disease is caused by infection with *Actinobacillus mallei* and is commonly seen in grooms, veterinarians and cattlemen in either an acute or chronic form. The skin of the face and the nasal mucous membranes are commonly affected. A typical skin lesion begins as an inflamed papule or vesicle which

rapidly becomes nodular and then pustular and ulcerated. The ulcers are irregular, excavated with undermined edges and the base is covered with purulent or sanguineous discharge. In the course of a few days or weeks secondary nodules appear along the lymphatics; these break down and result in confluent sloughing, ulcerating lesions involving extensive areas of the skin. Infection of the nasal mucous membrane is characterised by a preliminary catarrh and epistaxis followed in a few days or weeks by extensive ulceration and sloughing with purulent discharge loaded with bacilli. In severe cases the temperature ranges high and a fatal termination is heralded by asthenic diarrhoea and involvement of the intestines. Constitutional symptoms are less severe in chronic cases but a fatal termination from intercurrent diseases, nephritis and general exhaustion is almost the rule.

Treatment. Immediate excision and curettage followed by cauterising with phenol is the most important measure to save the patient. Injection of the antitoxin, Mallein, in 1 to 2 c.cm. doses is of considerable value especially in chronic cases which have to be treated more or less symptomatically in other respects.

Segregation and precautions regarding sterilisation of linens, utensils, etc., is of great importance in prevention of the disease which, fortunately, has become quite rare nowadays.

Tuberculosis of the Skin

The lesions produced by *Mycobacterium tuberculosis* are either primary or secondary to pre-existing lesions due to various causes. Whatever be the character of infection, the reaction of the skin to invasion with tubercle bacilli varies widely in different subjects and hence the clinical appearance, course, duration and response to treatment of skin tuberculosis vary widely as well. The criterion of diagnosis is, in all cases, based upon the histological changes seen in biopsy material and upon the results of animal inoculation with emulsion of tissues removed from the affected areas. Evidence of tuberculous lesions elsewhere in the body and reaction to tuberculin are taken as corroborative of histological diagnosis. The lesions are clinically classified as follows:—*Localised forms*—(i) Lupus vulgaris, (ii) Ulcerative tuberculosis, (iii) Verrucose tuberculosis, (iv) Scrofuloderma. *Exanthematic forms*—(i) Miliary tuberculosis, (ii) Lichen scrofulosorum, (iii) Papulonecrotic type, (iv) Erythema induratum or Bazin's disease, (v) Sarcoid of Darier, Roussey and Boeck.

(A) LOCALISED FORMS. (i) *Lupus vulgaris*. The lesion consists of very small minute nodules, translucent in colour and deeply embedded in the infiltrated true skin, and thereby giving rise to reddish brown patches which heal in the centre with production of deep depigmented scars and spread diffusely at the other parts of the lesion for an indefinite period of time. On diascopic examination the active

portions of the lesion can be seen to be composed of deep-seated granulation tissue with characteristic 'apple-jelly' colour. Fairly large plaques are formed by coalescence and development of new nodules and these may be elevated above the level of the skin. Adherent scales are frequently seen especially at the margins. The disease causes wide destruction of the tissues and leads to very ugly deformities, contractures and ectropion. There are two clinical types of lupus vulgaris, namely, atrophic and hypertrophic; both types may set in acutely and in rare instances in more than one area at the same time with a fair amount of constitutional disturbances; this is especially noticed when there are active foci of systemic infection as well.

The face, particularly the nose, is most frequently affected although the lesions may appear on any part of the body including the mucous membranes.

In the atrophic type of the disease, the nodules undergo spontaneous involution and ultimately disappear, leaving thin, scaly, atrophic and depigmented scars. On the other hand, healing may not take place and the margins then assume a gyrate or serpiginous outline and continue to spread with formation of minute fresh nodules.

The hypertrophic form is characterised by hard, thick, rough and depigmented cicatrices which are almost like keloids. In the genital region, ankles and dorsum of the feet the lesions often become papillomatous or even verrucose in character with a fair amount of exudation and formation of crusts. Papillomatous types of lesion are also found on the mucous membranes of the nose and lips, the individual patches being sharply defined and of reddish or grayish colour. Lupus vulgaris like all other tuberculous diseases, is slowly progressive and its chronic course may extend over many years with periods of intermission and exacerbation.

(II) **Ulcerative type.** This disease is almost always secondary to active tuberculosis of the internal organs and attacks the contiguous skin of the mouth, nose, anus, urethra and vulva. During the early stages, small yellow miliary tubercles form on the skin and these break down in the course of a couple of weeks into oval or rounded granulating, sluggish and painless open ulcers. The lesions are comparatively superficial; the edges are soft and irregular and the bases are raw, uneven and sometimes purulent. Formation of thin yellowish crusts is not very rare. In rare instances, ulcerative tuberculosis may be superimposed on pre-existing lesions of the skin like simple injuries and impetigo. This type is always due to localised infection from outside, the site of predilection being the soles of the feet, backs of the hands, fingers and buttocks.

(III) **Verrucose type.** The lesion begins as a group of small wart like papules which increase in number and coalesce to form brownish or reddish coloured oval patches. There is a marked hypertrophy of the horny layer giving it a papillomatous appearance and the surface may

appear as if ploughed up and fissured. The margin of the patches is dark red and is accompanied with fair amount of exudation or even suppuration and crusting. Patches are usually single and occur on the exposed parts of the body following contact with infected materials especially tuberculous cadavers or carcasses. In children, the disease is often seen on the buttocks knees and thighs as they are in the habit of pulling themselves along the floor and thus come in contact with infected sputum. In people walking bare feet the disease is commonly seen on the soles. Sometimes vegetative outgrowths appear at the periphery where extension takes place by coalescence of contiguous patches. The disease runs a very chronic course; spontaneous recovery occasionally takes place leaving thin depigmented scars at the affected areas. *Verruca necrogenica* or post mortem wart is another type of verrucose tuberculous lesion and occurs on the dorsal surface of the thumb or fingers particularly on or near the knuckles and interphalangeal joints; they generally appear at the site of some previous injury or abrasion. The lesions consist of pea or bean sized papular, indurated, warty outgrowths which are red or whitish in colour, and always keratotic. Extension occurs by peripheral spread but they hardly ever break down into open ulcers. Sometimes they disappear spontaneously leaving practically no scars. *Verruca necrogenica* is very rarely followed or accompanied by generalised tuberculosis. Occasionally these warty lesions are infected secondarily by streptococci or staphylococci with ensuing erysipelas or septicæmia. The disease almost exclusively affects butchers, packing house employees, pathologists, anatomists and dissecting room attendants.

(iv) *Scrofuloderma*. The involvement of the skin is by direct extension of the tuberculous disease from glands and lymphatic nodes or subjacent bones. The lesions are in reality the mouths of sinuses leading to the primary caseating or suppurating primary lesion. There is almost continuous discharge of purulent matter from these sinuses the walls of which are reddish, granular and bleed easily. Extensive ulcers are formed when several superficial sinuses run into each other. The subjective symptoms are trivial and constitutional disturbances are very slight or entirely absent. The disease often persists for years and in a large number of cases spontaneous recovery takes place with formation of rough, thick cord-like cicatrices resembling a keloid. Over 80 per cent. of the patients are children and young adults.

Treatment. General hygienic measures are of great importance. The patient should have plenty of good nourishing food plainly but agreeably cooked. Fresh air, sun light and change to a suitable climate are strongly recommended. General irradiation with ultra-violet light for hours at a time has proved to be of definite value.

Internally, cod-liver oil when tolerated should be given in full doses. Preparations of vitamin D, e.g., Ostelin, Irradol, Radiostoleum, etc., are also of proved benefit. Hypophosphites and lactate of calcium

should be given in 10 gr. doses with the two principal meals. Liq. arsenic hydrochlor. in 2 to 5 min. doses is also useful as an alterative and general tonic. Tuberculin in graded doses yields good results in the non-ulcerative lupus vulgaris and tuberculosis verrucosa cutis; ulcerative types do not respond well to tuberculin. A few cases respond well to thyroid extract in one grain doses.

Locally, the best cosmetic results are obtained by heliotherapy with the Finsen lamp but the tediousness of the prolonged treatment is a serious drawback. For rapid improvement X-rays may be substituted but the resulting scars are very hard and disfiguring, especially in case of lupus vulgaris of the face. For smaller lesions of the non-ulcerative type removal by freezing with carbon dioxide snow is the best. Larger patches should be removed either by excision or by surgical diathermy, cutting widely outside the affected area, and deep enough to reach the muscles. Local packs containing 5 per cent. oleate of mercury and 5 per cent. salicylic acid are very useful for verrucose tuberculosis. Salicylic acid and creosote paste prepared by mixing equal parts of each has been used at the Calcutta School of Tropical Medicine with very good results. The paste is spread on a piece of lint and applied to the affected area and secured with a bandage. This is removed when the patient complains of a burning sensation which is felt after about 48 hours. The lesions usually heal up with two such applications; 2 to 5 per cent. pyrogallallic acid ointment is also useful. The site is subsequently treated with soothing liniments and creams. Ektabin ointment prepared from detoxicated tubercle bacilli is beneficial in non-ulcerative types of lesions.

For tuberculous lesions on mucous membranes iodides are given internally in full doses and the patch is kept soaked in hydrogen peroxide in gauze pack. Cure is established by liberation of nascent iodide in the affected tissue. Sodium iodide ionisation is recommended in intranasal lupus vulgaris. The prognosis in tuberculosis of the skin is good as regards life but unfavourable as regards a permanent cure. Except for the verrucose type and lupus vulgaris, all the other types of local lesions are refractory to treatment and very often recur after an apparently complete recovery. Carcinomata may sometimes develop in old scars of lupus vulgaris.

(B) EXANTHERMATIC FORM. (i) *Miliary tuberculosis.* This rare form of skin tuberculosis is nearly always associated with systemic infection and is characterised by an acute generalised eruption of small brownish red papules which break down early and form indolent ulcers. These ulcers are shallow with a circular border which is of a dull reddish colour, the base is pale and uneven and studded with small nodules of miliary growth along with seropurulent discharge. The disease affects small children of strumous diathesis after attacks of measles, scarlet fever or early pulmonary tuberculosis or in adults with advanced pulmonary tuberculosis. Its appearance generally forebodes a fatal termi-

nation. Localised forms are sometimes seen affecting the skin over softening tuberculous glands. The bacilli reach the skin as minute emboli through the blood stream.

(ii) **Lichen scrofulosorum.** The lesions consist of groups of minute, keratotic, follicular papules of light reddish brown colour scattered over the trunk or extremities. Individual papules are firm, flat-topped and may be capped by a tiny pustule or thin scales. The disease is generally found in children with tuberculous affection of the bones or internal organs. It persists for years causing no subjective symptoms. Occasionally spontaneous recovery followed by recurrences are noticed.

(iii) **Papulonecrotic type** (also known as acnitis, folliclis, acne scrofulosorum) :—The lesions generally appear in successive crops on the extensor aspects of the extremities, face and trunk and are characterised by small, firm, discrete, follicular papules which undergo necrosis in the centre and heal spontaneously leaving deep pitted scars. Children and young adults with active systemic tuberculosis are usually affected. The lesions are roughly symmetrical and begin as papulovesicles which develop into nodules, break down and heal up in two to three months to be followed by fresh outbreaks. The papulonecrotic type of skin tuberculosis is often associated with other forms of tuberculous disease of the skin, particularly erythema induratum and scrofuloderma.

(iv) **Erythema induratum.** The disease is characterised by symmetrical, deep seated, indurated, nodular formations about the subcutaneous vessels of the lower legs and is almost exclusively found in young women with glandular tuberculosis. In their early stages, the lesions consist of tender erythematous indurations which slowly develop into deep-seated nodules, the overlying skin becomes dusky or bluish in the course of a couple of months. The centre of the nodules then begins to soften and ultimately breaks down into irregular deeply excavated ulcers with thick undermined edges. Contiguous and neighbouring lesions often coalesce to form large ulcers. Spontaneous recovery generally takes place with formation of deep depigmented scars but fresh indurated nodules develop while the older ones are undergoing involution and thus the disease may persist for years. Constitutional symptoms are slight or even absent. The cause of the disease is attributed to the toxin of *Mycobacterium tuberculosis* causing deep seated 'lymphatism' and inflammatory changes.

(v) **Sarcoid.** (i) *Sarcoid of Darier and Roussey.* The lesions are found on the extensor surfaces of the lower extremities and are characterised by painless, oval or rounded subcutaneous nodules which do not tend to break down or ulcerate. Development of these nodular formations is slow and after persisting for several months they undergo spontaneous involution. Like erythema induratum the disease almost exclusively affects young women who show a strong positive reaction to tuberculin.

(H) *Boeck's sarcoid*. The lesion consists of multiple nodular groups of superficial granulomatous infiltrations, firm and elastic to palpation but without any tendency to break down and ulcerate. The entire cutis is affected, the epidermis remaining almost normal. The surface is covered by a fine net-work of capillaries which is more apparent in the case of a fully developed sarcoid than in the early stages. Evolution is generally slow and the nodules may take months to attain a certain size. Spontaneous recovery generally takes place although it may be delayed as long as a couple of years or so. The face is the site of predilection but the other parts of the body may also be involved. The disease is essentially of a benign nature and causes no symptoms. Its relationship to tuberculosis is doubtful.

Treatment. In view of the fact that exanthematic types of cutaneous tuberculosis is almost always associated with active systemic infection, the importance of general hygienic and dietetic measures cannot be too strongly stressed. Fresh open air life, good nourishing food, sun baths or general ultraviolet irradiation are necessities in spite of the tendency of this group of diseases to spontaneous recovery. In the majority of instances treatment of the active systemic focus prevents recurrences and leads to a permanent cure. Cod-liver oil and preparations of vitamin D in full doses are recommended for every case irrespective of the clinical type of lesions and this may be combined with hypophosphite of calcium in 10 gr. doses three times a day. Preparations of gold sodium thiosulphate, *e.g.*, Sanocrysin, Krysolgan, Solganal A and B, etc., can be used intravenously or intramuscularly with great advantage.

Local treatment has to be varied according to the nature of the disease. Miliary tuberculosis is best treated with Ektabin ointment after swabbing out with weak hydrogen peroxide. A 0.5 per cent. ammoniated mercury ointment may also be used in place of Ektabin. Inunction with raw cod-liver oil has been recommended for lichen scrofulosorum but the objectionable fishy odour is far from pleasing to the patient. An emulsion of liquid paraffin containing 1 per cent. thymol and 3 per cent. of Goulard's extract often yields very good results. The papulonecrotic types of lesions are best treated on conservative lines with cold compresses of calamine or 1 in 5,000 acriflavin lotion. Scars may be softened by gentle massage with hydrous lanolin every night. For erythema induratum, rest and elevation of the affected limbs is the most important part of the treatment. In the preulcerative stage, pain and induration respond to continuous application of calamine and weak acriflavin lotions. When deep ulcers are formed, washing with normal or hypertonic saline followed by dry dressing with antiseptic dusting powders, *e.g.*, thymol iodide or aristol is recommended. An elastic cotton or crepe bandage is also very helpful. Indolent cases do well on circulatory stimulants like liq. strychnine

hydrochlor in 2 to 5 min. doses combined with injection of tuberculin in graduated doses and local ultra violet radiation.

TROPICAL ULCER OR NAGA SORE. The disease is characterised by single or multiple, round or oval ulcers on the exposed parts of the body, chiefly the legs, and occurs in epidemic form amongst indigent labourers in Terai areas during the damp humid monsoon months. The cases begin in May and increase during August, September and October and gradually fall in December. The lesions begin as small inflammatory papules which rapidly form into vesicles, rupture and progress into ulcers. Individual lesions vary somewhat in size and may be as large as 4 inches across; the edges are elevated, undermined and smooth or ragged with an inflamed halo around them; the base is depressed, granulomatous and sometimes covered with a false membrane. Satellite ulcers may develop by auto-inoculation near the original lesion or on other parts of the body. There is a thick, glairy, mucoid discharge which is sometimes sero-sanguineous. In the majority of instances the ulcers develop from some pre-existing minor wounds, the site of predilection being the anterior and posterior portions of the legs, dorsal parts of the feet and the ankles. Formation of crusts is occasionally seen. Some ulcers are extremely tender and painful while others are almost painless.

The disease is considered to be due to a Gram-positive diplococcus with secondary infection of fusiform bacilli and spirochaetes. It is probably transmitted to healthy subjects by some biting insect. Several members in the same family including children are affected by direct contact. A single attack does not confer immunity and the same individual may suffer every year with the advent of the rainy season.

Treatment. Best results are obtained when the patient can be kept at rest and a cold compress of hypertonic saline applied to the ulcers. Ambulatory cases respond well to a gauze pack soaked in a solution containing 10 to 15 per cent. phenol and 5 per cent. copper sulphate kept in place for 24 to 48 hours. Subsequently the wound is dressed with borovaseline or 1 per cent. ammoniated mercury ointment. Painting with a 3 per cent. solution of arsphenamine has been recommended but the results are unsatisfactory.

Prophylaxis in the way of protection from injuries is of great importance. It is also necessary to impress on the indigent labourers the necessity of personal hygiene and avoidance of overcrowding.

External Diseases due to Physical Causes

• **SUNLIGHT.** Extremes of heat and cold damage the skin by altering its normal blood supply through dilatation or constriction of the capillaries, arterioles and venules. In the tropics, the effects of heat of the sun are of importance particularly for European residents whose skin is naturally deficient in the protective filter, namely melanin

pigment. The actual damage, however, is caused more by the ultraviolet than the heat rays and hence erythema, sunburn and blistering of the skin is more intense at bathing beaches or in the open country where freedom from the dust and smoke, common to towns and cities, allows almost unimpaired action of the ultraviolet rays. The reaction varies a good deal according to the sensitiveness of the individual skin, blondes being more susceptible than brunettes. Subjective symptoms may appear within a few minutes of the exposure or may be delayed as long as the next day. The skin becomes intensely red and inflamed, there is a feeling of constant pain and burning, there may be actual vesication single or multiple, which in extreme cases, coalesce into a large bleb. When the reaction subsides, the skin is left more pigmented, and this gives a certain amount of protection against subsequent burns from exposure. In this way repeated exposures may induce sufficient pigmentation of the skin—'tanning of the skin'—to confer almost absolute immunity from solar dermatitis. Aged persons, however, react somewhat differently owing to the loss of elasticity of the skin and may develop keratoses and depigmented spots.

Treatment. Soothing creams, *e.g.*, rosewater ointment (U. S. P.) (spermaceti $\frac{1}{2}$ dr., white wax 3 dr., borax 15 gr., rosewater 5 dr. and liquid paraffin $\frac{1}{2}$ oz.) should be applied freely; the hyperæmic parts may be rubbed down with ice or the part is covered with a piece of lint or gauze wrung out of ice cold liquid paraffin and kept cold by gentle rubbing with ice.

Prophylaxis. Exposed parts should be smeared with a cream containing quinine hydrochloride (2 per cent.), bismuth oxycarbonate (5 per cent.) or disodium naphthol sulphate (5 per cent.) as these compounds absorb ultraviolet rays to a certain extent. They offer no protection against prolonged exposure. Black or red hats, veils and umbrellas offer good protection. Anointing the body with heavy vegetable oils is practiced by indigent people as protection.

DERMATITIS MEDICAMENTOSA. Local application of apparently harmless paints, plasters, liniments or ointments may set up most intensely acute dermatitis in some sensitive skins, the sequence of cause and effect being quite obvious both to the subject and the prescriber. The commonest drugs which cause acute dermatitis are of the nature of chemical irritants; the degree and intensity of the reaction varies according to the nature of vascular response of the skin to external stimuli. Hair dyes, lipsticks, nail paints, eyebrow pencils, depilatories and shaving creams have been active sources of acute dermatitis owing to the various chemicals incorporated therein. Some drugs taken internally also give rise to rashes. For detail see Drug Rashes.

Treatment. Discontinue the particular drug causing the irritation and apply cooling soothing lotions like liquid extract of hamamelis, cold cream or rosewater ointment. The affected parts should be

cleansed with olive oil or liquid paraffin, soap and water being avoided till the acute stage has passed off.

Prophylaxis. It is better to warn the patients to use all stimulating applications first on a small area of the affected part and watch its effects overnight. Extensive inflammation can thus be avoided.

DERMATITIS ARTEFACTA. These are self-inflicted injuries of varying degrees of depth and extent and are found only in highly neurotic subjects who use both chemical and physical means alike to cause the damage. The lesions are always in the accessible areas on the face, body, arms and legs and never on the back. They are quite bizarre both in shape and size and always trail off at one end. Treatment is extremely difficult especially in female patients who have to be kept under the most strictly careful watch. Psychoanalysis and mental therapy should be tried.

ERGO-DERMATOSES OR OCCUPATIONAL DERMATITIS. Various chemicals employed in industries cause a chronic eczematous condition of the skin amongst the workers. The initial damage to the protective horny layer of the skin is done by constant soaking of the hands in water. It has been found that even distilled water which is acid and hypotonic, produces desiccation of the epithelial cells. If it contains some inert salt in solution it may become concentrated and hypertonic from evaporation owing to body heat and lead to oedema of the cells. The dermatitis is thus induced on a hypersensitive or damaged skin so that the substances which the worker may have handled before without any ill-effects now cause intense inflammatory reaction. Repeated and prolonged contact with these products produce changes in the epidermis and vascularity of the skin and may sometimes lead to hyperplasia of the epithelium, keratosis and carcinoma. Barbers, washerwomen, workers in lime, paints and varnishes, photographers, bakers, jewellers, etc., all may develop occupational dermatitis and the diagnosis of this condition offers no great difficulty.

Treatment. In the acute stage symptomatic treatment is resorted to, the pain and irritation requiring suitable sedative local remedies more or less on the same lines as for acute inflammatory lesions due to other causes.

Prophylaxis. Whenever possible the source of irritation must be removed, but when it concerns the vital question of a man's bread and butter, it is difficult to ask him to give up his occupation. Ultraviolet radiation and intensive calcium therapy may prevent repeated extensive attacks.

Internal Diseases reflected on the Skin
DISEASES AFFECTING THE TEXTURE OF THE SKIN
AND ITS APPENDAGES

HYPERKERATOSIS OF THE HORNY LAYER, ICHTHYOSIS.

This disease, which is hereditary and familial, is characterised by the entire surface of the body being covered with dry, shiny scales, dirty grayish or brown in colour, harsh to the feel, and broken up into a 'harlequin' or 'fish scale' pattern by numerous furrows. This parchment-like condition is accompanied with loss of elasticity of the corium and defective development of the sebaceous and coil glands—*Ichthyosis neonatorum*. Lanugo hairs are absent and the scalp is completely bald in extreme cases, indicating involvement of the corium. Survival of such a child is of very short duration—*Ichthyosis gravis*. If the disease starts *in utero* still-birth is almost always the rule. The acquired disease usually appears within the first five years of life and is at first noticeable only during winter months, almost complete recovery occurring in summer. The skin is very harsh and dry, the horny layer has a shiny appearance and is traversed by numerous shallow cracks and ridges. There may be increased pigmentation, generalised or localised, owing to correlated depression of suprarenal function—*Ichthyosis nigra*. The distribution of the lesions is symmetrical with regular arborisations and formation of complex patterns. Local manifestations may be exaggerated into heaped up, pigmented, circumscribed, cornified excrescences on the skin—*Ichthyosis hystrix* (porcupine skin); or may appear as pigmented linear verrucose nævi—*Nævus unius lateris*—involving extensive areas of deeper tissues on the face, trunk or extremities. Onset of the disease is insidious and the progress generally slow without any marked improvement during summer months. The general health keeps fairly good although the subject remains very susceptible to slight variations in the atmospheric temperature. The mucous membranes are never involved.

HYPERKERATOSIS OF THE HAIR FOLLICLES; Keratosis follicularis. In this condition the horny epithelium surrounding the mouths of the hair follicles undergoes hypertrophy giving the skin a stippled or dotted appearance. The dots are usually small in size and are seen as solid horny plugs blocking the mouths of the hair follicles so that growth of hair is prevented. The stunted hair remains coiled up in the follicle and in some cases only the tip can be seen at the apex of the grayish keratotic cone. Each corneous plug may be surrounded by an erythematous halo and manual expression of these leaves minute shallow cup-shaped depressions which fill up again fairly rapidly. The unerupted hair may cause a good deal of irritation and the breach of surface produced by scratching may induce secondary pyogenic infection. The disease is most commonly found in xerodermic skin although normal skin may be similarly affected especially during winter.

LICHEN SPINULOSUS. It affects children mostly, the lesions being mildly inflammatory and consisting of minute grouped filiform spines protruding from the hair follicles. The elbows and knees are the sites of predilection although any part of the body may be affected. Spontaneous recovery takes place in a fairly large percentage of cases while others may shew recurrence at different sites every winter till the age of puberty.

Treatment. Local: The general principles adopted are first to soften the harsh dry scales with bland non-irritating oil followed by mild keratolytic ointments to induce exfoliation of scales and stimulate growth of healthy skin. The patient should be encouraged to anoint himself every day with olive oil or cocoanut oil which should be rubbed in with gentle massage and friction, preferably in the sun. He is then given a tepid alkaline bath for about 15 minutes, dried with a soft towel and salicylic acid ointment 30 gr. to 1 oz. of lanolin base is applied all over the affected area. Other keratolytic agents of stronger action are hardly required.

General: Good food, cod-liver oil and general hygienic measures are of importance. Bowel infection, protozoal, helminthic or bacterial, is often found in these cases and should be treated. Intensive thyroid medication cures a large percentage of cases and this is undertaken as follows. The patient is put to bed and kept at absolute rest for 12 hours and a mean count of his pulse rate is recorded. Next day he is given ext. thyroid sicc. $1/3$ to 1 gr. three times a day keeping a careful count of the morning and evening pulse rate. As soon as the pulse rate rises to 100 per minute, the thyroid extract is discontinued for 24 hours, by which time the pulse rate falls back to normal. Throughout the period of intensive medication the patient should on no account be allowed to sit up in bed even to relieve himself. The thyroid extract may then be continued in $\frac{1}{4}$ to 1 gr. doses twice daily for 2 weeks with the patient attending to his particular avocation. Cure is established in about six weeks provided the physiological functions of the thyroid gland of the patient are not already thrown permanently out of balance by other systemic diseases, e.g., syphilis. For infants and children intensive thyroid treatment is recommended with the same precautions about absolute rest as is the case of adults, a proportionate dose being given according to the age of the child. Lichen spinulosus and milder degrees of keratosis follicularis do not require intensive thyroid treatment, mild keratolytic ointments and paints generally establish a cure.

PITYRIASIS RUBRA PILARIS. A chronic hypertrophic disease of the epidermis characterised by hard yellow or pink papules of general or universal distribution and affecting chiefly the mouths of the sebaceous or sweat glands. Each lesion consists of a dry hard papule or a horny plug on the mouth of a sebaceous or sweat gland; they are at first discrete but tend to become confluent and involve extensive areas giving

rise to reddish, raised, thick, rough patches covered with brank-like scales. The sites of predilection are backs of the fingers especially of the first and second phalanges, backs of the hands, extensor surfaces of the arms, elbows, knees and the axillary folds. Deep fissures are sometimes formed at the joints. The skin of the face, palms and soles become thickened and inelastic and the nails hard, brittle and striated. Ectropion of the lower lids may occur. Lesions on the mucous membrane of the mouth are exceedingly rare. There are practically no subjective symptoms and the general health usually remains good. The aetiological factor is mainly a defective function of the thyroid gland together with parathyroid imbalance and defective calcium mobilisation in the system. Majority of the cases are seen amongst young adults, although children and old people are not exempt. Spontaneous recovery may take place but recurrences are common, even after two or three years of apparent freedom from the disease.

Treatment. *Local.* The skin should be well rubbed with olive oil or liquid paraffin for about half an hour before giving the patient an alkaline bath, after which a 10 per cent. salicylic acid ointment should be applied all over the affected areas. Carbolic carron oil is also very useful.

Internal. Intensive thyroid treatment followed by oral administration of thyroid $\frac{1}{4}$ gr., parathyroid $\frac{1}{10}$ gr., calcium lactate 10 gr., twice daily before food, establishes a cure.

SCLERODERMA. 'Hide-bound skin'. The condition is characterised by hyperkeratosis of the epidermis along with thickening and loss of elasticity of the skin owing to formation of bands of fibrous tissue in the corium. The distribution is usually regional although in extremely rare instances the whole body may be affected. Generalised types of cases are slowly progressive and almost always fatal. Strangulation of the cutaneous vessels by the constricting fibrous bands leads to extensive gangrene and sloughing of the skin; sometimes secondary pyogenic infection supervenes, followed by toxæmia. Complete loss of elasticity of the whole of the skin greatly impedes freedom of movement of the chest in respiration and death may occur from secondary asphyxia.

Localised scleroderma. It is characterised by occurrence of circumscribed or diffuse, hard, smooth, depigmented areas which are fairly adherent to the underlying soft tissues. There may or may not be any discolouration around these lesions. In the early stage of the onset the affected areas may be swollen and inflamed with excessive cornification but atrophy of the skin follows rapidly with formation of hard inelastic fibrous tissue in the corium. On the palms and soles the condition is known as *tylosis* in which flexion or extension of the fingers and toes become very limited in range. *Dupuytren's contraction* is probably scleroderma of the palmar fascia. Such bands of fibrous

tissue are sometimes formed at the tips of the terminal phalanges causing, at first, thickening of the skin in that region; later, the nails begin to show signs of atrophy and absorption—*sclerodactylia*—tactile sensation is markedly diminished and there is good deal of aching pain, especially at night. The digit is absorbed and telescoped into the next phalanx, so that in extreme cases, an entire finger may be lost owing to a process of rarefying osteitis. This pathological change, in some instances, commences at the base of the little toe and leads to spontaneous amputation of the entire member—*ainhum*—by formation of constricting band of fibrous tissue. The onset is insidious and the progress rather slow. The fourth toe may in some rare instances be affected but involvement of all the toes has not been recorded. *Ainhum* is less painful than *sclerodactylia*; a few of the patients do not complain of any subjective symptoms at all except in the last stage of the disease when the affected toe becomes gangrenous before dropping off.

Circumscribed patches of scleroderma with telangiectatic or purplish margin and atrophic centre are called *morphœa*. They begin as bluish red macules which soon change into depigmented, hard, dry, inelastic patches with smooth surfaces. The lesions may remain stationary or recover spontaneously. The small guttate variety of *morphœa* is sometimes called 'white spot disease'—which is a misnomer.

Treatment. The treatment of all types of scleroderma is very unsatisfactory. Every individual case should be carefully investigated both clinically and in the laboratory for any evidence of concurrent disease or active source of focal infection. Cases in which there is a good deal of hyperkeratosis respond to intensive thyroid treatment to a certain extent, but so far there is no drug which is known to check the over-productivity of the fibroblasts. Fibrolysin may be given a trial in 1 c.cm. doses intramuscularly every other day for 12 doses. Bi-weekly injections of muscle extract preparations such as 'sarcolan' or 'padutin' have been found very useful in many cases. Combined organotherapy with thyroid, suprarenal and gonad extracts produces considerable improvement in about 15 per cent. of cases. Syrup ferri iodide in 15 min. doses, iron and arsenic tonics and cod-liver oil are remedies of repute which sometimes cure by improving the general health of the patient.

WARTY GROWTHS (Verrucae). These are papillomatous, circumscribed hypertrophic lesions, gray or black in colour, in which the prickle cell layer grows to enormous thickness as also does the horny layer. Many of these have been proved to be infectious and auto-inoculable, especially the juvenile variety which is caused by a specific filtrable virus. Any place on the skin may be affected but on the scalp, face, lips and eyelids they are commonly associated with seborrhœic affection. Occurring on the soles of the feet, they render walking very painful and

simulate callosities, but unlike them, warts also grow in areas not subjected to pressure. They are roughly symmetrical and do not possess the soft core characteristic of corns. Several of these small outgrowths may fuse into one mass so that they appear as a single large hyperkeratotic surface. *Juvenile warts* usually remain as discrete, small, smooth, slightly raised papular lesions, the sites of predilection being the forehead, cheeks, nose, upper lip and backs of hands. They are of normal colour of the skin. *Seborrhæic or senile warts* are usually multiple slightly raised black keratoses and are found on seborrhæic types of skin showing senile trophy with age. These are usually covered with a greasy crust which on removal leaves a raw pulpy base. Some are extremely irritable and are sites of subsequent development of basal cell carcinoma. *Verruca acuminata* or venereal warts are associated with gonorrhœa and occur as multiple small pointed projections which multiply rapidly and form a large vegetating bunch on the penis, about the anus, on the mucous surface of the vulva and on the perineum. Rarely, they are seen in the axillæ, the groins, umbilicus or clefts of the fingers. They may grow to fairly large cauliflower-like masses and are sometimes very foetid owing to accumulation of the purulent discharge in the clefts between the filaments. The colour is usually pale yellow or pinkish.

Treatment. *Local.* Removal by curettage or excision is the simplest and best treatment for sparse discrete lesions, care being taken to thoroughly cauterise the base with pure carbolic, nitric or trichloroacetic acid or 20 per cent. silver nitrate to prevent recurrence. Hæmorrhage, secondary infection and scarring are the principal disadvantages. In extensive cases removal is not recommended. Refrigeration with carbon dioxide snow yields very satisfactory results provided each group is taken up separately under the applicator and frozen for about a minute or longer. The process is tedious and takes a very long time to establish a cure. Electrolysis and radiotherapy, separately or in combination, give most satisfactory results in extensive venereal warts, but a preliminary excision under anaesthesia may be necessary in some cases to expose the base to the effects of treatment and thereby prevent recurrence. Surgical diathermy is recommended especially for plantar warts but a single exposure to unfiltered X-rays brings about cure in most cases. All seborrhæic warts on senile atrophic skin should be examined histologically for signs of early malignancy and surgical treatment given accordingly.

Internal. Intensive thyroid treatment is of doubtful value and is not recommended except in combination with thorough local treatment. Proto-iodide of mercury in 1/6 to 1/4 gr. pills has been used but there appears to be no specific beneficial effect. Specific filtrable virus vaccines or autolysates have been tried at the Skin Clinic of the Calcutta School of Tropical Medicine with very encouraging results. To prepare the autolysate a freshly formed warty growth is removed entire under

strict aseptic precautions and emulsified in sterile normal saline, using finely ground sterilised pumice stone as the triturating agent. The emulsion is then filtered through an L3 Chamberland candle and the filter-passing virus is killed with 0.1 per cent. formalin. The filtrate is diluted and standardised so that 1 c. cm. contains 0.1 mgm. of the tissue material. Injections are given in gradually increasing doses every other day commencing from 0.1 c.cm., the maximum dose being about 0.5 c.cm. A course of six or eight injections controls the appearance of fresh crops and prevents relapses in young subjects. A few adults have responded very satisfactorily to this form of treatment. Bismuth salicylate has yielded very satisfactory results in rough types of warts; 2 c. cm. doses are given deep into the muscle twice weekly for eight doses and a second course is given after three months, if required.

MOLLUSCUM CONTAGIOSUM. As the name implies, this is a definitely infective hypertrophic lesion of the horny epithelium consisting of single or multiple, flat or rounded, greyish or flesh coloured papules, with a central depression containing a plug of caseous material—the molluscum body. In size they vary from a pin's head to a bean and the disease is most commonly found among school children who infect each other with the causative filtrable virus. The disease is sometimes met with in adults who pick it up from the Turkish baths, the barber's shop or beauty parlours. After an incubation period of 3 to 6 weeks, the initial lesions appear as very slightly raised papules about the size of a pin's head, with a depressed centre filled with curd-like mass composed of degenerated epithelial cells and keratin. Evolution is generally slow, the sites of predilection being the face, hands and genitals, although the entire body may be affected in very exceptional cases.

Treatment. It consists of manual expression of the individual molluscum bodies and touching up the cavities with pure carbolic acid by means of a fine camel-hair brush. They heal up in a week or so without formation of scars. The autolysate injections are useful and cure the patient in about 10 days.

Warty Growth of a Vegetative Nature but Soft to the Touch

ACANTHOSIS NIGRICANS. A rare disease characterised by hyperpigmentation and a warty condition of the skin of the neck, axillæ, genitals, groins, inner aspects of the thighs, flexures of the elbows and knees, umbilicus and anus. The face and the entire surface of the body are sometimes affected. The warty excrescences are very small and closely set and although the appearance gives an impression of a hard rough surface, the feel is quite soft and almost velvety to the touch. Similar lesions are occasionally seen on mucous membranes which become sodden and degenerated. Growth of hair and nails is markedly affected in extensive cases. Two clinical types have been described :—(1) The benign juvenile type which appears early in life and

occurs as isolated patches of vegetations, single or multiple but never with extensive or severe involvement of the skin. The general health continues good although the subject may feel very run down during periods of exacerbation. Complete involution may take place but the duration of the disease is of indefinite period. (2) The malignant type appears late in life and is commonly associated with the later stages of carcinomata of the internal organs. There is intensive involvement of widespread areas, the lesions being almost stationary without any periods of intermission. As a rule, they forebode a fatal termination within a short space of time. Involvement of the chromaffine cells is the principle ætiological factor in the malignant type which is brought about by pressure of intra-abdominal tumours on the suprarenals.

Treatment In the benign type of lesions, the best results are obtained by intensive local treatment with keratolytic ointments and plasters during the quiescent stage. Resorcin ointment 30 gr. to an ounce, salicylic acid ointment 1 dr. to 1 oz., or 10 per cent. salicylic acid plaster can be used with advantage. For small areas of limited involvement, carbon dioxide snow applied for 45 to 60 seconds can be used at 2 or 3 days, intervals. Periods of exacerbation call for general tonics, *e.g.*, iron, arsenic, quinine, calcium, etc. Any apparent focus of septic infection should be treated thoroughly at the same time. Residual hyperpigmentation requires local application of bismuth and perchloride lotion (mercuric perchloride. 1 gr., bismuth subnitrate 10 gr., pulv. tragacanth 4 gr., water 1 oz.) twice daily in combination with intravenous injections of pentavalent antimony compounds, *e.g.*, urea stibamine or neostibosan, the maximum single dose of these antimony compounds being 0.2 gm. Injection of bismuth salicylate or metallic bismuth in suspension is also worth trying.

PSOROSPERMOSIS OR DARIER'S DISEASE. It is characterised by symmetrical patches of papular dirty black warts affecting the neck, shoulders, face, the extremities, the front of the chest and the middle line of the back. It may sometimes spread over the entire surface of the trunk, buttocks, genitals, axillæ, gluteal crease, and behind the ears. Earlier lesions commence in the hair follicles as hypertrophic papules with greasy brownish-black crusts, and in course of time several of these coalesce to form large patches of malodorous, papillomatous growths which are intensely itchy and bleed readily. There is an offensive purulent discharge from the fissured and often ulcerated surface. The scalp is generally covered with greasy crusts. The lips are sometimes swollen fissured and ulcerated. Patches of keratosis and superficial ulceration of the tongue are not uncommonly met with. The nail beds show hyperkeratosis with malformation of the nails themselves. The palms and soles may also show patches of horny thickening.

Treatment. The treatment is very unsatisfactory and though the disease is a very rare one it runs a long protracted course, spontaneous

involution being unknown. Local sedatives and keratolytic ointments only afford temporary relief. Astringent dusting powders have been used empirically without much benefit. Best results have been reported by American authors from fractional doses of X-rays although intensive thyroid medication and non-specific protein therapy may be well worth a trial.

POROKERATOSIS. The disease is characterised by annular lesions with narrow elevated warty margins enclosing patches of slightly atrophied skin. They begin as small warty excrescences due to a chronic inflammation in the dermis and during evolution central atrophic skin becomes devoid of hair and sweating. Extension always takes place peripherally. The lesions are most pronounced on pressure and friction areas such as the hands and feet which are the sites of predilection of the disease. Any part of the body may be affected including the buccal mucous membrane where it appears as a white thick cord, the epithelium of the ridge becoming macerated by the saliva. The ætiology is not clearly understood although the disease is considered by some as being due to thyroid defect. There is a tendency towards familial incidence. The changes in the epidermis consist of hyperkeratosis and parakeratosis about the opening of the sweat ducts with infiltration of the corium about the sweat glands which undergo atrophy. Spontaneous involution may take place but, as a rule, the disease runs a chronic protracted course.

Treatment. Intensive thyroid treatment yields good results especially if combined with local application of 1 per cent. alcoholic solution of picric acid. Mild keratolytic ointment, *e.g.*, salicylic acid ointment 10-30 gr. to 1 oz., resorcin ointment 15 gr. to 1 oz., may have to be continued for a long time to prevent relapses.

Hypertrophic Lesions Involving the Connective Tissue of the Corium

PRIMARY. The lesions may be diffuse or circumscribed and are usually congenital in origin although in a few cases the first clinical sign is noticed in young adolescence.

DIFFUSE TYPE : DERMATOLYSIS. In this condition the skin and subcutaneous tissues are hypertrophic and loosely attached so that the skin hangs in folds. The neck, shoulders, face, thighs and scalp are usually involved. The skin is coarse, harsh and pigmented but the growth of hair and sweating are normal. The amount of hypertrophy and degree of looseness varies somewhat in individual cases and although the disease is of a slowly progressive nature, the growth is arrested after attaining a certain size. The ætiology is unknown. Except for the discomfort of the massive pendulous outgrowth the disease produces no symptoms.

Treatment. The treatment is surgical. Excision is not usually followed by recurrence.

CIRCUMSCRIBED TYPE. *Molluscum fibrosum*. The lesions consist of single or multiple flat, sessile or pedunculated tumour-like formations of varying sizes in the corium which may be present at birth or may be appreciable at about the age of puberty. A single growth may be very large and pendulous but multiple tumours vary a good deal in size. The majority of these tumours originate in the perineurium or the interstitial tissue of the peripheral nerves and those that are placed deep in the subcutaneous tissue are attached to the larger nerve trunks which are sometimes extremely painful owing to the pressure of these growths. The number of tumours may vary from half a dozen to several hundred and may present all the varied morphological appearances in the same individual. *Von Recklinghausen's disease* has been described as a separate clinical entity which is characterised by formation of numerous sessile and pedunculated tumours and massive areas of dermatolysis accompanied by patchy hyperpigmentation of the skin. The disease often runs in families and several members may be affected to varying degrees. There are no special symptoms.

Treatment is eminently unsatisfactory and surgical excision of individual pendulous growths is the only way of giving relief.

Acquired type. It is a very rare condition and has been found to occur during the later months of gestation. It consists of small tumour-like growths of soft consistency, mostly pedunculated, and affecting the front of the chest and mammary region. Spontaneous recovery takes place soon after child-birth.

SECONDARY. KELOID OR GROWING SCAR. Under ordinary conditions the fibrotic process leading to formation of scars is arrested by strangulation of the newly formed blood vessels in a healing wound and there is left pigmented or depigmented partly elastic scars which are stationary. If the formation of these new vascular twigs continues owing to abnormal response of the angioblasts, the growth of fibrous tissue also continues giving rise to hard depigmented overgrowths with claw-like processes extending well beyond the original site of injury. The epidermis over the keloid is thinned out from pressure and has a smooth glossy appearance with telangiectatic margins; the colour changes to brown in course of time and there may be a good deal of hyperæsthesia or actual neuritic pain owing to involvement of sensory nerves. The lesions vary a good deal in size and distribution, those occurring after burns or scalds being the most extensive and lead to contractures and disfigurement about the eyes or mouth. They rarely involute spontaneously although the growth may be arrested after some time.

Treatment. Best results are obtained in cases taken in hand early and treated by combined surgical and X-ray therapy. Old keloids are very resistant to X-rays or radium and plastic operation with skin grafting is the best remedy.

CORNS. These are circumscribed areas of horny thickening, conical in shape and produced by intermittent friction or pressure on the toes. The hard variety is formed on the external surfaces at the interdigital joints and has a shiny smooth surface, with the base of the cone upwards and the apex pressing on the subjacent soft tissues. Soft corns are formed between the toes and the hard surface is macerated owing to friction and sweating. They disappear spontaneously as soon as the cause is removed in the way of ill fitting or too tight footwear.

Treatment. Paring the corn down to the core and removing it with a sharp pointed bistoury affords instant relief. Painting the corns with salicylic acid $\frac{1}{2}$ dr., tincture cannabis indica $\frac{1}{2}$ dr., collodion 1 oz. for a week and then soaking in warm water brings out the entire corn with its core. Prophylaxis in the way of soft felt pads kept over the sites of pressure by adhesive ointment is of value. Sufferers must be warned that a too loose fit in shoes sometimes leaves the toes a good deal of freedom of movement in walking and thus induces growth of soft corns.

CALLOSITIES. These are hard circumscribed overgrowths of the horny epithelium over bony prominences subjected to intermittent pressure spread over a long time and differ from corns in that they do not possess a central core. They are very common on the palms of athletes and gymnasts or people handling implements of labour. Long hours of standing or walking on hard floors as in cases of shop walkers, is one of the important causative factors of callosities of the feet. Clinically, this condition is sometimes confused with plantar warts but the latter grow on areas not subjected to friction or pressure and possess multiple cores when the surface plaque of horny growth is shaved off. Callosities disappear spontaneously as soon as the cause of friction and intermittent pressure is removed; they rarely require any special treatment.

Atrophic Lesions of the Skin

PRIMARY. MACULAR ATROPHY. It is a rare disease of unknown ætiology of young adolescence, and usually commences as slightly reddish patches on the dorsum of the hands and the elbows. These patches are slightly oedematous and scaly but almost level with the surface of the unaffected surrounding areas and smooth to the touch, so much so that they may escape notice at this stage. The true skin is mainly involved, the epidermis remaining unaffected in the earlier stages. The distribution may be only local or symmetrical and regional; in very rare instances they are generalised. In course of time the atrophy is manifested by loss of elasticity and pliability of the skin; the normal lines of cleavage become exaggerated, and the surface epithelium becomes grayish, harsh and shiny. This pathological condition is due to replacement of the elastic fibres in the corium by growth of hard inelastic fibrous tissue which strangles the

sweat and sebaceous glands and hinders materially the nutritive lymphatic circulation in the epidermis and also the activity of the melanoblasts to a certain extent.

DIFFUSE TYPE. It is commonly associated with scleroderma but not with aetiological relationship with it. Lesions first appear on the dorsum of the hands and feet and slowly spread upwards to the arms, thighs, chest and back. The progressive involvement of the integument may be punctuated with periods of apparent improvement but complete involution never occurs. Affected subjects are extremely susceptible to changes in the atmospheric temperature and cannot undertake any physical exertion owing to atrophy of the sweat glands and consequent 'lack of cutaneous respiration.' Ulcerations and carcinomata often start from the atrophic patches.

LOCALISED HEMI-ATROPHY OF THE FACE. It is an extremely rare disease which occurs chiefly in childhood or soon after birth and trauma of insignificant intensity may be the exciting cause. There is shrinkage of all the structures on one side of the face, the affected side progressively become smaller and X-ray pictures reveal proportionate atrophy of the underlying bones as well. A few cases are associated with scleroderma. In exceptional cases the skin over the two malar bones only is affected leaving the other areas quite healthy.

Treatment. The treatment is very unsatisfactory in so far as there are no known remedies to check the progress of the disease. Administration of cod-liver oil combined with muscle extract injections are worth trying. Locally, inunction with olive oil or hydrous lanoline softens the epidermis and thereby improves the appearance of the skin to a certain extent. Patients should be warned against too frequent washing of the atrophic areas with soap and water and exposure to strong sunlight and harsh winds.

SECONDARY. This is seen after prolonged illness and is characterised by dry, smooth, shiny, grayish skin with atrophy of the hair and nails. The skin and its appendages generally become normal with the improvement of the general health but permanent alopecia and dystrophy of the nails is seen in a small percentage of cases. Linear atrophies with regional distribution result from various causes leading to rupture of the elastic fibres in the corium, e.g., pregnancy and lactation. The condition requires no special treatment.

Atrophy of the skin is sometimes noticed over the tender areas in neuritis and in paralysed limbs owing to involvement of the trophic nerves. Recovery follows improvement of the inflammatory or degenerative changes in the nerves supplying the affected area. *

Senile atrophy of the skin is seen in the aged people. The elasticity is lost, the skin becomes wrinkled, thin, glossy and telangiectatic. Sometimes a diffuse brownish discoloration and leathery thickening is met with. The appendages also undergo atrophy; warty growths begin to

appear on the face, back of the hands, chest and back and carcinomatous changes supervene on these warts later.

Atrophy following other skin affections, *e.g.*, lupus erythematosus, syphilis, tuberculosis, leprosy, etc., hardly calls for special mention.

Abnormalities in the Colour of the Skin

LEUCODERMA OR WHITE SKIN. *Congenital.* Complete failure of the basal cells in oxidising and storing melanin results in albinism which, as a congenital condition, is associated with white hair and pink eyes. The skin may show a few dark freckles and *tache de Morgan* or discrete small blood-moles, which are often the seats of epitheliomata later in life. The subjects are extremely susceptible to sunlight and suffer from chronic solar dermatitis on the exposed parts, namely, the face, hands and feet. They should be kept away from strong sunlight as much as possible as there is no cure for congenital albinism. A milder degree of this condition is sometimes seen as congenital error in pigment drift resulting in a 'spotted skin' or actual *piebaldism*. The colour of the hair and iris usually remains true to the racial character of the patient. Slight errors sometimes correct themselves with the attainment of maturity especially in women after child birth. Both white and dark races are affected but it is more noticeable in the latter.

Treatment is of very little efficacy. Addition of larger quantities of peas, beans, pulses, soaked gram, etc., have yielded some good results after prolonged use but probably the improvement is spontaneous in such cases.

ACQUIRED PRIMARY. The age of incidence is during young adolescence, the disease rarely commencing under 2 years or above 60. Any part of the body may be affected, including the muco-cutaneous areas. It usually begins insidiously as a small depigmented herald spot which may be diffuse or sharply circumscribed. Several spots may appear on different parts of the body at the same time and the progress is so rapid in some cases, that the major portion of a limb, trunk or face may become dead white in the course of a few months. Usually the spread is rather slow and spontaneous involution and complete recovery is not very uncommon. Four clinical types are met with namely, (1) *melung type* affecting the palms and soles only; (2) *muco-cutaneous type* affecting the lips and angles of the mouth, the eyelids, the anus, the prepuce and the vulva; (3) *'dhoti' and 'sari' type* affecting the pressure area about the waist where cloth is worn by Indians; (4) *generalised type*. Any particular case may show two or more of the clinical types of lesion. About 20 per cent. of patients give a history of dysentery; a few start after protracted illnesses like typhoid, pneumonia or chronic dyspepsia which is probably of bacillary dysenteric origin. Leucoderma is hardly ever seen in kala-azar patients.

Treatment. Medicinal. In view of the fact that the digestive tract is the most important manufacturing centre of the vegetable amine substances from which melanin is produced and stored in the skin, it is advisable to give the patients 'intestinal antiseptics' for prolonged periods and correct all errors of digestion. The following have been used at the skin clinic of the Calcutta School of Tropical Medicine with success.

(i) Mist. hydrarg. perchlor. in 1 oz. doses twice daily after food, (ii) salicin 10 gr. twice daily after food, (iii) hydrarg. cum creta 1 gr., pulv. ipecac 1 gr. twice daily after food, (iv) zinc sulphocarbolas 4 gr. has been tried in a few cases but the drug causes gastro-intestinal irritation after prolonged use, (v) emetine hydrochloride 1 gr. intramuscularly, one dose is given every day for six consecutive days with a view to partially depressing the function of the suprarenals. The patient should not be allowed to take any physical exertion during the course of emetine treatment on account of the depressing effect of the drug on the heart. The importance of latent foci of infection in the bowels should not be lost sight of and wherever possible every patient should have his stools examined for protozoal, helminthic and bacterial infection, and specific treatment given according to the findings.

Local. Of all the drugs that have been used, oil 'Bouchi' (*Psoralea corylifolia*) has yielded the best results. The oil should be applied on leucodermic spots with gentle friction, preferably at night, as the irritating action may be intensified by solar rays. The application can be repeated during the day according to tolerance. Some people are extremely sensitive to oil of 'bouchi' and sparse application results in intense inflammatory reaction and blistering of the skin. The oil should be used suitably diluted with olive oil in such cases and can be combined with 10 gr. of ichthyol to an ounce of the dilute oil.

Diet. High protein diet is recommended for cases of leucoderma. Peas, beans, pulses and dal should be given in increased quantity. Gram seeds soaked in water over-night may be given raw the next morning. Carrots are also beneficial on account of its rich pigment content.

Prognosis is unfavourable in the melanic and muco-cutaneous types. Cases of over five years standing do not respond to treatment owing to almost permanent loss of function of the melanoblasts.

ACQUIRED SECONDARY. Any ulcerative lesion of the skin leaves depigmented scars if the loss of substance involves the corium and consequently damages the melanoblasts. Burns of the second degree, lupus erythematosus, lupus vulgaris and tuberculides, ulcerative syphilides and yaws and granuloma inguinale, all leave permanent white scars which can be masked to a certain extent by carefully handled tattooing. The important non-ulcerative lesions are the first stage of dermal leishmaniasis, the third stage of leprosy, advanced stage of leukaemia, and syphilis in the late secondary and tertiary stages.

Treatment should be directed towards the underlying cause as leucoderma is only a symptom in these affections.

CHLOASMA OR DARK SKIN. *Congenital:* Generalised dark colour of the skin can hardly be considered as a malady but single or multiple patches, occurring in different parts of the body cause very bad disfigurement especially on the face and neck. Localised chloasma of this type occurs commonly in the sacral region of new-born babes and is known as a *mongolian spot*; the colour is bluish on comparatively darker skin, almost purple in fair children, and black in extreme cases. The centre of the patch is the darkest and the edges fade into the general colouration of the skin. After persisting till the 5th or 7th year of life mongolian spots disappear spontaneously. Congenital flat moles, when diffusely extensive, may resemble chloasma but careful observation shows that they grow slowly with age and are more sharply circumscribed without fading margins.

ACQUIRED PRIMARY. Generalised darkening of the skin is seen in a very small percentage of cases after puberty owing to the recessive individual character becoming dominant. Bronzing of the skin is sometimes noticed during gestation and in old age due to disturbance of the suprarenal function. The normally hyperpigmented areas become more accentuated and the muco-cutaneous surfaces also become pigmented. There is no special treatment for the chloasma of pregnancy as the pigmentation disappears soon after child-birth. Senile bronzing is usually slowly progressive in character, and is sometimes associated with a low blood pressure.

LOCALISED. *Chloasma vulgaris* or the common type is seen on the malar prominences, the bridge of the nose and the forehead. The spots are usually oval or rounded in outline and the margins fade into the colour of the normal skin. The colour varies from light yellow to almost black, several small patches often coalescing to form a fairly large one on the face. There are no subjective symptoms. Any part of the body may be affected including the mucous membranes in extensive cases. The disease is more common in women in the early forties and is correlated with the retrograde changes of the climacteric suggesting abnormal physiological functions of the ovary and suprarenals.

TREATMENT consists of using bleaching lotions and creams which induce slow desquamation of the horny layer and shedding of the pigment particles along with it. The general health should also be well looked after and fatigue and overstrain are better avoided. Best results are obtained by combining local treatment with organotherapy, extracts of thyroid, suprarenal and gonads offering the most suitable combination. The following line of treatment have been found most efficacious for common chloasma:—Lotion containing mercuric chloride 1 to 2 gr., bismuth subnitrate 10 gr., tragacanth powder 5 gr., water

1 oz., to be painted on dark patches. Salicylic acid 15 gr. can be combined with an ounce of this lotion. Internally, ext. thyroid sicc. $\frac{1}{8}$ gr., ext. suprarenal sicc. $\frac{1}{2}$ gr., ext. orchic subst. sicc. $\frac{1}{2}$ gr., ext. ovarii sicc. 2 gr. is given for female patients. For male patients ext. orchic subst. sicc. is given in 2 gr. doses and the ext. ovarii sicc. is reduced to $\frac{1}{2}$ gr. The powder should be taken twice daily on an empty stomach.

ACQUIRED SECONDARY. Localised patchy and diffuse hyper-pigmentation of a secondary nature appears at sites of friction and irritation from diverse sources. The most important physical agents are heat and sunlight, the hyperpigmentation in such cases being preceded by erythema. Mechanical pressure and friction of clothes, *e.g.*, wearing the 'dhoti' and 'saree' round the waist, pressure of truss pads, garters, braces, the back and front collar studs, etc., produce dark patches at the sites of contact with the skin; cure is spontaneous, though somewhat slow, as soon as the cause of irritation is removed. Trauma either mechanical or resulting from violent irritative lesions like scabies and prurigo, leave the skin somewhat hyperpigmented especially in subjects who are hypoadrenic in their endocrine balance. Seborrhœic dermatitis also induces patches of chloasma on the forehead, cheeks, nose and face generally, and in some cases all over the body in hypoadrenic subjects. Treatment of the primary cause brings the colour of the skin back to normal. Intra-abdominal tumours of a malignant nature, Addison's disease and Grave's diseases cause generalised or diffuse chloasma, the mucous membrane of the mouth and tongue also show black patches fairly early in the course of these disease. Rheumatoid arthritis, and tertiary lesions of syphilis also cause hyperpigmentation of the skin.

XERODERMA PIGMENTOSUM. It is a very rare and invariably fatal disease characterised by parchment-like atrophy of the skin with occurrence of numerous hyperpigmented patches on the face, scalp, neck, forearms, backs of hands and other exposed parts of the body. Three distinct stages of this affection have been described and in the vast majority of instances the disorder is apparent before the end of the first year of life. In the first stage, persistent erythrodermia of the exposed parts even after short exposures to sunlight followed by slight puffiness and roughness of the skin are the most prominent symptoms. The skin develops a mottled appearance owing to a diffuse angiomatous condition of the capillaries. The second stage commences about the third year of life with abatement of the erythrodermia and appearance of large number of freckle-like spots and scaling of the skin of the affected areas. A few flat warts also make their appearance. The conjunctivæ become markedly hyperæmic and there is photophobia. During the third stage white depigmented spots with telangiectatic borders appear between the pigmented areas, the warty growths become very numerous and in the course of another year or so many of the

warts undergo malignant changes. Several of the pigmented spots may coalesce to form fairly large patches and the affected areas assume a peculiar sepia colour. The sweat glands undergo partial atrophy but the sebaceous glands are not affected. Owing to the atrophy of the corium and excessive formation of horny epithelium, contractures of the nose and mouth, ectropion with ensuing corneal ulcers are frequently met with. The disease is essentially a familial one, two or more children being affected in the same family. The causative factor is probably a congenital or inherited susceptibility or predisposition which results in abnormal response of the skin to stimulation with certain of the rays in the solar spectrum.

Treatment. Best results are obtained from prophylactic measures in the first stage of the disease. The exposed parts should be covered with an ointment containing 5 per cent. of di-sodium-naphthol sulphonate which absorbs the ultra-violet rays. X-ray and radium therapy has been recommended for the second and third stages.

Prognosis is very unfavourable; the progress of the disease is usually rapid and the patient dies of generalised carcinomatosis before he reaches the second decade of life.

Diseases Affecting the Vascularity of the Skin

ERYTHEMATA. Simple transient erythema is produced by external agents like heat, sunlight, chemical and mechanical irritants, and they act by producing dilatation of the capillaries. Spontaneous recovery is the rule as soon as the cause is removed. The most important internal cause is psychic or emotional as is seen in blushing. Permanent dilatation of the capillaries may follow the action of the external agents over a long period in a subject whose capillary tone is poor. Hypotonic condition of the capillaries may be due either to toxic absorption from focal sepsis or to inherent hypo-pituitary and hypo-adrenic conditions. Defective calcium metabolism is also an important aetiological factor. The important clinical varieties are:—

(1) *Erythema rubra nasi* or *facial erythrodermia*. The nose, cheeks, forehead and the neck assume an unusually flushed appearance without any apparent cause. There are usually no subjective symptoms. Patients may show marked erythrodermia of the hypothenar eminences of one or both hands. In a certain percentage of cases a very fine telangiectatic condition of the alae nasi and the cheeks is noticed.

(2) *Erythema ab igne*. This is caused by a permanent dilatation of the capillaries and arterioles induced by prolonged exposure to excessive heat. It is almost exclusively seen in cold countries, more often in women than in men, and affects the anterior tibial region of both legs which are exposed to the radiant heat of stoves or ovens. In the early stages the skin has a pink mottled appearance, but with the onset of reticulated erythema of the later stages, a certain amount of pigmentation

supervenes, so that a patch may shew simultaneous variation from pale pink to purplish dark brown. Too frequent use of the hot water bag may produce these vascular changes at the site of application.

TREATMENT. The first essential is to remove the cause. Locally, cooling soothing lotions, *e.g.*, calamine lotion should be used as a continuous application. For facial erythrodermia a 5 per cent. ointment of disodium naphthiol sulphonate should be used when going out in the sun. Internally, calcium lactate 10 gr. with parathyroid 1/10 gr should be given twice daily on an empty stomach.

(3) *Erythema pernio or chilblains.* The papillary capillaries undergo marked dilatation with cold, and the permeability of the endothelium is increased allowing exudation of serum in the papillary layer. The exposed parts like the fingers, toes, ear and nose are usually affected, some people being more susceptible than others. Cold feet during winter months is the most important predisposing cause but under-nourishment and defective calcium metabolism are no less important factors in producing the disease after exposure to moderate cold. The affected areas are red, sometimes bluish owing to venous engorgement, swollen and extremely irritable but quite cool to the touch, and often covered with sweat. There is good deal of pain and burning owing to the papillary oedema, which in extreme cases interferes with rest at night

TREATMENT. Local. The affected parts should be bathed in warm water 4 or 5 times a day and massaged gently with plain lanolin or simple ointments. The feet should be kept dry and warm and exercised to improve the circulation. Warm Goulard's lotion is useful in relieving the pain and burning. The inner side of the socks should be well powdered with camphor and French chalk (camphor gr. 30 to 1 oz of French chalk) before putting them on.

Internal. Calcium lactate 10 gr. with parathyroid 1/10 gr. should be given twice daily on an empty stomach. Other calcium salts, *e.g.*, calcium gluconate, colloidal calcium, etc., are of proved efficacy. In severe recurrent types of cases intramuscular injection of colloidal calcium, or intravenous injection of calcium chloride in 5 or 10 per cent solution may be required. A diet of high vitamin contents and general tonics are recommended. Local or general ultra violet radiation, when available, brings about quick amelioration of symptoms.

TOXIC ERYTHEMAS. Generalised. Certain toxic substances having their origin in bacterial activity in a focus of sepsis or derived from the end products of protein digestion in the intestines, are absorbed into the circulation and produce dilatation of the different vascular plexuses at the different levels in the skin. Depending on the level of activity and "iso-electric points" of these substances, there may be produced simple erythema, erythema with oedema of the skin and epidermis; or erythema with bullous formation. Inflammatory changes may

also occur in the corium. The distribution of the lesions may be local, general or universal, in which last case the mucous membranes are also affected. The extent and distribution varies a good deal, the eruption itself being made up of pin-head sized red macules which are generally so closely set as to form fairly large irregular patches all over the body. The trunk, upper arms, thighs and face are the sites of predilection with a tendency to involve the hair follicles. Clinically, some toxic erythematous rashes often bear a close resemblance to scarlet fever (*E. scarlatina*²²*oides*) or measles (*E. morbilliforme*) but are not associated with fever or other general toxic symptoms. Localised macular rashes may, in rare instances, be ushered in with rigor, joint pains and fever of short duration and have to be differentiated from 'filarial fever' by the absence of lymphangitis, local pain and tenderness. Recurrences are not very uncommon, a few cases showing definite periodicity in these attacks. There is a feeling of heat and tension of the affected skin and desquamation of the surface epithelium sets in as soon as the erythema has subsided.

Treatment. During the attack, the patient should be kept in bed and elimination aided by suitable aperients and diuretic mixtures. A complete change of the diet is very helpful. Locally, frequent inunction with 0.5 per cent. carbolic olive oil or calamine lotion with 10 per cent. glycerine relieves the burning and tense feeling of the skin. Internally, calcium salts either singly or in combination with parathyroid can be used to tone up the fine arterioles and capillaries of the upper layers of the dermis.

Recurrent cases require thorough investigation regarding the presence of latent focal sepsis in the tonsils, teeth or bowels. The urogenital tract may also harbour such foci, especially in women. The curative treatment has to be carried out according to the nature and site of the infection; surgical interference may be necessary for apical abscesses, septic tonsils or cervical erosions. General tonics and change of climate are recommended when repeated attacks seriously undermine the health.

Erythematous Lesions accompanied with Inflammatory changes in the Skin

ERYTHEMA MULTIFORME. Acute. As the name implies, this disease is characterised by protean local lesions consisting of red macules, papules, plaques and vesicles, generally of symmetrical distribution. They usually start as small erythematous herald spots slightly raised above the skin surface which, in the course of 24 hours, enlarge into large papules, or plaques; the inflammatory process is often of great intensity so that large blebs, filled with serous, pustular or even hæmorrhagic exudate, form within a few hours. The papillary and sub-papillary plexuses show a good deal of dilatation with exudation of

serum and perivascular inflammatory infiltration. There is oedema of the cutis with accumulation of serum underneath the epidermis, the entire thickness of which may be lifted up to form the bleb; leucorrhæxis or erythorrhæxis is seen in very acute cases. The sites of predilection are sides of the neck and face, the dorsal surfaces of the hands, forearms, feet and legs and in very exceptional cases the mucous membrane of the mouth is also affected. The lesions are bright red in colour fading on pressure, and gradually changing into a purplish tinge at the periphery. The disease may be self-limited lasting for a short time or it may be prolonged for months or even years. Constitutional symptoms are generally absent, except in cases with acute onset, but pain and irritation are generally present at the site of the lesions. The general health may remain good, but in chronic cases it is much impaired. There is a certain amount of diversity of opinion regarding the ætiology—the generally accepted view is that it is an allergic condition due to toxic absorption from the gastro-intestinal tract which may be derived either from bacterial infection of the intestinal mucosa or from the end products of digestion of animal food. The important clinical types are *erythema papulatum*, *erythema tuberosum*, *erythema bullosum*, *erythema iris*, *erythema marginatum*.

Treatment. During the attack, the treatment is mainly symptomatic. Patients should be kept in bed and have all physical exertions curtailed. The diet should be light and plainly cooked and the animal foods reduced to a minimum. The kidneys should be well flushed with large drinks of water and the bowels stimulated with mild aperients. Locally, calamine lotion or liniment is the best application in all stages of the disease. Fully-formed blisters should be punctured aseptically and dressed with a dusting powder consisting of equal parts of zinc oxide and starch with 1 per cent. of aristol by volume. Internally, salts of calcium are given either singly or in combination with parathyroid, iron, arsenic and strychnine tonics are indicated where the general health is poor. All stimulating drinks and beverages are to be withheld. The following are the important investigations which help a radical cure:—

- (i) The peripheral blood is to be examined to determine a true rise in the eosinophile population which is always indicative of 'animal protein leak' into the circulation.
- (ii) Dermal sensitiveness test with food extracts to eliminate those articles from the dietary which are inducing the 'allergic state.'
- (iii) Serial examination of the stools for evidence of protozoal, helminthic or bacterial infection so that specific treatment may be given according to the nature of positive findings.
- (iv) Examination for other foci of sepsis, namely, in the teeth and the maxillary and nasal sinuses, the throat and tonsils, and the cervix uteri in female patients.

URTICARIA. This disease is characterised by development of white, pink or red wheals of short duration, accompanied by itching and feeling of burning in the skin. The individual lesions vary a good deal in size, are rarely defined and contiguous lesions very often coalesce to form large plaques with an erythematous halo around them. After persisting for a few hours the wheals disappear spontaneously to reappear almost with clock-like regularity the next day. The total duration of the disease generally does not exceed ten days to a fortnight but in some cases it may persist for months or even years. The onset is sudden and in the majority of cases unaccompanied with prodromal symptoms. Any part of the body is liable to be affected including the mucous membrane of the larynx, and this in intensely acute cases, constitutes a source of danger to the life of the patient. In cases of moderate severity the skin resumes a normal appearance after the wheals have subsided but the blood vessels may remain in a state of imbalance so that stroking or pressure may produce a large welt. These cases show 'dermographism' which can be provoked by any blunt-pointed article, the tip of a penholder, for example. Areas of pressure from garters or waist bands may stand out as thick welts as soon as these are removed. Sometimes the attack is so sharply intense that bullae form on the wheals. Clinically, this condition is known as *urticaria bullosa* and the contents of these blisters are, in rare instances, filled with purulent fluid—*urticaria pustulosa* or with blood—*urticaria hemorrhagica*. Localised papular type of urticaria, *urticaria papulosa*, is seen on normal pressure areas, namely, the buttocks and back in badly nourished children. A chronic variety, *urticaria perstans*, has also been described.

The ætiology is essentially an allergic phenomenon produced by the end products of digestion of some animal protein food which the patient is not accustomed to take, or the end products of the average daily protein food against which the system develops a sensitiveness. Shell fish and tinned or canned foods are by far the commonest causes of acute urticaria. Lesions of the bowels due to chronic amoebic or bacillary type of infection play a very important part in allowing the 'amines,' derived from the digestion of animal food, to leak into the circulation and produce their toxic actions on the capillaries and arterioles in the papillary and sub-papillary plexuses. Injection of animal sera and ingestion of some drugs are sometimes followed by acute urticarial eruption. In a few rare instances physical agents like heat and light and diverse psychic and emotional conditions have been known to bring on an attack.

• The wheals are produced as the result of acute dilatation of the papillary and sub-papillary plexuses with a good deal of exudation of serum in the pars papillaris. There is inflammatory perivascular exudation, which latter is most intense in the region of the sweat glands. This dilatation is due to (i) failure of the constriction effect of the

sympathetic fibres in which case there are other evidences of hypo-adrenic condition and eosinophilia; (ii) sustained parasympathetic effect of almost persistent dilatation without any evidence of hypo-adrenia or rise in the eosinophile population.

Treatment. Locally, during the attack, cooling soothing lotions, *e.g.*, calamine lotion, equal parts of rectified spirit and water, 0.5 per cent. carbolic lotion, are useful in relieving the irritation. Iced fomentations are required when the plaques are intensely acute in onset the bullous formations may be aborted by this measure.

The general management of a case calls for an immediate examination of the blood film of the patient for evidence of eosinophilia in which case adrenalin 0.2 c.cm. combined with pituitrin 0.3 c.cm. should be given intramuscularly at once and repeated for the next three consecutive days. Ephedrine in $\frac{1}{2}$ to $\frac{1}{4}$ gr. doses can also be given by the mouth twice daily for 3 to 5 days.

A careful survey of the dietary is required to eliminate any unusual animal food like shell fish or oysters (which are hardly ever eaten in India) or tinned meats. In the absence of a definite history, sensitiveness of the skin should be tested against extracts of protein foods which constitute the patient's average daily diet, and those items which produce a 'nettle rash' lesion on scarified skin are completely omitted for three weeks. This test sometimes shows a positive reaction to all the extracts used (generalised sensitiveness) and too much importance cannot be given to dietetic restrictions in these cases. A small dose of calomel (2 gr.) followed by a saline cathartic the next morning is very useful as a routine measure in robust subjects. Cases which show very high eosinophile count in the blood are best treated with soamin injections, twice weekly. About eight injections are required, the total quantity of soamin used being about 16 gr. Other arsenical preparations can be given by the mouth but the response is usually slow. Cases which do not show any rise in the eosinophile population should be treated with drugs which act as depressants to the sympathetic nerves, *e.g.*, emetine hydrochloride 1 gr. intramuscularly on 6 consecutive days. Aspirin, belladonna and derivatives of barbituric acid are also of use in this type of case. Every case should have a thorough investigation into the condition of the bowels and latent amœbic or bacillary infections detected by repeated examination of the stools in the laboratory, so that specific treatment can be given at an early date. Internally, calcium lactate 10 gr. with parathyroid 1/10 gr. is given twice daily for toning up the capillaries. The adrenalin and pituitrin injections can be followed up with a course of 'mixed gland products' (thyroid 1/4 gr., suprarenal 1/2 gr., gonad substance 2 gr., given twice daily on empty stomach) for three weeks. A small percentage of persistent refractory cases sometimes respond well to injections of peptone, auto-hæmo or auto-sero-therapy.

GIANT URTICARIA OR ANGIO-NEUROTIC OEDEMA. It consists of localised deep oedema of acute and sudden onset and generally affects one limb or a part of the face. There are hardly any prodromal symptoms, the patient wakes up in the morning with a hand or foot or one side of the face enormously swollen accompanied with a feeling of toughness and sometimes pain. After persisting for two to five days the swelling subsides but may recur in the same or some other part of the body. The affected part looks red and inflamed but is cool to the feel. A few cases persist for days together and in rare instances different parts of the body may be affected one after the other without any abatement of the first lesion. The ætiological factor is the same as that of ordinary urticaria, the only difference is that the deeper plexuses are involved in giant urticaria and the exudation takes place in the deep fascia.

Treatment. The same line of investigation and treatment is adopted in both urticaria and giant urticaria.

URTICARIA PIGMENTOSA. It is a chronic inflammatory disease of the skin in which the lesions commence as acute urticaria but instead of subsiding within a few hours, persist indefinitely and undergo pigmentary changes. The individual lesions are firm, well defined wheals with an erythematous halo. They are pale in colour in the beginning and after a week or so become chamois coloured, brownish and then almost black. Contiguous lesions may coalesce to form a fairly large plaque type of lesions. There is good deal of itching as a rule, but a few cases do not complain of any irritation at all. It usually begins in early infancy or within the first decade of life and persists for some time. Spontaneous recovery takes place in a fairly large number of cases. Any part of the body may be affected but the trunk hardly ever escapes. Cases with intensely acute onset may show bullous formation. Crops of new lesions develop from time to time while the older ones gradually subside leaving atrophic spots or scars. Very little is known about the ætiology. Histologically *urticaria pigmentosa* shows perivascular infiltration with mast cells instead of leucocytes as in the case of ordinary acute urticaria. As a rule the disease disappears spontaneously with the onset of puberty. It has been suggested that adults with a persistent thymus sometimes develop *urticaria pigmentosa*. The general health remains good. Treatment is very unsatisfactory. Of the various remedies that have been tried, pilocarpine and atropine give best results. The itching has to be treated with antipruritic lotions and creams. Deep X-ray therapy of the thymus region has been tried with a certain amount of benefit but it is doubtful whether the results of such treatment are permanent.

PITYRIASIS RUBRA OR EXFOLIATIVE DERMATITIS. This is an acute or sub-acute inflammatory disease generally affecting the

entire surface of the skin which becomes red, and is accompanied with good deal of desquamation of the surface epithelium. An attack may be ushered in with slight rise of temperature, malaise or gastro-intestinal disturbances, but in majority of cases it begins suddenly as symmetrical localised patches which are pinkish or red at first and slightly rough to the feel. In the course of a few days the colour changes to dark red, the individual lesions tend to spread and become covered with thin, loosely adherent, flaky, grayish scales which are usually small on the exposed parts like the face and hands, but are of fairly large size on the covered areas of the body. These localised patches may heal spontaneously after 3 to 5 weeks but recurrence is almost the rule, and greater areas are involved with each recurrence till the entire surface of the body is affected. There is very little œdema or thickening of the skin in the early stages of the disease, but these changes become more and more marked with each relapse. Excepting for a few cases of intensely acute onset, there is no oozing of serum and bullous formations are never seen at any stage of the disease. During exfoliation, the thick horny layer of the palms and soles may come off as glove-like casts. The hair and nails are markedly affected and both may be shed in the latter part of the ailment. There is little or no itching in the early stage but the skin is extremely tender and sensitive to changes in the atmospheric temperature and solar radiation. A feeling of toughness and tension is always complained of by the patients. The skin may remain pigmented for a long time after recovery. Long-standing cases may develop permanent alopecia, onychia and dysidrosis owing to fibrosis of the corium and atrophy of the sweat glands.

The ætiology has been the subject of a good deal of controversy, but in the experience of the Skin Clinic of the Calcutta School of Tropical Medicine the disease has been classified as allergic in origin. A very large percentage of cases show focal infection in the bowels with imbalance of the endocrine functions owing to the chronic toxic absorption. Almost all cases shew hypo-function of the suprarenals. The histological changes are confined only to the subpapillary layer, the papillæ themselves are enlarged and somewhat elongated with moderate infiltration. The inflammatory exudate is most marked in the region of the sweat glands in chronic cases, which explains the permanent anidrosis after recovery.

A few cases have been known to terminate fatally with symptoms of general toxæmia after repeated attacks involving the whole body.

Treatment. The treatment is mainly symptomatic during the first onset. The skin should be kept moist and pliable with continuous application of plain olive oil or liquid paraffin. For the excessive redness of the skin calamine lotion is the best local application which can be combined with liq. plumbi subacetatis fortis, 5 min. to every ounce, provided there is not much oozing. The weeping is best controlled by bland dusting powders like kaolin or a mixture of equal parts of starch

and zinc oxide. The patient should take a warm bath, preferably in the morning, without using any soap, and be at rest as much as possible during the day. Exposure to sunlight is to be avoided. A thorough investigation into the presence of latent foci of infection, especially in the bowels, is to be undertaken as early as possible so that specific treatment can be given according to the nature of the infection. A total and differential count of the leucocytes in the peripheral blood is helpful and cases with a marked rise in the eosinophile population respond well to arsenical preparations which can be given either as Fowler's solution or Donovan's solution in 2 to 5 min. doses twice daily after food. Stovarsol or carbarsone may also be given for a short period not exceeding 7 to 10 days. The dilatation of the blood vessels is due to lack of sympathetic tone and hypoadrenia. This condition is best treated with pentavalent antimony compounds of which neostibosan (von Heyden 693) gives the best results. The dosage is 0.1 gm. gradually increasing to 0.5 gm., intravenously; one injection is given every day for 10 consecutive days. As a rule the drug is tolerated well but it is advisable to take the usual precautions against the untoward effects of intravenous therapy of heavy metallic salts by examination of the urine for albumin and casts. The dose is of course regulated according to the patient's body weight and general build. The bowels and kidneys should be kept functioning, the diet should consist of plainly cooked and easily assimilable foods. Alcohol and other stimulating drinks are contraindicated. The patient may require general tonics for the run-down condition of his health, for which quinine, iron, arsenic and cod-liver oil have been used. In long standing cases secondary thickening of the skin is treated with keratolytic ointments and paints containing resorcin, salicylic acid, acetic acid in a suitable proportion which is not too strong and irritating to the skin of the patient.

ECZEMA. It is a symptom complex of any chronic dermatitis and not a disease *sui generis*, as the symptoms and pathological changes are found in most of the chronic inflammatory diseases of the skin. It is characterised by four cardinal symptoms, namely, pain and irritation, redness, heat and swelling of the part affected. Clinically, two types are met with, the dry and weeping eczemas. The principal underlying cause of this syndrome is the response of the superficial cutaneous plexuses to external and internal stimuli which may be latent or apparent. The lesions begin as localised papular or vesicopustular eruption with a good deal of inflammation and infiltration of the true skin. These vesicles often burst and keep oozing serum—hence the name 'weeping eczema'. After persisting for some time, which may be prolonged to several months, there is a certain amount of abatement of symptoms, but the affected area remains thickened and harsh. Recurrence is very common and secondary changes in the skin begin to appear with each fresh attack. These changes may

involve the texture of the epidermis and the dermis as well as the pigmentation of the skin. Complications arising from secondary infection of the vesicles with pyogenic cocci are very common and completely alter the clinical picture in majority of cases. The aetiology is obscure in most cases. The lesions are caused by dilatation of the papillary and interpapillary capillary twigs with oedema of the papillae and the rete accompanied by perivascular inflammatory exudate.

It has been observed that the two main factors concerned in the production of a protean lesion like eczema are (i) external parasitic infection, and (ii) the susceptibility of the skin affected. In this country ringworm and seborrhoea are the two commonest primary infections of the glabrous skin and also scabies, especially in children. Secondary infection with streptococci and staphylococci are concerned in the production of induration of the skin, oozing of serum and formation of pustules. The vulnerability and susceptibility of the skin depends on the fineness of texture of the epidermis and is controlled by the activity of the endocrine glands which, incidentally, is a racial or familial trait. It is for this reason that some eczemas tend to run in families. On the other hand, this susceptibility may be due to acquired allergic conditions following focal infection, especially in the bowels, or sensitiveness towards some particular kind of animal food. Chemical and other irritants acting on one particular area of the skin for a long time produce local kataphylaxia and thus enhance the acquired susceptibility.

Treatment. The treatment has to be undertaken in three stages. First of all the secondary infection is to be treated with local applications according to the nature of the infecting organism. Staphylococcal infection requires antiseptic baths and compresses with 5 per cent. boric lotion, lysol lotion 1 in 20 or chinisol solution 1 in 100, after which 5 per cent. gentian violet solution in 20 per cent. alcohol should be applied night and morning. Autovaccine therapy may also be tried, although it is not of any great curative value. Streptococcal infections should be treated with continuous applications of cooling evaporating lotions of which calamine lotion is the best. Cold compresses with 1 in 3000 acriflavin lotion is also of benefit. Autovaccines are very useful in reducing the induration and deep inflammation of the cutis. When the secondary infection is cured the primary infection can be treated with Whitefield's ointment, ringworm paint or sulphur lotion according to whether it is ringworm or seborrhoea. The peripheral blood should be examined for evidence of eosinophilia and the stools examined serially to detect chronic amoebic or bacillary type of dysenteric infections so that specific curative treatment may be given to control the susceptibility of the skin. The diet should be regulated especially in cases of extensive streptococcal infection; sensitiveness towards any particular kind or group of food materials should be carefully investigated and the offending items eliminated. Internally, general tonics with quinine,

iron and arsenic may be helpful; endocrine therapy is indicated in cases showing signs of hypo-function of the thyroid, pituitary, suprarenals or gonads.

DERMATITIS REPENS OR ACRODERMATITIS PERSTANS.

This is a subacute or chronic inflammatory disease of the skin and is characterised by patches of raw glazed-looking denuded rete surrounded by a slightly elevated, ragged or irregular undermined edges formed by the broken horny epithelium. A fair amount of serum or pus can be squeezed from the undermined edges. The disease usually begins at the site of some minor trivial injuries as a red erythematous patch with formation of vesicles, within a day or two after the initial abrasion. These vesicles soon rupture and give rise to the characteristic lesions which tend to spread peripherally. The disease is more commonly seen on the fingers but occasionally on the toes and soles of the feet. A few cases occur without any primary injury. It is slowly progressive in character but healing generally takes place at the centre of the lesion more rapidly than the spread at the margins. Constitutional symptoms are absent and local pain and itching is almost negligible. The aetiology is rather obscure but in majority of cases it is due to a condition of kataphylaxia or loss of the defensive power of the tissues against pyogenic organisms. Some chronic cases go on for months or years in spite of treatment.

Treatment. All the ragged epithelium at the undermined edge should be clipped off. If there is excessive oozing of serum the most effective treatment is dusting with tannic acid. Local antiseptic baths with 1 in 5000 acriflavine lotion or dressing with hypertonic saline control the spread effectively. Bland ointments like borovaseline or plain zinc ointment should be applied at night. Internally, tonics with iron, arsenic and quinine in combination, or calcium lactate with parathyroid, act well. Vaccine therapy is recommended and is usually followed by marked improvement. Prophylaxis in the way of protection from injuries is very important.

Inflammatory Diseases of Unknown Toxic Origin

PITYRIASIS ROSEA. The lesions are of acute onset and characterised by fairly numerous pink or reddish scaly patches of various sizes and shapes with a slightly raised border and yellowish coloured centre. An attack may be heralded by slight fever and malaise with hard shotty enlargement of the submaxillary or inguinal glands, but other constitutional symptoms are absent. In quite a large number of cases prodromal symptoms do not appear at all. Individual lesions usually begin as small red papules on the back or the front of the chest and lower abdomen in the region of the waist line; these papules enlarge fairly rapidly and develop into rounded, oval or irregular maculo-papules, sometimes of considerable size. Contiguous lesions often coalesce into

segmental or gyrate lesions covered with fine bran-like scales. The eruption is asymmetrical and may be limited only to the trunk but the upper arms and thighs are also involved in a large number of cases. The face, palms and soles always escape. A few cases complain of a good deal of itching especially when they perspire, but subjective symptoms are generally absent and the general health remains good. The total duration of an attack is from 3 to 6 weeks and relapses are uncommon. In exceptional cases the disease may be prolonged to 2 or 3 months and each crop of eruptions generally follows on the heels of the previous healing ones. Spontaneous recovery takes place in majority of cases, the redness subsides, the raised margin sheds a fair amount of scales and soon becomes level with the general surface of the skin. There are no after-complications. The ætiology is not definitely understood but there are good grounds to assume that this disease is caused by a filter-passing virus. A small percentage of cases develops acid dyspepsia soon after recovery.

Treatment. *Local.* The patient should receive soothing ointments such as ichthylol ointment $\frac{1}{2}$ to 1 dr. to an ounce, or 2 per cent. ung. acid salicylic after a warm bath in 1 in 10,000 Condy's fluid. When there is a good deal of irritation, salicylic acid ointment may be combined with menthol and carbolic acid—5 gr. of each to every ounce.

Internal. Salicin in doses of 10 gr. twice daily and gradually increasing to 20 gr. per dose often aborts an attack. Hydrag. cum creta 1 gr. combined with pulv. ipecac 1 gr. is also of value. Ichthylol may be given internally with good results.

LICHEN PLANUS: Primary. The lesion is characterised by dry, shiny, purplish or violet-coloured papular eruptions, arranged in groups with a linear or annular distribution and affecting mostly the flexor aspects of the limbs, the trunk, face and neck. The mucous membranes of the mouth, vulva and the glans penis are also involved although the typical lesions are not often seen in these situations. Each papule is polygonal in shape and, occurring on the normal lines of cleavage of the skin, exaggerates the harshness of the texture so that a group of papules seem to form mosaic patterns on a deeply furrowed skin. The disease is sometimes acute in onset with slight constitutional symptoms and affects large areas on the thighs, forearms, lower portion of the back and abdomen. In severe cases the affected skin becomes diffusely red and cedematous but very soon assumes a violet or lilac colour. Small herald spots, few in number, may appear several weeks ahead either on the limbs or on the buccal mucous membrane. Spontaneous recovery may take place after a few months leaving the skin deeply hyper-pigmented or the disease may progress and affect other parts of the body. Occasionally atrophy of the affected areas is met with. A few patches very frequently persist as the so-called chronic variety particularly on the shin areas. The lesions are unsightly.

The chronic type is far commoner than the acute and shows periodic exacerbations during which new spots appear and spread although the older lesions remain localised on the parts already affected. After persisting for several months or even years spontaneous involution may take place. A few cases are progressive in nature so that the lesions become hypertrophic. Intense itching is the most outstanding subjective symptom although all the patches are not equally irritable. Clinically, the hypertrophic or verrucous type may show linear distribution along scratch marks—*lichen planus linearis*. The affected skin may be atrophic so that the lesion closely resembles morphæa—*lichen planus atrophicus*. The skin may be intensely red and congested—*lichen planus erythematosus*, or show bullous formations—*lichen planus bullosus* and *multiforme*. In very rare instances hæmorrhage occurs in the skin—*lichen planus hæmorrhagicus*. The patches extend by coalescence of the papules. The ætiology of the disease is unknown. Acute onset sometimes follows nervous shock or excitement. Focal infection of the teeth and tonsils play a very important part and a certain percentage of cases shew sensitiveness to pollens, animal emanations and food proteins without any other definite evidence of an allergic condition. The trend of recent work points to the disease being caused by a filter-passing virus. The disease is most frequent during active adult life, but children are not totally immune. The changes in the skin consist of a sharply defined infiltration of the papillary and subpapillary layer with connective tissue cells extending as far down as the region of the coil glands. The papillæ are enlarged and œdematous and the papillary capillaries dilated. The horny layer is thickened and the rete shows a certain amount of hypertrophic changes.

Treatment. General. The patient should be kept on good nourishing and plainly cooked food and encouraged to lead a hygienic outdoor life as far as possible. All sources of mental worry and anxiety should be carefully avoided. The bowels and kidneys require attention as elimination through these channels is of importance. Mild aperients and alkaline citrates may be used in almost every case with good results.* A thorough investigation into the presence of septic foci in the teeth, tonsils, nasal sinuses or the bowels should be undertaken where laboratory facilities are available. Correlated allergic conditions should be determined and the source eliminated.

Internal. Preparations of mercury, arsenic or bismuth give the best results. The bichloride or biniodide of mercury may be given intramuscularly in 1/12 to 1/6 gr. doses suspended in olive oil. The patient receives one injection every day for 12 consecutive days with good results especially in acute cases, chronic cases often require two or three courses of injections at 6 or 8 weeks' intervals, all precautions being duly taken against the toxic cumulative effects of mercurial salts. Oral administration of liq. hydrarg. perchlor. in $\frac{1}{4}$ to 2 dr. doses twice daily is also of value. Arsenic in the form

of soamin injections biweekly or Neosalvarsan weekly often give very satisfactory results. Bismuth in the form of oily suspension of the metal or as bismuth salicylate solution in 2 to 3 gr. doses, given intramuscularly, are also useful.

Local. The acute cases require soothing antipruritic applications, e.g., liniment calamine with 8 to 5 min of phenol added to each ounce, or ichthyol lotion 10 to 20 per cent. Chronic hypertrophic verrucose types should be first cauterised with 5 to 10 per cent solution of liquor potassi followed by application of 5 per cent salicylic acid ointment. Chrysarobin ointment can also be used. Lichen paint of the School Pharmacopœia offers a good combination of antipruritic and keratolytic agent which is painted on with a brush night and morning. Raw coal tar is also of value. An efficient combination for chronic hypertrophied lesions is as follows:—Menthol 1½ dr., thymol 2 dr., chloral hydrate 1 dr., chloroform and oil of eucalyptus 2 oz., oil gaultheriæ 4 dr., alcohol up to 8 oz. Lesions on the buccal or vulval mucous membranes are best treated with 5 per cent lactic acid or 0.5 per cent. chromic acid. Ultraviolet therapy may be used with advantage to relieve the itching of the skin. X-ray treatment has been recommended in fractional doses at weekly intervals and complete involution usually occurs in about two months' time.

Secondary lichen. It occurs at sites of old irritative lesions of the skin such as ringworm, seborrhæic and chronic allergic dermatitis. The condition may sometimes be brought about or exaggerated by too frequent use of strong irritant drugs and keratolytic agents which exert a stimulating effect on the rete accompanied by inflammatory vascular changes in the superficial layer of the corium. Treatment consists of removing the cause of irritation and use of milder keratolytic agents such as salicylic acid ointment 15 to 20 gr. to an ounce, to which may be added liq. picis carbonis ½ dr. and menthol 5 to 10 gr. Chronic cases with obstinate patches require X-ray treatment.

LICHEN NITIDUS. It is characterised by shiny, flat, flesh- or pink-coloured papules which are always discrete and slowly progressive in nature and produce no subjective symptoms. The commonest site of occurrence is the genitals although the breasts, thighs, arms and the lower abdomen may also be affected. The lesions involve the mouths of the pilo-sebaceous glands and are sometimes slightly scaly. Spread of the disease may be arrested for some time and spontaneous recovery is not very uncommon. The disease itself is often overlooked because of the absence of irritation which distinguishes this condition from lichen planus. The aetiology is unknown; some authorities believe that there is some relationship to tuberculosis.

Treatment. It is rather unsatisfactory. Local treatment with an ointment containing resorcin and salicylic acid (20 gr. of each in an ounce

of lanolin base) gives the best results when continued for some time. Internally iodine in gradually increasing doses has proved to be of some value. Stubborn cases should receive a trial with intravenous injections of gold sodium thiosulphate.

PSORIASIS. It is a chronic recurrent inflammatory disease characterised by circumscribed patches of erythematous lesions with dry silvery scaling surface. It generally affects the scalp, the ears, the extensor aspects of the extremities and the sacral region. The diagnostic features of the disease are the presence of micaceous, sometimes laminated, scales which are loose at the periphery and more or less firmly adherent at the centre of a patch; when these scales are removed the underlying skin is found to be markedly erythematous with points of bleeding from the tips of the papillæ. The onset is usually insidious beginning in the scalp where it is often diagnosed as dandruff in the earlier stage. Initial lesions may appear at the common sites of predilection or on any other part of the body as small guttate erythematous papules covered with fine silvery scales; the face, palms and soles generally escape. Spread of the disease is generally slow, the individual lesions enlarge by peripheral extension, and coalescence of contiguous patches often gives rise to gyrate patterns. Involution occurs in the centre of the patches and the edges become thick and tough owing to accumulation of scales. Acute exanthematic onset with appearance of numerous guttate lesions all over the body has been noticed in a few rare instances. The course of the disease is very inconstant. Individual lesions may remain localised and stationary for months with periods of improvement especially during the changes of the season. Spontaneous recovery at one place may be followed by appearance of fresh lesions at other parts of the body; there may be complete freedom from the disease for some years after which recurrence at the old sites or in an acute form may be ushered in without any warning. The general health is not affected although chronicity and recurrence is the rule; psoriasis does not induce alopecia. On the fingers and toes heaped up crusts accumulate beneath the nails and give rise to deformities such as grooving, discolouration and cracking of the free edge. Lesions in the axillæ, submammary folds, pubis, groins and gluteal folds often become extensively erythematous and sodden owing to perspiration and friction of clothes macerating the skin. Burning and itching renders the diagnosis difficult in such cases especially on dark coloured skin. Extensive generalised affection of the whole body is not very uncommon. The face, palms and soles may shew a few guttate lesions only in the acute exanthematic form of the disease but the condition should always be distinguished from syphilis which is far commoner than acute psoriasis. The disease is seen mostly in adults, affecting males more than females. Several clinical varieties have been described, *psoriasis guttata* in which the lesions resemble discrete drops; *psoriasis follicularis* in

which the lesions are situated at the mouths of the sebaceous and sweat glands; *psoriasis nummularis* in which the lesions are coin-shaped; *psoriasis osteacea* in which the scales are so thick and tough that they resemble the outside of an oyster shell. Other varieties such as *psoriasis gyrata*, *psoriasis discoides*, *psoriasis rupioides*, etc., have been described.

The aetiology is unknown although the parasitic theory has the largest number of supporters. The causative organism is considered to be a filtrable virus. There is good deal of hyperkeratosis and thickening of the rete with perivascular and perifollicular infiltration, the interpapillary vessels showing marked dilatation.

Treatment. General. Although psoriasis is generally a disease of the so-called healthy subjects, attention should be paid to diet and proper elimination and adoption of general hygienic measures is also of importance. A plainly cooked mixed diet, which is easily digested, is recommended; the patient should be encouraged to drink plenty of fluids and plain water to flush the kidneys. Fat-free diet has been recommended by many authors. Constipation, when present, should be treated with mild aperients and liquid paraffin; moderate exercise in the open air is helpful but vigorous exertions of any kind which induce a good deal of sweating should be avoided. Attempts should also be made to relieve mental worry as much as possible. A laboratory investigation for latent foci of infection should be undertaken wherever possible.

Local. The most effective local remedies are chrysarobin, salicylic acid and coal or wood tar. The scales are first removed by alkaline baths or soft soap and each individual patch is scrubbed with a piece of soft pumice stone till the papillæ of the skin are exposed as indicated by small bleeding points in the patch under treatment. Ung. chrysarobin (10 to 20 gr. to an ounce of lanolin), is applied and allowed to act for 4 to 6 hours. The centre of the lesion becomes white and anæmic and an erythematous reaction appears around the patch. Chrysarobin ointment is now removed with olive oil and some bland ointment (e.g., Lassar's paste or ung. borovaseline) applied on the treated patches. The treatment can be repeated the next day if there is no severe inflammatory reaction. Sensitive subjects may shew chrysarobin dermatitis which requires calamine lotion or other cooling preparations locally. In the scalp the hair is clipped short and a stronger ointment, containing 40 gr. of chrysarobin to an ounce, can be used. The patient should be warned not to touch his eyes while the ointment is on the scalp lest severe conjunctivitis set in. Chrysarobin can also be conveniently used as a paint dissolved in traumaticin (chrysarobin 10 gr., gutta percha 1 dr., chloroform 1 oz.) and thus save soiling of clothes and linen which stain permanently purplish black. This can also be attained by using a 2 per cent. alcoholic solution of chrysarobin on the lesions and subsequently painting with collodion. A very useful chrysarobin derivative is now available under the commercial name cynoglin; this is used as a

paint dissolved in chloroform or pure acetone in strength of 2 to 4 gr. to an ounce. It does not stain linen. Extensive areas of the skin should not be treated at one time with chrysarobin as absorption of the drug may cause acute nephritis. The urine should be examined frequently even when a patient is receiving chrysarobin applications over small areas but for a fairly long time. Salicylic acid is best used as an ointment in strength of 20 to 120 gr. in an ounce of lanolin or vaseline and can be combined with 5 to 50 per cent. crude coal tar. Better results are obtained when local applications are used with a certain amount of friction after softening and removing the scales with soft soap or alkaline baths. Coal or wood tar can be used pure but it is preferably used as a 10 to 15 per cent. ointment in a lanoline base. It can also be used in combination with salicylic acid; Ung. picis cum salicylic of the School Pharmacopœia is a very useful preparation. All strong keratolytic drugs should be withheld whenever there is any sign of secondary irritation and cooling preparations like calamine lotion or plain olive oil should be applied instead. For psoriasis involving the entire scalp, lotions or pomades containing 10 per cent. resorcin and 5 per cent. salicylic acid are recommended for use at night. Psoriasis of the nails is very difficult to treat owing to the hard nail matrix preventing the remedial preparations from reaching the site of the lesion. The nail is first softened with caustic soda solution—Fehling's solution No. 2 is the best—and paints containing 1 to 5 per cent. chrysarobin in colloidion are used afterwards. X-ray exposures are of benefit but requires prolonged treatment which is not unaccompanied with the risk of X-ray dermatitis. Ultra-violet therapy has been recommended and is of benefit in acute exanthematic types in bringing down the inflammation. Its value in chronic cases is doubtful but general irradiation sometimes induces rapid involution. Chronic inveterate patches can be treated with X-rays but on the scalp the risk of permanent alopecia has to be borne in mind.

Internal. Salicin in gradually increasing doses acts beneficially in a large number of cases. Commencing from an initial dose of 10 gr. twice daily, the quantity is increased by 10 gr. every week till 30 gr. is reached. The maximum dose is kept up for three weeks. Other intestinal antiseptics, *e.g.*, liq. hydrarg. perchlor, zinc sulpho-carbolas, etc., have been used without any special advantage. Preparations of arsenic have also been recommended and can be administered either in the form of Fowler's solution or Donovan's solution. It is necessary to keep up the maximum dose for about six weeks and all precautions against the cumulative effects of the drug should be taken during the course of treatment. Cacodylates and arselyn may also be used by injection. The use of an autolysate prepared from the scales and diseased tissue has given encouraging results, but the best results are obtained when this is combined with a thorough local treatment in experienced hands. The removal of scales and scrubbing with pumice

stone followed up with application of chrysarobin or cignolin has effected the largest number of cures at the Carmichael Hospital for Tropical Diseases. Relapses, however, do occur and at the present state of our knowledge, there are no means of preventing them.

Inflammatory Diseases Characterised by Multiple Bullous Lesions of the Skin

EPIDERMOLYSIS BULLOSA. It is a rare hereditary condition in which blisters of varying size form on the skin as the result of trivial injuries or friction. In the majority of instances the disease is noticed in early infancy, the lesions appearing mostly on the back over the bony prominences or over the napkin area. Individual lesions are generally filled with clear serum but may, in rare instances, contain blood. The blisters rupture within a day or two of their appearance and heal fairly rapidly provided there is no secondary infection of the raw surface with pyogenic cocci. There are practically no residual scars on healing but the affected areas may become slightly depigmented. Repeated attacks may occur at the same site, and when the fingers and toes are thus affected, the growth of the nails is arrested. Deeper structures are sometimes involved especially when there is secondary infection of the ruptured vesicles and thus lead to contractures and other deformities. The disease has been known to have made its first appearance during young adolescence and has been described as the acquired variety. The aetiology is unknown but is assumed to be a defective development of the cementing fibrils which fix the epidermis to the subjacent tissues. The entire epidermis is lifted up in the formation of the blisters and there is slight dilatation of the papillary and sub-papillary vessels. The general health is in no way affected except in cases of extensive secondary infections. Subjective symptoms are conspicuous by their absence.

Treatment. The treatment is very unsatisfactory and protection from injuries even of a trifling nature should be undertaken rigorously. The blisters should be punctured aseptically and dressed dry with equal parts of zinc oxide, starch and boric acid. Calcium lactate with parathyroid in suitable doses is worthy of a trial. Where the affected child is born of a consanguineous marriage, blood transfusion from a person outside the family has been recommended. Spontaneous recovery with attainment of puberty is not very uncommon.

PEMPHIGUS. An acute or chronic inflammatory disease characterised by sudden occurrence of successive crops of bullæ on an apparently normal skin and accompanied with constitutional symptoms of varying severity. The mucous membrane of the mouth and entire gastro-intestinal tract as well as the conjunctivæ become ulcerated in the acute form of the disease which often terminates fatally from

toxæmia and exhaustion. The ætiology is not definitely known but a bacterial infection of some kind probably plays a very important part in the causation of the disease.

Clinical varieties. (1) Acute—malignant and benign; (2) Chronic—*pemphigus vulgaris*, *pemphigus follicaceus* and *pemphigus vegetans*.

Pemphigus acutus malignus. This is a disease most commonly seen amongst butchers and dealers in animal carcasses and generally commences from some injuries on the exposed parts of the body. The onset is accompanied with severe constitutional symptoms like fever, vomiting and prostration. Blebs of varying size appear on the limbs, body, face, scalp and buccal mucous membrane in successive crops; contiguous vesicles coalesce to form large blisters which may be as much as 10 cm. in diameter. The contents are generally serous but may become hæmorrhagic in very acute cases. The blisters soon rupture and leave raw sanguineous weeping surfaces which tend to spread progressively at the margins and shew no tendency to heal. Masses of detached epidermis and oozing blood-stained serum undergo decomposition and give rise to a very offensive odour. There is no itching or irritation but the affected areas are very painful which, together with joint pains, renders the patients immobile. Extensive ulcers form in the mouth, trachea and the whole of the gastro-intestinal tract, the conjunctivæ also become ulcerated, toxæmia deepens and the case terminates fatally from the effects of toxæmia, inanition and exhaustion within two or three weeks. Intercurrent diseases like pneumonia or cardio-renal failure very often hasten the end. In a few cases yellowish crusts form on the ruptured vesicles, the lesions cease to spread and recovery takes place only to pass into the chronic form (*pemphigus vulgaris*) of the disease.

Pemphigus acutus benignus. The constitutional symptoms are less severe and ulceration of the mucous surfaces is absent. Ruptured vesicles are soon covered with yellowish crusts and heal spontaneously leaving hyperpigmented scars. Some authorities classify this form under a separate heading with bullous impetigo. The disease is sometimes seen in children following vaccination against small-pox.

Pemphigus (chronicus) vulgaris. It is commonly seen in debilitated subjects beyond middle age and affects the face, mouth, neck or the genitals. The lesions may however appear on any part of the body and become generalised in distribution. As a rule, crops of vesicles appear in one part of the body and after persisting for some time disappear completely, leaving the patient almost free for more or less long periods of time. The first few attacks may be mild but the constitutional symptoms and extent of the disease become more and more severe with each recurrence. The mucous membrane of the mouth, throat, etc., are ulcerated and the patient develops the toxæmic prostrated appearance of pemphigus acutus malignus prior to a fatal termination in the course of a few months. The contents of the vesicles are at first serous but later becomes sero-sanguineous or sero-purulent. Death from intercurrent

pneumonia or cardiac and renal failure is more common in this type of the disease.

Pemphigus foliaceus. A rare and grave type of chronic pemphigus in which the bullæ are flaccid and imperfectly formed with a tendency to generalised exfoliation of the skin. There is no cohesion of the epidermis with the deeper layers so that the cuticle can be easily removed by friction or pinching (Nikolsky's sign). The blebs develop rapidly and involve almost the entire surface of the body; the contents, which are purulent from the very beginning, are set free by rupture of the vesicles soon after they are formed, the epidermis peels off leaving large raw surfaces covered with sero-purulent fluid. Large, fairly thick and loosely adherent crusts form on the surface and the discharges accumulate underneath and undergo decomposition giving rise to a foul sickening odour. To the palpating finger the surface of the body feels as if the epidermis is floating on a bag of fluid. Mucous membranes of the mouth, throat and trachea become raw and ulcerated and the hair and nails may be lost. Subjective symptoms are trifling or absent but constitutional symptoms of a mild degree persist throughout the course of the disease. Periods of quiescence follow exacerbation but the condition of the skin never clears up completely. The disease may be prolonged to several months and a fatal termination from intercurrent diseases is the rule. *Pemphigus foliaceus* is believed by some dermatologists to be due to secondary infection of the vesicles of *pemphigus vulgaris* with the pyocyanous bacillus (*Pseudomonas pyocyanea*).

Pemphigus vegetans. It generally commences as a bullous lesion on the mucous membrane of the mouth, throat and lips but as the vesicles rupture very soon after their appearance physical examination reveals only the raw moist bases. Blisters soon begin to appear on the nose, genitals, axillæ, groin, and the scalp and soon rupture. The raw bases instead of healing up become covered with papillomatous exuberant vegetations which are capped by crusts and exude a thick sero-purulent fluid of offensive odour. The subjective symptoms are slight and there are fairly long periods of intermission in the course of the disease, during which marked improvement is noticed without a complete cure. Constitutional symptoms are absent in the earlier stages but later on fever and nephritis set in as complications. The lesions in the mouth are very troublesome and hinder intake of nourishment. The patient becomes very susceptible to pneumonia and bacillary dysentery, either of which carries him away.

Treatment. *Acute cases.* The patient should be put to bed on a water or air mattress preferably, and his general health should be well looked after. The mouth should be gargled frequently with Condy's fluid or dilute B. C. lotion and painted with boroglycerin. A bath in 1 in 10,000 acridavin or weak Condy's lotion once a day is very helpful in keeping the skin clean and preventing secondary infection. The food should be bland, non-irritating, and concentrated and given in small

quantities at frequent intervals. Internally, tonics particularly cod-liver oil, arsenic, iron and quinine are of value; of these, arsenic has been known to exert a curative effect in a few cases. It can be administered by the mouth as Fowler's solution or given intravenously as one of the arsphenamine preparations. Subcutaneous injections of coagulin are worthy of trial. Recently, Bayer 205 has been reported to have curative effect in some cases but its action on the kidneys should be carefully watched and the urine examined every day for presence of albumin. Locally, liniment of calamine is soothing. Continuous application of large quantities of plain dusting powder is also helpful. Extensive denuded areas should be kept moist with lint soaked in 1 in 5,000 acriflavin lotion.

For *pemphigus vulgaris* a conservative line of treatment yields the best results. Autogenous vaccines prepared from a culture of the contents of the vesicles have beneficial effects in checking recurrences. *Pemphigus foliaceus* requires frequent antiseptic baths and local application of dusting powder along with general tonics and cod-liver oil internally. Autogenous pyocyaneus vaccine is of considerable value. *Pemphigus vegetans* is treated on the same lines and auto-crotherapy has been found successful in a few cases.

DERMATITIS HERPETIFORMIS. It is a chronic, irritative, relapsing, inflammatory disease in which erythematous, papular, bullous or pustular lesions appear suddenly on the surface of the body and which tend to spread by peripheral extension. There are very mild constitutional symptoms which very often escape notice of the patient. The vesicles are very tough and do not rupture except through trauma and there is a tendency towards arrangement in groups. The disease has a varying clinical character but intractable and severe itching and burning is almost invariably present. An individual case may show erythematous, papular, bullous and pustular lesions all at the same time except in children who generally show the bullous and vesicular types of lesions. The sites of predilection are the posterior folds of the axillæ, the buttocks, abdomen, the forearms and the face. The lesions are very roughly symmetrical and the mucous membranes may be involved in very acute cases. Axillary, epitrochlear and inguinal glands become enlarged and inflamed as the result of secondary infection of the vesicles after they are ruptured. No age is exempted from an attack but the disease is more common amongst adult males in poor condition of health and nervous system. The disease may be prolonged to several weeks or months with periods of exacerbation alternating with those of quiescence. The ætiology, although not definitely known, is very closely associated with chronic auto-intoxication; pregnancy has also been found to be a very potent factor in women. Eosinophilia and indicanuria point to the disease being of allergic origin. The seat of the lesions is in the corium; the papillæ are oedematous,

the papillary and sub-papillary vessels are dilated, there is fair amount of perivascular infiltration and the entire epidermis is lifted up in the formation of vesicles.

Treatment. The first essential is to determine and eliminate all sources of toxæmia and this involves a careful investigation into the presence of septic foci in the teeth, tonsils and bowels. Attention should also be paid to digestion and elimination through the bowels and kidneys, mild cathartics and diuretics being exhibited whenever necessary. A dermal test for sensitiveness towards food or epidermal proteins is of great value and a complete cure can sometimes be obtained by total omission of the offending article of food. Internally, arsenic in the form of Fowler's solution or liquor arsenicalis hydrochloridum give encouraging results and in severe cases soamin, tryparsamide or neo-arsphenamine may be tried intravenously. Salicylates in full doses have been recommended but their effects are rather uncertain. Non-specific protein therapy in the form of autogenous serum, T. A. B. vaccine or milk sometimes yields very good results. Locally, alkaline, sulphuretted or bran baths have a soothing effect. The affected areas should be wiped dry without friction on emerging from the bath and a thick layer of calamine lotion containing 0.5 per cent. of carbolic acid and 5 to 20 per cent. of liquor carbonis detergens applied on lint. In severely irritable cases relief is often obtained by incising the vesicles and letting the contents out. Areas of excoriation should be treated with weak antiseptic ointments of which a 1 per cent. ammoniated mercury is by far the best. Bromides, luminal and other hypnotics are used when the intractable itching causes insomnia and consequent exhaustion.

Bullous Lesions caused by Filtrable Virus

HERPES SIMPLEX. The lesions consist of one or more groups of vesicles on erythematous and slightly oedematous bases and are always of acute onset. The commonest sites of predilection are the face and genital regions although the buttocks, arms and legs are sometimes affected. On the face, the lips, the nose, the ears and the cheeks are mostly involved and in the genital area the lesions appear on the prepuce, glans, sulcus, labia, mons veneris, clitoris and occasionally the urethra and cervix. The mucous membranes are hardly ever affected except on very rare occasions; there is slight fever and malaise when the vesicles appear in the mouth. The site may be irritable or there may be a feeling of pain and burning for a day or two before the actual appearance of the eruption. Other subjective symptoms and constitutional disturbances are generally absent. Herpes simplex very often accompanies pneumonia, influenza, meningococcal meningitis and malaria and shows a certain amount of familial tendency in its occurrence. Some subjects seem to have a predisposition and suffer with repeated attacks of herpes in approximately the same situation. Such recurrences may

follow intercourse, menstruation and intake of alcohol, spices, etc. The contents of the vesicles are at first serous but become sero-purulent in a couple of days or so. The walls of the vesicles are rather tough so that spontaneous early rupture does not occur. Involution sets in about a week after the appearance of the vesicles, some of which rupture and heal by formation of yellowish crusts while others get dry and drop off in about a fortnight's time. There is no residual scarring except when there is secondary suppurative infection. The cause of the disease is a filtrable virus of low virulence and having a saprophytic existence on the mucous membranes under healthy conditions.

Treatment. All possible sources of reflex irritation should be carefully looked for and removed. Locally, in the eruptive stage, a cold compress with 2 per cent. alum acetate solution is very useful. Painting the area with spirits of camphor and alcohol followed by dusting freely with zinc and starch dusting powder or powdered alum relieves the pain and burning. A thick coating of surgical collodion which is renewed every day is of value in preventing rupture and secondary infection of the vesicles. Lesions at the angles of the mouth can be touched up with a caustic pencil and dressed dry with talcum powder. In the genital region especially on the apposing mucous surfaces of the vulva, strict cleanliness is essential. The area should be swabbed with hydrogen peroxide and dusted with 5 per cent. aristol dusting powder (aristol 20 gr., zinc oxide and starch 4 oz. of each) three times a day. Recurrent cases require investigation into presence of focal sepsis in the teeth, tonsils, upper respiratory passages, bowels or pelvis.

HERPES ZOSTER. The lesions consist of groups of vesicles on an erythematous base and occur along the distribution of the fibres of nerves originating from one or more posterior root ganglia. The onset is acute and fairly rapid and is in many cases heralded by malaise, fever and persistent neuralgic pain. The cause of the disease is a filtrable virus of the same category as chicken pox and people coming in close contact with a person affected with herpes zoster have been known to have developed chicken pox after an incubation period of fourteen to sixteen days. Individual lesions have the same character as *herpes simplex* but are more intense and extensive and large patches consisting of a dozen or more vesicles appear in successive crops on the same side of the body. The contents of the vesicles are usually serous but may become sero-purulent owing to secondary infection; in rare instances the contents are hæmorrhagic. Lymph glands in the neighbourhood of the affected areas may be enlarged and tender. The average duration of the disease is about two to three weeks. A single attack confers immunity. On healing, the vesicles leave hyper-pigmented scars owing to involvement of the deeper layers of the epidermis. Certain drugs like arsenic and diseases of the cerebrospinal system notably

syphilis, tumours and traumatic injuries predispose to an attack. The site of appearance of herpes zoster may remain hyperæsthetic for months after an attack. The most serious sequel to herpes zoster of the face is affection of the cornea and the eyeball when the nasal branch of the ophthalmic division of the fifth nerve is involved.

Treatment. It is advisable to give the patient a good purge with calomel or blue pill followed by saline cathartics the next day. When the cornea is affected cold compresses with 2 per cent boric lotion are applied every 4 hours. The eye should be examined frequently by an ophthalmologist for serious corneal ulcers. The skin lesions are best treated with thick layers of talcum powder and cotton wool dressing. A hot water bag is very agreeable and relieves the neuralgic pain in mild cases. Aspirin, hypnotics of the barbituric acid series or even morphia may be necessary in severe cases. Extensive secondary pyogenic infection of the vesicles may require surgical interference and free drainage, the healing in such cases is generally uncomplicated. Mild galvanic currents and ultra-violet radiation sometimes give immediate relief; for severe pain pituitrin injection (0.5 c.cm.) is often useful.

Hæmorrhagic Lesions of the Skin

PURPURA. The disease is characterised by the occurrence of reddish or purplish eruptions due to extravasation of blood into the skin and mucous membranes. The lesions are flat and circumscribed and on a level with the general surface. Depending on the degree, extent and depth of occurrence these hæmorrhagic lesions are termed petechiæ, ecchymoses and hæmatomata. Purpura is either primary or secondary to other diseases.

Primary purpura. (1) *Purpura simplex.* The disease is of sudden onset without constitutional symptoms and is characterised by appearance of small petechiæ chiefly on the legs and mucous membrane of the mouth. The individual hæmorrhagic spots develop fully within two or three days and then fade gradually, the total duration of the disease being about a week or ten days. Successive crops may keep on appearing for months with slight fever and malaise, but the general health is not seriously impaired. Children and old debilitated people are usually affected but young adults sometimes, though rarely, suffer as well.

(2) *Henoch's purpura.* It is also found in children and is associated with vomiting, colic and diarrhoea of varying severity. The onset is sudden with joint pains but no rise of temperature and in severe cases the vomit and stool may contain blood. Hæmaturia may occur in a few instances and nephritis is a serious complication of the disease. Recurrent attacks do occur and a fatal termination is not very uncommon. The disease is probably allergic in origin and is due to sensitiveness towards some common articles of food.

(3) *Purpura rheumatica*. The petechiæ are ushered in with fever, sore throat and multiple arthritis and the entire surface of the body and mucous membranes may be involved. *Purpura rheumatica* may be accompanied with urticarial, erythematous or bullous lesions of the skin similar to erythema multiforme or erythema nodosum. Pleurisy, pericarditis and endocarditis are serious complications. The disease may persist for several weeks or months but the average mild cases recover in two to three weeks. Recurrences do not occur as a rule.

(4) *Purpura hæmorrhagica or morbus maculosus*. In this type extensive hæmorrhages occur into the skin, the mucous membranes, the serous membrane and meninges. The onset is sudden and without warning and is manifested by fairly free bleeding from the gums, nose, stomach, bowels, uterus and urethra. These hæmorrhages may be of a severe nature and end fatally in the course of a week or so. Large areas of ecchymoses and hæmatomata appear on the skin, the entire buccal mucous membrane may be discoloured and hæmorrhagic. Young girls are more commonly affected and they show a marked fall in the platelet count. The disease may persist for months or years in a mild form with periods of intermission and improvement in bodily health.

Secondary purpura owe their origin to various causes of which the following are some of the more important :—

(i) Acute infectious diseases, *e.g.*, typhoid fever, cerebrospinal meningitis, plague, typhus, measles, small-pox and scarlet fever; (ii) Chronic nutritional disorders, *e.g.*, scurvy; (iii) Systemic disorders, *e.g.*, diseases of the heart, nephritis, pernicious anæmia, leukaemia, tuberculosis, and icterus gravis; (iv) Toxic purpura is caused by drugs like iodine and iodides, mercury, chloral hydrate, copaiba, quinine, ergot, belladonna, turpentine, salicylates. Snake venom also causes purpuric eruption; (v) Nervous purpura: severe fright or very strong emotions are sometimes followed by an acute onset. (vi) Mechanical pressure or gravity occasionally give rise to purpuric spots in susceptible individuals. Impediment to the circulation in the capillaries as occurs in embolism may cause a severe attack of purpura.

The important ætiological factor in the causation of purpura is the markedly increased permeability of the endothelial cells forming the capillary walls. Streptococcal toxins are mostly responsible for the onset of symptoms in purpura simplex and purpura rheumatica; in Henoch's purpura the allergic state which leads to extreme permeability of the capillaries of the skin and mucous membranes is the principal ætiological factor. The cause of purpura hæmorrhagica is not known.

Treatment. Except for the milder degrees of purpura simplex all cases of purpura should be treated as serious and the patient put at rest in bed with the first onset of signs and symptoms. Great care and gentleness should be used in handling the patient as slight pressure may lead to formation of ecchymoses or even hæmatomata. The foot end of the bed should be raised. The diet should be completely

changed and lightly cooked plain wholesome food given in small quantities at frequent intervals. All sources of focal sepsis should be carefully looked for and eliminated and a dermal sensitiveness test is always helpful in determining acquired sensitiveness towards common articles of food. Constipation, when present, should be treated with liquid paraffin or olive oil ; other laxatives are better avoided. For purpura rheumatica autogenous vaccines prepared from streptococci infecting the throat and tonsils or rheumatic phyllacogen is of great value. Attention should be concentrated on improving the tone of the capillary walls and diminishing their permeability and this can be attained by administration of calcium lactate 10 gr. combined with parathyroid 1/10 gr. twice daily by the mouth. Adrenalin is not a safe remedy owing to the fact that by raising the blood pressure it may lead to late hæmorrhage from the mucous membranes. In Henoch's purpura or morbus maculosus with extensive bleeding from mucous surfaces, normal horse serum 10 c.cm. or hæmoplastin 2 c.cm should be given intravenously as an emergency measure. Glucose should be given freely by the mouth or when necessary it can be given intravenously as a 12.5 per cent. solution in normal saline. Great care should be taken in using the ligature or digital pressure on the arm to make the median vein stand up prominently lest the area of pressure becomes hæmorrhagic. Acid sulphuric aromaticus in 15 to 30 min. doses has been recommended but this has no specific action except for its sedative effect. Blood transfusion and heteroserotherapy is sometimes curative for purpura hæmorrhagica. Vitamin D in large doses has a beneficial effect in most cases.

Treatment of secondary purpuras consists in removal of the underlying cause.

Inflammatory Diseases of Embolic Origin

ERYTHEMA NODOSUM. It is characterised by painful oval or rounded, raised, bright-pink coloured nodules surrounded by a halo of erythema and is ushered in with malaise, joint pains and rise of temperature. The evolution of these nodules is fairly rapid, attaining full development in six to twenty-four hours, and after persisting for about three weeks, they disappear spontaneously. The extensor aspects of the extremities are mostly involved, the lower more commonly than the upper. The lesions are usually symmetrical in distribution, few in number, tense to the feel and shiny in appearance; they are situated deep in the corium. Occasionally a few nodules of soft consistency are met with but they are always very painful and tender on pressure. Retrogression is heralded by change in colour from bright red to darkish red and purple; the consistency becomes soft and fluctuating almost simulating an abscess. These nodules rarely break down except when some secondary pyogenic infection is introduced accidentally. On healing, a dark or brownish stain is left for some time.

There is a certain amount of deep scarring which does not involve the epidermis. In exceptional cases, the nodules keep on appearing in crops and the total duration of the disease is prolonged to several months. The aetiological factor in a fair percentage of cases has been traced to streptococcal infection in the tonsils and teeth; the disease is a fairly common complication of rheumatic fever and has also been found in association with malignant endocarditis of non-rheumatic origin. There is marked dilatation of the papillary and sub-papillary plexus with oozing of serum accompanied by leucorrhoea and erythorrhoea. Some of the capillaries are embolised by streptococcal vegetations and there is aggregation of leucocytes around them.

Treatment. During an attack the patient should be kept at rest in bed; the bowels should be moved by suitable aperients whenever necessary and the kidneys flushed with drinks of plain water or other sweet drinks. Internally, an alkaline mixture containing 10 gr. of natural salicylate of soda with double the dose of the bicarbonate is given three times a day. Quinine in 5 to 10 gr. doses and salicin in 10 to 20 gr. doses, given twice daily, are also useful. Locally, 10 per cent. ichthyol ointment acts as a sedative, and this may be alternated with application of plain calamine or Goulard's lotion during the day. A thorough investigation into the presence of septic foci in the teeth and tonsils is of great importance in preventing a relapse which is not very rare. Autogenous streptococcal vaccine from these foci of infection is of proved curative value. Patients in run down or otherwise poor condition of health require iron arsenic and quinine tonics and cod-liver oil as an adjuvant to specific treatment.

LUPUS ERYTHEMATOSUS. The disease is characterised by the occurrence of pink, infiltrated plaques covered by adherent scales which tend to spread at the margin and heal in the centre with formation of atrophic scars and telangiectases. The lesions are quite superficial and do not ulcerate but are extremely persistent and slowly progressive in nature. When the scales are removed the follicles of the affected area appear dilated and some are filled with horny plugs. These epithelial plugs are usually firmly adherent to the under surface of the scales. Clinically, two types are met with, (i) the acute disseminated exanthematic type and (ii) the chronic circumscribed or localised type. Multiple lesions may appear in both types of case, the patches being of various configurations. Coalescence of neighbouring lesions often takes place at their extending periphery, thus involving extensive areas on the face, head and neck, hands, vulva and the perineum. The mucous membrane of the mouth is also commonly affected.

(i) **THE ACUTE DISSEMINATE TYPE.** The lesions may appear suddenly without prodroma and are accompanied by high fever and general constitutional disturbances. In a few instances the acute exacerbation may be superimposed upon the chronic circumscribed type.

No part of the body is exempt from affection although the palms and soles escape in the majority of cases. Individual lesions may be nodular or vesicular in character and in very severe cases hæmorrhagic. Crops of lesions appear at different parts of the body at the same time. Some patches heal up spontaneously while others develop into the circumscribed type of lesion. The buccal mucous membrane is almost always affected. Repeated attacks may ultimately lead to a fatal termination from pneumonia or pulmonary tuberculosis. This type of the disease is comparatively rare and causes practically no subjective symptoms. A few cases complain of a burning sensation.

(ii) **THE CHRONIC CIRCUMSCRIBED TYPE.** The onset is insidious and is not accompanied with any symptoms. Characteristic lesions consist of well defined, dry, pink or reddish patches, varying in size from a pea to the size of the palm of the hand and are covered with greyish adherent scales. The sites of predilection are the flush areas of the cheeks and the bridge of the nose, the mastoid area, the lobes of the ears and the scalp and front of the chest. On the face the distribution is often symmetrical on both cheeks with a narrow strip-like lesion along the nose giving rise to the typical butterfly shaped patch. The skin is only slightly infiltrated and the inflammatory changes are practically confined to the edges where extension of the lesion takes place. Atrophic changes with depigmentation and scarring in the centre of a patch and telangiectasis or 'gun barrel blue' discoloration of the margin constitute the typical clinical picture. Occasionally the healed areas are deeply pigmented. The mucous membrane of the month is involved in about 25 per cent. of cases; the lips, eye-lids and tongue are also affected. Lesions of the mucous membrane may appear only as slight thickenings with abrasions or scaliness of the affected part. Thin atrophic scars are left on healing. On the scalp the patches are hairless, harsh, sclerosed and extremely irritable.

The course of the disease is somewhat erratic but slowly progressive. Spontaneous recovery occasionally takes place without any residual scarring, but recurrence is almost always the rule. The disease generally appears between the second and fourth decades of life and women are more often affected than men. The principal ætiological factor is septic embolism of the fine capillary twigs in the papillæ derived from latent foci in the teeth, tonsils or nasal sinuses.

Treatment. Acute cases are treated on general lines and each case has to be carefully investigated for latent focal sepsis especially in the teeth and tonsils. All metabolic defects or circulatory derangements should be corrected. Absolute rest and small fractional feeds of concentrated nutritious liquid diet are indicated when constitutional symptoms are severe. Elimination through the bowels and kidneys should receive attention. Locally, cooling soothing lotions are used as cold compress during the day and the affected parts are smeared with pure olive oil at night. A tepid sponging towards the evening often

induces restful sleep at night. Of the various local remedies calamine lotion and white lotion (sodium chloride 1 part, sodium bicarbonate 2 parts and boric acid 3 parts in 100 c.cm. of distilled water) give the best results.

The chronic circumscribed cases also merit a thorough investigation into latent septic foci which should be located and eradicated. General hygienic measures are of importance. The diet should not contain any hot spices or condiments and stimulating drinks, particularly alcohol, are forbidden. Exposure to bright strong sunlight or extremes of heat and cold are harmful.

Local. Acutely inflamed and oedematous spreading lesions should be treated with continuous wet dressing of calamine or white lotion till the inflammation has subsided. Individual patches are then painted with 5 to 20 per cent. alcoholic solution of salicylic acid or resorcin, morning and night, to induce exfoliation. Perchloride of mercury may be added in strength from 1 in 5000 to 1 in 2000. The application is discontinued if there is any sign of irritation. When the scales have come off the patches are painted with phenol or trichloroacetic acid. Freezing with carbon dioxide snow sometimes gives good results.

Ultra-violet radiation in strong doses of five to thirty minutes are useful for obstinate patches and marked improvement follows when the reactionary hyperæmic stage has subsided. Complete recovery may sometimes take place but exacerbation after a period of quiescence is more common. General radiation should be undertaken with great care, as a sub-erythema dose often causes dissemination. X-rays and radium therapy have been tried with occasional successful results but as the chronic character of the disease requires prolonged treatment, X-ray and radium dermatitis and burns are serious sequelæ.

Internal. Tonics with combination of iron, arsenic and quinine are of great help in stimulating the defence mechanism of the body. Calcium lactate in 10 gr. doses combined with 1/10 gr. of parathyroid are given twice daily for toning up the capillaries. Cod-liver oil and its preparations are indicated when the general health is poor. Focal sepsis has to be treated with suitable autogenous vaccines and other specific measures. Preparations of gold, e.g., sanocrysin, solganal A and B, and krysolgan have been used intravenously with varying success and of these krysolgan is more often used on account of the stability of the compound in solution. All due precautions are necessary in exhibiting gold products and frequent examination of the urine for the presence of albumin and free erythrocytes are essential. The initial dose of krysolgan is 0.0015 gr. and the maximum 0.075 gr.

Best results are obtained by adopting measures which combine general, local and so-called specific therapy and treatment has to be varied and adopted according to the nature, duration and situation of the lesions.

ALOPECIA AREATA. The disease is characterised by sudden and total loss of hair in patches and affects usually the scalp but may involve other hairy areas of the body namely the beard and moustache, eyebrows, pubis or the body. The affected area is round or oval in outline with a few loose hairs at the periphery and the skin is smooth and glossy. The hair is broken off flush with the scalp and when pulled out present an 'exclamation mark' appearance due to atrophy of the bulb. In extreme cases total baldness may supervene in a few days by steady falling of the hair in large bunches. Spontaneous recovery is heralded by growth of very light-coloured downy hair which are soon replaced by stronger and stouter hair. This second crop is at first very light-coloured or white but gradually changes to normal colour and texture. The improvement may be arrested at any stage resulting in permanent baldness or the patches of white hair may persist. Occasionally the disease continues indefinitely and is characterised by successive growths of weak short-lived hair.

The disease is of inflammatory origin and is due to septic embolism and toxic inflammatory changes in the blood vessels of the papillary portion of the corium. The most important focus of sepsis is in the teeth in the form of dental caries or apical abscesses. Streptococcal infection of the tonsils is also present in a fair number of cases. Endocrine and nervous imbalance are other important aetiological factors. The disease usually affects grown up children and young adults of both sexes; universal or total alopecia is more common in adult men.

Treatment. Every case requires investigation in the presence of sepsis in the teeth and tonsils which should be treated by extraction, operative measures and autovaccine therapy according to the merits of the case. All sources of mental worry and anxiety should be removed. Vascular tonics like calcium lactate 10 gr. with parathyroid 1/10 gr., general tonics and cod-liver oil are very useful. Hexamine in 10 gr. doses given over a fairly long period usually cuts short the duration of the disease. Endocrine glandular products are required for cases with evident defect or imbalance of the ductless glands. When mental or nervous factors are present sedatives and hypnotics are indicated.

Local. Stimulating applications are indicated of which 95 per cent. phenol gives most satisfactory results. It should be applied as a thin film and allowed to remain for about an hour. For treating patches on the eye-brows or the face it should be diluted with equal part of glycerine. An ointment containing pilocarpine nitrate 1 gr., betanaphthol 1 dr., lanolin 2 dr. to an ounce of vaseline is recommended; this should be applied with friction over the patches twice daily.

Disease Caused by Spasm of the Blood Vessels

RAYNAUD'S DISEASE. It is characterised by symmetrical acrocyanosis, asphyxia and gangrene of the soft tissues of the fingers, toes and sometimes the ear and nose. The attacks are paroxysmal in nature and the ischæmia is caused by spasmodic constriction of the arteries supplying the affected part. During the spasmodic phase the part becomes pale, cold and numb and later on blue. Return to normal conditions takes place during the earlier stages without any impediment to the circulation but after several attacks the affected areas remain persistently cyanosed and painful. Superficial necrosis sets in and a gangrene of the dry type may follow, causing spontaneous amputation of several digits.

The exact cause of the disease is unknown. The syndrome is produced by local sympathetic irritability causing at first intermittent and then almost continuous spasmodic constriction of the arteries. It is sometimes associated with scleroderma. Highly strung and neurotic types of young adults are affected, the women more often than men.

Treatment. In the early stages the treatment is palliative with hot baths, massage and high-frequency current combined with general tonics, calcium and cod-liver oil. Preparations of muscle extract yield very good results, which can be used both orally and intramuscularly. When gangrene sets in the treatment is purely surgical. Periarterial sympathectomy is followed by permanent cure.

Neuroses of the Skin

PRURITUS (Itching). It is more a symptom than a distinct clinical entity and accompanies various skin diseases of both external and internal origin. It may be defined as intractable irritation of the skin, usually of a spasmodic nature, without any evidence of dermatitis or other inflammatory lesions on the surface. As a rule, localised areas on the trunk or limbs are affected but involvement of the whole body is not very rare. Acute cases shew objective signs which are the results of scratching, namely, blotchy erythema, excoriation, blood crusts, fissures and wheals. In chronic cases of fairly long duration pigmentation and lichenification supervene as secondary changes in the skin. Every case of pruritus should be investigated thoroughly to determine the underlying cause of which the following are important:—(1) Systemic diseases like diabetes, carcinoma, leukaemia, arteriosclerosis, Bright's disease, Grave's disease, certain disorders of the nervous system, Mycosis fungoides. (2) Intoxications, *e.g.*, high blood icterus, faulty elimination and stasis in the bowels, fermentation and chronic dysentery. (3) Ingestion of certain foods, especially shell fish and tinned products. (4) Ingestion of certain drugs which are eliminated through the skin, *e.g.*, copaiba, arsenic, etc. The commonest external causes are:—

(1) Mechanical, such as harsh or woollen clothes, corsetry and tight lacing, stretching of the skin as in pregnancy, etc. (2) Chemical, *e.g.*, too frequent use of soap, aniline dyes used for colouring socks, stockings, and underlinen, chemical insecticides, etc. (3) Parasitic, *e.g.*, scabies, ringworm and seborrhoeic dermatitis.

Treatment. General. Removal of the cause is the first essential and in attaining this, every case has to be treated on its own merit. Co-operation of the patient is a very important factor and highly strung or neurotic subjects are sometimes extremely difficult to treat because the habit of scratching is kept up subconsciously. Administration of calomel in a 2 to 4 gr. dose at bed time followed by a saline cathartic the next morning is a good routine measure to adopt. A complete change of diet is also of value. Exhibition of sedatives may be required for relieving the irritation, especially when the patient is tired and exhausted for want of sleep at night. Bromides in full doses and barbituric acid derivatives can safely be given at bed-time to induce restful sleep. Harsh woollen clothes should be replaced by garments of soft silk or cotton and the room should be kept comfortably cool and well ventilated.

Local. A soothing bath containing bran, bicarbonate of soda or menthol is given twice daily. The temperature is kept at about 78° to 80° F. and cold water is gradually added till the temperature drops to about 55° to 60° F. A cold spray before emerging from the bath is advised. The skin should be dried by gently patting with a soft towel and dusting powder or antipruritic lotions applied liberally. Of the various anti-pruritic remedies phenol in a 2 to 5 per cent. lotion and menthol in 0.5 per cent. alcoholic solution give best results. Liq. carbonis detergens in 2 to 8 per cent. alcoholic solution is also of value. Cocaine can be used as an antipruritic remedy only when the patient is under careful and strict supervision. The use of phenol lotion even in a fairly weak solution over extensive areas for a long time may induce local gangrene and toxic effects from absorption of the drug. Generalised ultra-violet radiation sometimes brings immediate relief. Repeated exposures are necessary in the treatment of chronic cases and the abatement of symptoms is always gradual. Radium therapy has been advocated for localised and stubborn pruritus especially of the muco-cutaneous regions.

Chronic localised pruritus of the anus, vulva or scrotum may be due to external local or internal toxic causes. A thorough physical examination is always indicated to determine and eradicate external sources of irritation. Secondary changes like hyperkeratosis and lichenification set in early in the disease and the skin and the mucocutaneous junctions present a peculiar glazed appearance. The secondary changes are very often responsible for persistence of subjective symptoms.

TREATMENT. Before commencing local treatment the bowels should be opened well with suitable cathartics and the diet changed to plainly cooked, nutritious and wholesome foods. All kinds of tinned foods should

be completely stopped. Stimulating drinks, especially alcohol, are contra-indicated. The patient should be encouraged to drink fairly large quantities of plain water to keep the kidneys well flushed. External parasitic infections should be treated on specific lines and antipruritic lotions and ointments can be applied when occasion arises. Best results are obtained from X-ray therapy and it may be necessary to continue the exposures for some time before permanent cure is established.

PRURIGO. It is a chronic inflammatory disease characterised by the appearance of successive crops of small, flesh-coloured, extremely itchy papules with a predilection for the extensor aspect of the limbs and the lower abdomen. These papules become excoriated owing to the scratching and the skin between the papules is often xerotic or eczematoid. A large percentage of these cases shew dermographism. Lesions may occasionally appear on the trunk, face, forehead and the scalp but the skin of the groins and axillæ are always free. Cases very often commence as papular urticaria of early childhood and, instead of recovery, the clinical appearance changes to the characteristic lesions of prurigo which may then persist indefinitely. Secondary changes of the skin, e.g., excoriations, pustulation, lichenification, scarring and enlargement of superficial glands, especially of the groins, are usually present in well-established cases. The incessant irritation of the skin and slow intoxication give rise to nervous instability, secondary anaemia, loss of appetite, constipation and mental and moral impairment. The ætiology of the disease is not known but it is very closely related to the allergic group of inflammatory diseases with which it is often associated.

Clinically, three varieties have been described: (a) *Prurigo mitis* is a comparatively mild affection and the constitutional disturbances are not very marked. (b) *Prurigo ferox* is the severe form of the disease characterised by incessant scratching, constitutional disturbances and mental impairment. The disease is usually localised in certain areas although the whole body is sometimes affected. *Prurigo ferox* is a comparatively rare disease. (c) *Prurigo nodularis* is an extremely rare form of chronic inflammatory disease characterised by formation of nodular eruptions, chiefly on the lower legs, and constant intractable irritation which prevents the patient from taking rest by day or night. The onset is insidious and is sometimes associated with urticaria. Women are affected more often than men. Secondary changes in the skin are not very marked but the general health is always affected for want of proper sleep and rest. The ætiology is not known and unlike *prurigo mitis* and *prurigo ferox* the disease appears later in life.

Treatment. General. A thorough investigation into the presence of septic foci and other sources of auto-intoxication is essential. The diet should be changed radically and good nourishing food, plainly but agreeably cooked, is indicated. Tonics with combination of iron, arsenic,

quinine and strychnine are necessary in cases with a low condition of health. Thyroid extract in half grain doses twice daily can also be given for its tonic effect. General ultra-violet light baths are beneficial.

Local. Antipruritic lotions and ointments containing 1 to 2 per cent. of phenol and 2 to 3 per cent. of liquor carbonis detergens relieve the irritation to a great extent. Beta naphthol 2 per cent. with coal tar 10 per cent. in lanolin base is useful when secondary hyperkeratosis is present. Prurigo ferox responds quickly to X-ray therapy and radical cure may be established within two to four weeks, especially in children. In the case of adults a good many recur after complete freedom from symptoms for some months.

Prurigo nodularis calls for strong chrysarobin (2 to 5 per cent. in a lotion) and X-ray therapy for relief of symptoms. Freezing with carbon dioxide snow or complete excision of the nodules give satisfactory results although a few nodules may recur and require treatment for the second time. Phenol and liquor potassæ, 15 per cent. of each, dissolved in olive oil sometimes give immediate but temporary relief.

GRANULOMAS. These are solid areas of cellular infiltration of the pars reticularis of the corium induced by specific micro-organisms or their toxins and consist chiefly of endothelial cells. Granulomas are classified as follows:—

I. Those that pass through three distinct stages before the granulomatous lesions are fully developed, namely:—(a) Initial lesion followed by lymphatic permeation. (b) Invasion of the blood stream, septicæmia and production of cutaneous rashes. (c) Granulomatous stage with or without ulceration. Examples are syphilis, yaws and leprosy.

II. Those that shew two stages in their evolution, namely, (a) Initial lesion followed by lymphatic permeation and spread to the nearest lymph node. (b) Formation of granulomas along the lymphatics when further spread is obstructed by sclerosis and fibrosis. Examples are tuberculosis, blastomycosis and sporotrichosis. All these lesions break down and ulcerate.

III. Those with only one stage, namely the initial lesion at the site of implantation with both centripetal and centrifugal spread. Examples are actinomycosis, oriental sore, rhinoscleroma and infective granuloma.

In dermal leishmaniasis there is no initial lesion but the parasites are lodged in the peripheral vessels and give rise to leucodermic spots at first, the granulomatous nodules developing afterwards. The lesions hardly ever ulcerate.

Botriomycosis or granuloma pyogenicum is not a true granuloma but a condition of excessive growth of granulation tissue owing to the irritation of an infective organism, usually the staphylococcus.

Treatment. The treatment of different types of granulomas has been dealt with in various chapters.

DICTIONARY OF DISEASES AND TREATMENT

ACNE VULGARIS. See page 1158

ACTINOMYCOSIS. See page 1159

ACUTE ABDOMEN. It is an emergent condition where the question of immediate surgical operation will have to be seriously considered. In a few conditions, the treatment may be purely medical. There are extra-abdominal diseases such as acute pneumonia, especially in children, coronary thrombosis, the gastric crises of tabes, uræmia, Henoch's purpura and diabetes, which occasionally give rise to pain and vomiting simulating acute abdominal diseases. In such conditions as the inflammations of various kinds of the abdominal viscera and their appendages, namely, acute appendicitis, peritonitis, salpingitis, pancreatitis, cholecystitis, perforations of gastric, duodenal, stercoral and typhoid ulcers, hæmorrhages from ruptured ectopic gestations and ruptured blood cysts of the ovary, torsions of an ovarian cyst or of the gall bladder and lastly the different types of acute intestinal obstruction, the question of immediate operation is to be considered without unnecessary delay. The non-surgical acute abdominal conditions include the various types of colic such as the intestinal, renal, biliary or lead colic, acute constipation and such emergent conditions as pyelitis, Dietl's crises, abdominal influenza, typhoid and tuberculous peritonitis.

CERTAIN DIAGNOSTIC FEATURES OF ACUTE ABDOMINAL EMERGENCIES

Temperature. Usually the temperature is not high in acute abdomens, and it is quite unusual to find a temperature above 102°F., but children run higher temperatures than adults, while elderly people run lower temperatures than the middle aged; a temperature of 99° or 100°F., in an acute surgical abdomen, is the most usual condition. It is only in acute gall-bladder diseases and in inflammatory conditions that a high temperature is met with. A steadily rising pulse is a sign of grave prognostic importance. In acute abdominal catastrophes during the period of shock, the pulse is rapid and thready. A very sudden acute abdominal lesion may, therefore, give rise to thin, rapid pulse and a subnormal temperature in the beginning. After some time the pulse begins to rise and attains a normal count. This occurs in the reactionary stage and may give a misleading impression of improvement of the patient's condition.

Vomiting. This occurs in many of the acute illnesses and is particularly met with among children. Repeated vomiting with acute pain in the abdomen and a distinct pallor on the patient's face often suggest a

grave condition. The change of smell and colour of the ejected materials from the ordinary smell of food to a faecal odour usually indicates some form of obstruction of the bowel either paralytic or organic. Faecal vomiting is often a sign of impending death.

Pain. The site of origin, the nature and the mode of radiation of pain are important diagnostic features in acute abdomens. Inflammatory pain starts very gradually while the patient is resting and gets steadily worse in the course of a few hours; the patient lies still and never writhes about in bed. The pain in appendicitis, pancreatitis, etc., seems to start while the patient is in bed in the early hours of the morning. On the other hand, pain in acute obstruction or colics is of a gripping nature, and the patient often writhes about. A sudden onset of pain of great severity suggests perforation or acute strangulation of the gut.

EXTRA-ABDOMINAL CONDITIONS. Pneumonia. In many chest conditions such as early pneumonia or pluerisy, especially the diaphragmatic variety, the pain is acute and referred to the abdomen. Other signs of acute abdomen such as rigidity of the abdominal wall, vomiting, etc., may also be present but, as opposed to true acute abdominal cases, the temperature is high, the pulse-respiration ratio is characteristic and the rigidity is not a genuine one.

Uraemia. Uræmic cases simulate acute obstruction with symptoms of abdominal distension, pain and vomiting. Intense toxæmia also suggests the condition.

Coronary thrombosis and acute coronary embolism often simulate an acute abdomen with an acute pain in the upper part of the abdomen, a rapid pulse and vomiting ultimately leading to a state of collapse.

INTRA-ABDOMINAL CONDITIONS. Typhoid. The disease is essentially an abdominal one and sometimes presents signs and symptoms of acute appendicitis. Appendicitis when present is caused by bacillus typhosus associated with general enteritis. A true emergent condition supervenes only when a typhoid ulcer perforates necessitating immediate surgical intervention. In the so-called abdominal influenza the pain is of a colicky nature and not of an inflammatory type. Vomiting and distension of the abdomen are present but the temperature generally shoots high.

Colics. The pain of biliary and renal colics has particular sites of origin and definite distribution. The pain in biliary colic starts in the right hypochondrium, radiates towards the epigastrium, behind to the back and ultimately terminates near the shoulder blade. A biliary colic may settle down with morphia. In renal colic, the pain starts at the back near the renal angle under the last rib and radiates round and down to the front into the groin, testicle or thigh. Vomiting is more marked in biliary colic. Intestinal colic is often due to ingestion of indigestible materials and causes a violent gripping pain, which sometimes resembles an acute obstruction.

Genuine acute abdominal emergencies include cases of inflammation, obstruction, perforation and hæmorrhage.

Inflammation. These cases usually give rise to a slowly rising pulse and temperature, pain comes on gradually and an area of rigidity and tenderness develops over the inflamed viscus. Of the various inflammatory conditions, acute pancreatitis and appendicitis need a detailed description.

Acute pancreatitis. The pain here is even more acute than that of perforation and shock is invariably present. Prostration is marked from the onset, and the pulse is rapid, thin and feeble. Abdominal rigidity is always present especially in the upper part.

Acute appendicitis. The ætiological factors are still obscure. Undoubtedly it is a disease of civilization with its adequate supply of pure rich food of all descriptions. It may occur at any age, it is rare in the aged and most common in the 2nd, 3rd and 4th decades. Organisms such as *Bact. coli*, staphylococci, streptococci, *B. welchii*, tubercle bacilli and actinomycotic fungus have all been isolated from acute cases, occasionally in pure cultures, but usually the infection is mixed. Urgent gangrenous appendicitis is only seen amongst the meat-eating people and is twice as common in the male as in the female.

The pain in acute appendicitis starts as a general abdominal discomfort round the umbilicus, described by the patient as a stomach-ache and is usually of gradual onset and associated with general malaise. Nausea, retching or vomiting follow abdominal pain and vary in their intensity; patients usually vomit once or twice only. The temperature is usually 99-100°F., and if it is higher than 101°F., a careful examination for other causes should be made before diagnosing appendicitis.

The pain, varying in intensity and radiation, ultimately settles down in the right iliac fossa. The pain in acute appendicitis is made worse on walking or on extension of the thighs due to stretching of the psoas muscle. A sudden cessation of pain and a feeling of well-being or marked improvement suggests gangrene or perforation with the relief of tension. If the appendix is lying on the bladder, it may give rise to frequent or painful micturition. A retrocæcal appendix may be close to the gall-bladder and so mimic acute cholecystitis. The bowels are usually constipated. The results of an enema are nil and this indicates a reflex inhibition of the bowel activity caused by the presence of inflammation in the lower abdomen. Acute appendicular obstruction shows a different clinical picture. It is characterised by the sudden onset of severe, colicky, general abdominal pains, sometimes doubling up its victims and causing them to roll about. The restlessness is of diagnostic significance; it indicates a mechanical pain, whereas inflammatory pain usually immobilises its victims; they lie still on their back, sometimes on their side with the legs flexed; the tongue is furred and moist, and the breath offensive.

Hyperæsthesia is tested for with a pencil-point, stroking the abdomen in longitudinal and transverse directions. In 40 to 50 per cent. of cases it is present in the right iliac fossa and it is said to be an indication of an unruptured appendix. The right iliac fossa is usually painful and tender and shows varying degrees of muscle tension or rigidity centred half way between the umbilicus and the right anterior superior iliac spine. The rigidity in the right iliac fossa is the response of the parietes to the close underlying inflammation. Rectal examination should never be omitted. Anything from a slight tenderness in the right iliac fossa to appendicular masses like tense collars about the rectum or bulging abscesses may be discovered. The complete series of changes starting with appendicular obstruction to gross general peritonitis may occur within four hours.

In one, two or three days, the symptoms may pass on to those of general peritonitis or may completely subside. If resolution does not take place, a local abscess is formed with a tumour in the right iliac fossa, in the pelvis or in the loin. The slight pyrexia persists, constipation will continue or diarrhoea may occur. In abscess formation, after the fifth or sixth day, the pain may become more severe as the tension in the abscess cavity increases, and according to its situation, it may track through the abdominal wall and open into the groin or it may burst into the rectum, vagina or general peritoneal cavity with disastrous results. A retrocæcal abscess may track up and form a subphrenic abscess later.

Obstruction. Intense griping pains and increasing vomiting are met with in these cases. Rigidity is usually absent and tenderness is more or less diffused all over the abdomen. There is marked visible peristalsis. The common causes of obstruction are strangulated hernia, volvulus and intussusception. Intussusception occurs usually in babies and has very characteristic symptoms. The acute catastrophies which occur in connection with abdominal diseases are in truth the acute terminations of chronic diseases and are rarely acute new diseases.

Perforation. The perforation of an ulcer in the stomach or duodenum is almost invariably preceded by the history of a chronic ulcer and that some exacerbation of symptoms may have been observed in a few preceeding days. The pain is sudden in onset and of acute burning type. The temperature is usually subnormal and the patient lies absolutely still with a thin rapid pulse. The abdominal parietes present a board-like rigidity and are intensely tender. Shock is never a symptom of perforation. It is a symptom of peritonitis which follows quickly upon leakage from the stomach or duodenum. Percussion yields a high-pitched tympanitic note, which is always suggestive of a mixture of gas and fluid in the abdominal cavity. Liver dullness may or may not be absent, but as a general rule it is diminished. In duodenal ulcer, the perforation is on the right hand side of the spine and the fluid runs down to the right iliac fossa which is painful tender

and rigid as in appendicitis. Perforations are also met with in cases of typhoid and dysenteric ulcers.

Hæmorrhage. This is seen in ruptured ectopic gestation. It occurs in the second or third month of pregnancy. There is a sudden onset of violent pain and collapse and the patient becomes pale and restless, the pulse runs up rapidly with all other signs of an internal hæmorrhage. There is no swelling, no rigidity but a diffuse tenderness is present all over the abdomen.

TREATMENT. A correct diagnosis of cases as far as possible with an immediate operation is required in these cases to ensure the safety of the patient. In some forms of acute abdominal diseases, the indications for urgent operation are clear and universally admitted. In perforations of all kinds, in ruptured ectopic gestation, and in the more acute forms of obstruction, such as volvulus, intussusception, and the various forms of internal strangulations by bands and apertures, operation at the shortest possible notice is clearly indicated. Opinions differ regarding the suitable time for operation in acute appendicitis. The statistics all over the world have proved conclusively that the mortality of cases treated by operative measures within the first 24 hours is practically nil, provided there are no complications. In children the axiom is, always to operate immediately and remove the appendix, irrespective of the duration of the disease and of the condition of the appendix. In case of acute appendicitis seen within the first 48 hours of the attack, it is generally agreed that the appendix should be removed. If cases are brought when symptoms have subsided, operation may be postponed till the quiescent stage. The treatment of intermediate cases varies. Cases showing improvement from day to day and from hour to hour should receive a constant watch. In such cases, the leucocyte count should be done twice a day, pulse registered every hour and the patient should be, if possible, under direct supervision of an expert surgeon. When these are not available, Ochsner and Sherren advocate Fowler's position, water and glucose by mouth followed by liquid diet if the temperature and pulse subside. If with such treatment, the leucocyte count shows steady increase or a sudden drop or the pulse steadily rises and rigidity spreads or if the pain suddenly disappears an immediate surgical operation is indicated. If the case is brought later than forty eight hours after onset the probable consequences are that the patient may go downhill, rally or get better. In such cases complications such as generalised peritonitis due to perforation and gangrene may supervene. The risk of operation must in all cases be undertaken if the condition of the patient gets worse. If a lump is found to be forming in the appendicular region and the condition of the patient is stationary, operation may be postponed. In that case if operation is undertaken, the protective barriers will be broken and the resting condition will flare up. The patient may be operated upon, generally three months after the subsidence of such an attack. The urgency of operation is much lessened if

cases are seen later still, about the fifth, sixth and seventh days after onset. The patient will either be very definitely improving or else probably getting an abscess. In the former case, operation can be withheld until he has recovered and in the latter case though the abscess will need an evacuation there is often no very great urgency about it for a few hours or days, and it will in fact sometimes be wiser to wait for a short period to allow the abscess to come nearer to the surface. Acute salpingitis and acute pancreatitis present considerable difficulty for a correct diagnosis. Immediate operation is not generally suggested and one can wait till an abscess forms. Many acute cholecystitis cases will gradually settle down without operation, though this procedure often entails a considerable risk. The condition of the gall bladder serves as a useful guide regarding an urgent operation. A hard, tensely distended gall bladder with the risk of perforation or gangrene often requires an operation and particularly where symptoms increase and demand relief.

In the various forms of organic obstruction, surgery alone will effect a cure. Strangulation, volvulus and intussusception are usually more urgent than obstruction due to growths and pressure of tumours. When the enema result is nil, and a diagnosis of obstruction confirmed, the sooner the operation is undertaken the better. In cases of hæmorrhage due to erosion of a vessel by a spreading ulcer as met with in cases of gastric and duodenal ulcers, the treatment includes absolute rest in bed, stoppage of feeds by mouth, injection of $\frac{1}{4}$ gr. of morphine, administration of glucose and saline by the rectum, an electric bath and sometimes in severe cases of hæmatemesis, a blood-transfusion. Generally medical treatment is of no avail in these abdominal emergencies while on the other hand the safety of the patient is endangered by delay. For details of surgical technique involved in individual cases, reference must be made to works on operative surgery.

AGRANULOCYTOSIS. Agranulocytosis or neutropænia is a recently recognised disease (Schultz 1922) characterised by a septic inflammation of the throat with toxæmia and marked leucopœnia affecting especially the polymorphonuclear cells.

Neutropænia occurs under the following conditions:—

1. Infective diseases such as kala-azar, typhoid, typhus, measles, influenza, mumps, malaria, dengue.
2. Diseases due to physical and chemical agents such as radium particularly the alpha rays, X-rays, arsenic, benzene, arsenobenzol preparations, drugs containing amidopyrine such as veramon, novalgin, gordon, cibalgin, dismenol, compral, allonal, amytal, amidopfen, cichopyrine.
3. Blood diseases such as leucopenic, lymphatic and myeloid leukaemia—the so-called aleukæmic leukaemias.

4. Severe sepsis.

5. Idiopathic neutropenia.

Two types of agranulocytosis are generally recognised, one is a primary type, the aetiology of which is obscure and another, a secondary type which is a direct result of some recognised septic condition. The condition simulates aplastic anaemia aleukæmia, leukæmia, Vincent's anagina, influenza, atypical Hodgkin's disease or diphtheria. Agranulocytosis may also occur as an event in a long illness. Recent work has established that a large number of cases of agranulocytic angina are due to the toxic action of certain drugs such as arsphenamines; dinitrophenols and pyramidon.

The disease is seen more in middle-aged females. It generally starts with general malaise, lassitude, headache and soreness of the throat and the mouth. The condition rapidly progresses to an ulcerative or necrotic stomatitis involving the lips, gums, tongue, tonsils, fauces, pharynx and tongue. Sometimes the skin and the intestines are likewise affected and there is pyrexia and general prostration. The enlarged cervical glands are secondary manifestations to the oral condition. The blood picture is characteristic. The total white-cell count is reduced to very low figures even as low as 100 to 200 per c.mm. and there is an absolute and relative reduction in the number of granulocytes—the neutrophilic, eosinophilic and basophilic polymorphonuclear cells. The red cells; hæmoglobin and platelets are little affected. A few cases show moderate or severe anaemia of the microcytic type and very rarely of the macrocytic type. A chronic type or agranulocytosis has recently been shown to occur without the oral symptoms, the granular cells remaining for a long time between 10 to 30 per cent. with total counts of 4,000 to 6,000 per c.mm. The condition is considered to be due to the non-formation of the granular leucocytes rather than their excessive destruction. The primary cause is thought to be depression of the bone-marrow functions. The evidence of regeneration of the myelopoietic tissues as shown by the myelocytic response favours the view that agranulocytosis is primarily a marrow dyscrasia. The organisms cultured from the throat lesion and blood are not specific causal agents, but are regarded as terminal invaders.

TREATMENT. A thorough inquiry should be made regarding the use of toxic drugs responsible for the production of agranulocytosis, such as benzene, arsenical and gold preparations, dinitro-phenols and the benzamine group of drugs. The use of these drugs should be strictly forbidden. No treatment is of any value in fulminating cases. The different forms of treatment which appear to have beneficial effects are: (1) Repeated transfusions of 250 to 500 c.cm. of citrated blood every other day or at longer intervals. (2) Irradiation of the skeleton with small doses of X-rays. This treatment is based on the law that small doses stimulate, while large doses destroy, radio-sensitive cells.

(3) Injection of leucocytic extract in an attempt to stimulate the reticulo-endothelial system. Hopeful results have recently been obtained from the administration of a mixture of the sodium salts of pentose nucleotides (prepared from nucleic acid). In severe cases 20 c. cm. of pentnucleotide are intramuscularly injected, twice daily, for 3 to 4 days. When the white cell count begins to rise, the dose is reduced to 10 c. cm. In less severe cases 10 c. cm. of the drug is injected twice daily for a week. The total and differential white cell counts should be done daily to note the progress of the disease during the course of treatment. Clinically, cases have been found to improve after such treatment. No untoward effects are known to follow the intramuscular injections of the drug.

Local treatment of the oral lesions include gargles with hydrogen peroxide, sprays with potassium chlorate and swabbing with a solution of copper sulphate (10 gr. to an ounce).

AINHUM. It is a type of band scleroderma affecting the toes and fingers causing rarefying osteitis of the phalanges often of the little toe, more rarely of the fourth and still more rarely of the little finger. It may end in natural amputation of the affected toe. The band which is at first moderately broad becomes deeper and deeper and by pressure gradually absorbs the underlying phalanx, so that the end of the little toe is about twice its normal size. There are no subjective symptoms unless there is ulceration. The course of the disease is obscure. A trophic origin has been suggested while some consider it to be due to hypothyroidism. The lesion may be associated with other lesions of hypertrophic nature, *viz.*, *cutis plicata*, *tylosis*, *pityriasis rubra pilaris*.

TREATMENT. In the early stages, large doses of *thyroid*, *viz.*, 2 gr. thrice daily combined with *parathyroid* 1/20 gr. and *calcium lactate* 10 gr. twice daily are given. During treatment the patient should be kept strictly in bed and the pulse noted every 4 hours; it should not exceed 85 to 95 per minute. This pulse rate should be kept for 3 weeks to get the full effect of hyperthyroidism. If there is any ulceration or secondary infection, it should be treated surgically.

ALLERGY. The word allergy is derived from two Greek words meaning other energy. Von Pirquet coined the term allergy to indicate an altered reaction in man to foreign proteins and implied that an antigen-antibody reaction was its basis in general. Later, the meaning of the term was extended to indicate all forms of hyper-sensitiveness to foreign proteins whether any antigen-antibody reaction was present or not. Allergy has now come to mean 'exaggerated susceptibility to various foreign substances or physical agents that are harmless to the great majority of ordinary normal individuals.' The reaction appears after inhalation, ingestion, injection or skin contact of minute quantities of the substances in question and differs from any toxic action the substance might produce in large doses. This hypersensitiveness may be

spontaneous or may be induced as in serum sickness. Allergy differs from anaphylaxis, which is the term applied to manifestations of hyper sensitiveness in laboratory animals, in that anaphylaxis is always induced and is always due to antigen—antibody reaction. This hypersensitiveness may be manifested at different sites in the body and these different manifestations are given different names. Thus in the respiratory tract we have paroxysmal rhinitis, hay fever, and asthma; in the skin urticaria, giant urticaria, dermatographia and dermatitis venenata, etc.; in the gastro-intestinal tract certain forms of gastritis and vomiting, enteritis, diarrhoea and mucous colitis; in the nervous system migraine and certain cases of epilepsy. Bray considers that certain forms of enuresis are allergic in origin.

The offending substance or substances may be introduced into the body from outside or may be produced in the body itself. Thus it may be inhaled as in hay fever and pollen asthma, may be ingested as in food and drug allergy, may be injected as in serum sickness, or may be brought in contact with the skin as in dermatitis venenata and urticaria or it may be due to physical agents such as heat and cold. A small group of allergic manifestations may be ascribed directly to insect bites and stings. When produced in the body, the offending substances may originate in an infective process within the body or it may owe its origin to some pathological condition of the gut. It appears that infective foci whether of teeth, tonsils, sinuses, bronchi, etc., liberate a substance which circulates and sensitises various tissues and is capable of producing symptoms in either skin, respiratory or gastro-intestinal tracts. In the cases dependent on some pathological conditions of the gut the substance or substances in question either result from the bacterial action on the protein, or the proteins are broken down in some abnormal fashion and the altered protein gains access to the circulation. In the tropics the allergy secondary to some pathological condition of the gut is much more important than any other form of allergy. This is probably due to a lowering of the defence mechanism of the liver caused by intestinal amebiasis or some other condition causing hepatitis. That the detoxicating and proteopexic functions of the liver are defective in cases of allergy has been shown by Barber and Oriel who have found important biochemical changes in the blood and the urine of allergics.

DIAGNOSIS. 1. *History.* In cases of suspected allergy it is essential to go carefully into the history of the patient. Careful enquiries may elicit many points of great diagnostic value in allergic conditions. (a) Most allergic conditions commence early in life. It is important to find out the age at which the patient first noticed the onset of the condition. (b) A history of inheritance is commonly found in allergic cases. (c) Season of onset and the seasonal variations in the disease are of importance. This may give a clue to the offending flowers and foods, etc. (d) There is a regular periodicity in the early stage

of allergic conditions. If they are severe and persist for several years they tend to become continuous. (e) Association of the disease with some particular place, food, or animal may be elicited. Particular attention should be paid to the surroundings at home and work, such as presence of factories and stables near at hand, presence of or association with pets and poultry, horses or cows, presence of pillow cases stuffed with chicken feathers, etc. As regards food, at times the provocative articles of diet can be named by the patient, but in the majority of cases he has to be carefully dieted before any food can be incriminated.

2. *A total and differential blood count* is made, most of the allergic patients have a high blood eosinophilia.

3. *Protein skin tests* are often of value in confirming the diagnosis when a careful history makes it possible to discover a specific substance responsible for the patients' symptoms. When no clue is afforded by the history at all we turn to the routine protein skin tests for help. These tests are based on the fact that those substances, which when inhaled, ingested or taken into the body by any other means are capable of producing allergic symptoms, will also produce an urticarial wheal when brought in contact with the lower layers of skin.

The dermal tests are usually done on the forearm. The forearm is carefully cleansed with alcohol and scratches are made on it transverse to the long axis of the arm. The scratches are made only $1/8$ th of an inch in length and they are made without drawing blood. One spare scratch is made to serve as a control. A drop of N/10 sodium hydroxide solution is put on each scratch and the substance to be tested is rubbed into them, one substance into one scratch, the control scratch receives no substance. After fifteen to twenty minutes the test fluid is wiped away and results are read by comparing the site of each scratch with the control. A positive result is denoted by the appearance of an urticarial wheal at the site of the scratch. The material for testing can be purchased ready made or can be made in the laboratory.

The supernatant fluid obtained by macerating a small amount of the substance in a small quantity of N/10 sodium hydroxide solution can be used for the test. A better way for preparing an extract for dermal tests is to extract it with Coca's fluid. Coca's fluid is made by dissolving sodium chloride 10 gm., sodium bicarbonate 15.8 gm. and carbolic acid 8 gm. in two litres of distilled water. Before extracting house dust it should be washed in ether to remove fatty matter and then a 1 per cent. extract in this fluid is made. The extract should then be filtered through a porcelain filter and the filtrate should be tested for sterility (aerobically and anaerobically) before it is used for the test. The test should be performed with very weak dilutions to avoid undesirable effects. It is best to commence testing with one in a million dilution.

4. *Prasnitz Kustner reaction*. When it is not advisable or practicable to do the usual skin tests as in infants, nervous patients, patients with interfering skin lesions or extremely dermatographic skin or where

the patients cannot attend for testing on account of distance or illness, Prausnitz Kustner reaction which is a reaction by proxy is tested. This consists in injecting a small quantity of the serum from an allergic patient intradermally into a non-sensitive subject and then testing the site of injection with antigens which the allergic patient is thought to be sensitive to.

Five to ten c. cm. of the blood is withdrawn from the patient and the serum is separated with aseptic precautions. The forearm of the subject on whom the test is to be done is cleansed with alcohol and the serum of the donor is injected at two or more sites depending on the number of proteins to be tested. About 1/10th of a c.cm. of the serum is used for each injection and the site of injection is marked with ink or marking pencil. At least two or three hours should be allowed for the serum to be completely absorbed. Then each site may be tested locally for specific proteins.

5. The best proof of a substance being responsible for the allergic symptoms of a patient is that the substance when brought in contact with the patient should precipitate an attack.

6. In most of the cases of allergy a hypodermic injection of 1/1000 solution of adrenalin hydrochloride relieves the symptoms and this forms a good therapeutic test.

7. *The ether reaction for proteoses in urine.* Oriel has described a reaction that occurs with great frequency during allergic conditions. If the urine from cases of allergic and febrile diseases is acidified with sulphuric acid and shaken with a fifth of its volume of ether, the ethereal layer formed on standing, instead of being clear as in normal people becomes opaque and has a waxy appearance. In strongly positive cases the tube may be inverted without spilling the contents.

If the reaction is carried on in a separating funnel and the lower layer consisting of urine is run off, the supernatant layer when shaken with an equal volume of alcohol yields a precipitate of a nitrogenous substance which has been called 'proteose.' The proteose is supposed to be the secondary antigen produced by the action of the sensitised liver cells on the primary antigen and has been used for desensitising the patient. In this connection the work of Manwaring is interesting. He proved that the liver of a sensitive dog produced a secondary antigen which was an alteration product of the original antigen and that this secondary antigen was capable of giving rise to sensitisation. A twenty-four hours specimen of urine is collected from a case showing active symptoms and a little of chloroform is added as a preservative. Approximately 400 c.cm. is placed in a separating funnel, rendered acid to congo red with sulphuric acid and shaken with 100 c. cm. of ether. Should the specimen contain urates it is rendered alkaline with dilute caustic soda to dissolve them and subsequently made acid. When the two layers are separated, the ethereal layer is treated with an equal volume of alcohol and the precipitate is allowed to settle. The precipitate is then collected by

centrifugalising in sterile centrifuge tubes. It is then suspended in sterile distilled water and again centrifuged, when dry, the precipitate is dissolved in sterile N/10 sodium hydrate solution. The quantity of sodium hydrate required, varies with the case but 2 to 3 c.cm. are usually sufficient. Taking the usual aseptic precautions 1 c. cm. of this solution is added to 9 c. cm. of carbo-saline. The dilution is called 1 in 100. Further dilutions of 1/1,000, 1/10,000, 1/1000,000 and 1/1,000,000 are then made. The sterility of the solutions is then tested by inoculating on agar slopes and incubating for 48 hours. The dilutions are then used for diagnostic and therapeutic purposes.

8. *Examination of stools.* The allergic cases secondary to gut infection may show *Entamoeba histolytica* infection or the presence of the ova of various helminths. The McConky-neutral-red-lactose agar plate may show various non-lactose fermenting bacilli causing post-dysenteric lesions. These findings are rather important from the treatment point of view.

9. *A bacteriological and cultural examination of sputum* is made in cases of respiratory allergy, keeping the Gram-negative bacilli of Rye specially in view.

10. A thorough search is made for any *focus of sepsis* which may be present in teeth, tonsils, nasal sinuses, gall bladder, appendix or genito-urinary tracts.

11. *A fractional test meal* usually shows hypochlorhydria specially in children. This finding may be an important factor in the production of allergy.

Walzer and Walker while working on urticaria found that the Prausnitz-Kustner reaction was more likely to be positive when hypo- or achlorhydria was present and that it often failed in the presence of hyperchlorhydria. This observation is of importance as the work of Schloss in marasmic children has shown that protein in a form capable of producing active sensitisation may be absorbed from the intestinal tract. It is quite reasonable to assume that the absorption is more likely to take place when the digestion is delayed and the proteins are incompletely broken down than when the digestion is complete.

12. Important biochemical changes in the blood and urine are found during the attack. Hurst has suggested that in asthma there is some alteration in blood chemistry which renders an asthmatic subject liable to an attack of asthma from stimuli which in a normal person would produce no response.

Barber and Oriel have found that the amino-acid content of the blood is raised during acute paroxysms of allergic manifestations and blood chlorides seem to be markedly diminished. Similar changes have been found in urine; immediately before and during the paroxysms there is a decrease in urinary output accompanied by an increase in free acid and ammonia and diminution in chloride excretion. Following the

paroxysm the quantity of urine is increased and the urine becomes less acid or even alkaline and contains excess of chloride.

Liver function tests. Experiments of Manwaring demonstrated that the liver was the site of the anaphylactic reaction in dogs and that shock did not occur when the liver was thrown out of the circulation. It is very probable that liver dysfunction plays an important part in the production of allergy specially in cases of intestinal origin in man. Osman suggested that in asthmatic children there is a diminution of glycogen reserve. The proteopexic function of the liver, *i.e.*, its power of fixing protein and its derivatives appears to depend on an adequate supply of glycogen. In the absence of an adequate amount of glycogen in the liver, proteins tend to pass the barrier of the liver and gain access to the general circulation. If this inadequate proteopexic function of the liver is combined with hypochlorhydria which makes the absorption of protein capable of producing sensitisation more likely, the chances of such proteins reaching the circulation are much increased. Bray found in a series of 55 allergics that manifestations of liver dysfunction were twice as common in patients with some gastric dysfunction as in normals. Apart from this proteopexic function the detoxicating function of the liver is also to be taken into consideration. It transforms products of protein digestion into urea and renders non-toxic the products of bacterial action on undigested proteins. The biochemical findings in the blood and urine of allergics provide ample evidence of a basic toxic factor in these conditions. The chief source of this toxicosis is the bowel and the inadequate detoxicating function of the liver allows the toxins to pass into the general circulation.

It can be safely assumed that the allergic reactions of man specially those of intestinal origin depend to a large extent on liver dysfunction, but it is rather difficult to measure the extent of liver damage by means of the laboratory tests for hepatic functions. This is due to the multiplicity of functions with which the liver is endowed and to the wide margin of safety that it has got. An idea of the efficiency of the liver may be obtained by a correlation of several tests.

TREATMENT. Immediate treatment. An intramuscular injection of adrenalin hydrochloride is most effective in relieving the acute allergic symptoms. The earlier the injection is given the smaller is the dose required. Adequate local treatment is given for the skin, nasal and ocular conditions. For the skin calamine liniment and Lassar's paste usually suit but some people may be sensitive to these drugs. For the itching and burning of the eyes Feinberg recommended the following eye-drops: adrenalin (1:10,00) 1.0 c. cm., dilute acetic acid 0.3 c. cm. resorcin 0.3 gm., distilled water 32.2 c. cm. For the local treatment of the nose Bray recommends the following ointment: menthol 2 gm., eucalyptol 5 min., adrenalin chloride 1/20 gr., ephedrine sulphate 5 gm., and soft white paraffin upto 1 oz. A little ointment is to be smeared in the nose several times a day. A mixture containing potassium iodide

and antispasmodics such as lobelia, belladonna, kuth, tinct. ephedra vulgaris, etc., is given between the attacks in cases of asthma.

Treatment of the allergic state. The proper treatment of the condition depends on the results of the investigation of the patient. If the history, skin reactions or elimination diets give a clue to specific sensitisation the following lines may be adopted:—

(a) Avoidance or removal of the cause. To avoid or remove the specific cause is the ideal method of treatment but is practicable only in a minority of cases. Specific foods may be completely avoided. In cases of animal emanations the pets should be removed, hairs and feathers in bedding and pillows may be substituted by cotton, etc. Dust and pollen are most difficult to avoid unless an allergen-free cubicle or an allergen-free mask is used. A change to a hill station of 4,000 to 7,000 ft. altitude is very beneficial in this connection as the atmosphere at this height is free from air-borne allergens.

(b) Specific desensitisation. Next to avoidance comes specific desensitisation. Results with desensitisation are never so satisfactory as with avoiding the cause. It is to be used in those cases in which the specific causes cannot be avoided or removed entirely as when many common articles of diet are involved or when the sensitiveness of the patient is dependent on some occupation which he is not in a position to leave. Specific desensitisation may be attempted by ingestion of gradually increasing doses when the allergen is a common food. The treatment is commenced with a very small amount of food. It is given daily and then the doses are increased very slowly. In cases of allergy due to dust or pollen or animal emanations desensitisation is carried on by repeated subcutaneous injections of the sterile extract made from the substance. The protease isolated from the urine of the patient may be used for specific desensitisation. It is always necessary to ascertain the reaction of the patient to different dilutions before any therapeutic injections are given. The dermal tests are made on patients with different dilutions and the dose for intradermal injection is regulated accordingly. Injections are given first bi-weekly and later once a week, the dose is increased very cautiously.

Along with avoiding the cause or desensitisation the co-existing infections or abnormalities of the respiratory or the gastro-intestinal tract should be adequately treated. Desensitisation with ingestion of small doses of a food gives better results if the food is given with a small amount of hydrochloric acid and pepsin.

Other measures. In the majority of cases even a thorough investigation would fail to incriminate any particular food, animal emanations, etc. In such cases the treatment is to be carried out on the following lines.

In allergy of alimentary origin the antigen absorbed may not be a whole food protein, but there may be toxins liberated by the action of bacteria on incompletely digested proteins which may be the cause of

the conditions or the proteins may be broken down in an abnormal fashion and the altered proteins pass up to the liver whose proteopexic function is deficient and thus they gain access to the general circulation. In treating such cases at least four factors have to be taken into account.

(1) Any infection found in the gut has to be carefully treated. The *Entamoeba histolytica* infection is treated with emetine or carbarson, the hookworm infection is got rid off with carbon tetrachloride; an autovaccine is needed to confer immunity against the pathogenic organisms isolated from the stools. Intestinal stasis if present should be adequately dealt with. (2) An acid-pepsin mixture is of great benefit when there is evidence of hypochlorhydria. (3) The patient should be kept on more or less vegetarian diet, meat and fish should be cut down to a minimum. (4) The liver should be well looked after. Adam advocates acid liver mixture after meals and a weekly blue pill along with balancing the diet. In order to improve the proteopexic function of the liver which depends on its glycogen reserve, Oriel recommends 2 to 4 oz. of glucose to be taken daily in divided doses. Glucose may be taken with meals or dissolved in water and flavoured with orange or lemon juice or it can be taken morning and evening on an empty stomach.

A thorough search should be made for any focus of infection in the teeth, tonsils, sinuses, bronchi, gall bladder, etc. Such foci as can be removed should be dealt with surgically. When the source of infection cannot be completely eradicated, autovaccine prepared from the organism isolated from the focus should be used. Special significance is attached to the vaccine prepared from the Gram-negative bacilli isolated from the sputum. Knott and Oriel have found that these bacilli during their growth in the bronchi produce histamine. Oriel considers that local production of histamine in the bronchi in addition to causing a contraction of the plain muscle surrounding the bronchi would also tend to increase the permeability of the epithelium lining the bronchioles and facilitate the entrance of foreign proteins and possibly bacteria.

Non-specific desensitisation or protein shock therapy. Many substances have been used for this purpose with varying results in the hands of different workers.

Peptone. Auld recommends intramuscular or intravenous injection of peptone. He uses Armour's No. 2 peptone and makes a 5 per cent. solution for intravenous injection and a 7½ per cent. solution for intramuscular use. Both the intramuscular and the intravenous injections are given every fourth or fifth day in the following doses :—

1st dose	...	0.3 c. cm.	6th dose	...	1.3 c. cm.
2nd "	...	0.5 c. cm.	7th "	}	...
3rd "	...	0.7 c. cm.	8th "		
4th "	...	0.8 c. cm.	9th "		
5th "	...	0.9 c. cm.	10th "		

After the tenth dose a few further injections are given weekly reducing the strength of each dose. In resistant cases Auld uses serum peptone agar. After about 4 hours of fasting 4 or 5 oz. of blood are removed in a sterile tube from the arm of the patient. This blood is left at room temperature till the next day, when the serum is pipetted off into another tube. To each ounce of the serum is added 24 gr. of Armour's No. 2 peptone, 6 min. of a well boiled solution of agar containing 1 gr. of agar in 60 c.cm. of water and 4 min. of chloroform. Then the tube is put in an incubator at 37°C. for two to three hours. It is then left at room temperature till the next day when the supernatant fluid is pipetted off. Treatment with this serum peptone agar is begun with a dose of 10 min. intravenously, going up by 5 min. each time until a dose of about 50 min. is reached. Injections are given once or twice a week.

Auto-hæmotherapy. Blood is withdrawn from a vein at the elbow and is reinjected subcutaneously or intramuscularly, whole blood, defibrinated blood, or freshly separated serum may be used for this purpose. The initial dose is 2 c.cm. and the injections are repeated in increasing doses at intervals of two to seven days until a dose of 10 c.cm. is reached.

Milk. Schiff suggested injections of milk. Two ounces of milk are sterilised in a rubber-capped bottle by boiling for 1 hour. Injections are given intramuscularly three times a week commencing with a dose of 0.5 c.cm. and increasing by 0.5 c.cm. until a dose of 8 c.cm. is reached.

Tuberculin. Treatment by tuberculin is specially recommended by Van Leeuwen. The success does not depend on the specific action of tuberculin but on the local reaction produced by the injection of tuberculin. A von Pirquet test is first made to ascertain the degree of sensitivity of the patient and the doses are regulated accordingly. In very sensitive cases the commencing dose should be one-hundredth million of a milligram and it should be increased very cautiously. In other cases the commencing dose can be from 1/10,000,000 to 1/1,000,000 of a mgm.

T. A. B. vaccine. The T. A. B. vaccine has been recommended to be given intravenously every five days. The commencing dose is 50 million organisms, followed by 100 million and increasing by 100 million until a dose of 500 million is reached.

Sulphur. Van Leeuwen uses a 1 per cent. suspension of sulphur in olive oil injecting 1 c. cm. intramuscularly. This is usually followed by a painful local reaction, fever, malaise, etc. The dose in such cases may be reduced and then repeated.

Endocrine therapy. In cases of allergy in which an endocrine basis is suggested gland therapy may be of value. The suprarenals, thyroid, and sex glands are most commonly involved. The desiccated glands may

be given by mouth. Injections of arsenical preparations such as soamine are used to tone up the endocrine system.

AMOEBIASIS. DIAGNOSIS. *Stools.* The stool must be fresh and free from urine, oil, and antiseptics. If possible, the whole stool should be sent for examination: (a) Note the macroscopic appearance; (b) test the reaction, and (c) examine under the microscope—(i) fresh preparation in saline, (ii) fresh preparation in iodine, (d) culture, (e) stain by Heidenhan's method when identification is difficult. Repeated daily examinations are often necessary for accurate diagnosis.

TREATMENT. (Acute cases). *Emetine* (see page 368). *Kurchi-bismuth-iodide* (see page 403). *Liquid extract of kurchi* (see page 402). The extract may be given alone or may be combined with 'Isapaghula' (*Plantago ovata*) (see page 416). Care should be taken to keep the bowels acting. *Emetine-bismuth-iodide* (see page 381). *Carbarsone* (see page 411).

In chronic cases complicated with secondary organisms the patients are immunised with a course of autovaccine prepared from the pathogenic bacteria found in the stool either before or during the specific treatment of amoebiasis. Complications like hepatitis, etc., should be treated with emetine injections only.

Intestinal flagellates. In giardiasis stovarsol in doses of 4 gr. (0.25 gm.) twice a day for 10 days before food is recommended. Carbarsone and treparson may be given by the mouth. See page 651.

ANÆMIA. The term anæmia is applied to the condition in which there is reduction of red blood cells and hæmoglobin or of the amount of blood as a whole. *Oligocythæmia* means diminution of the number of red cells. *Oligæmia* means a diminished total amount of blood, while *oligochromæmia* means diminution in the amount of hæmoglobin. Anæmia occurs either as a result of hæmorrhage, the destructive action of a toxin or the decreased vitality of blood-forming organs or deficiency of certain internal secretions.

There are various classifications of anæmia, many of which are imperfect. The following classification by Davidson is satisfactory.

1. *Nutritional deficiency anæmias.* (a) Due to defective production or faulty assimilation of the specific anti-anæmic material found in the liver.

(i) Primary macrocytic hyperchromic anæmia, i.e., pernicious anæmia. (ii) Secondary macrocytic hyperchromic anæmia, i.e., due to sprue, bothrioccephalus, cancer of the stomach, multiple anastomoses, gastrectomy, pernicious anæmia of pregnancy (increased demand, i.e., relative insufficiency), dysentery, etc.

Many cases of the diseases in Group (a, ii) have a failure in iron assimilation and thus pass into Group (b, ii).

(b) Due to defective absorption and assimilation or reduced intake of the factors necessary for hæmoglobin formation. (i) Primary

microcytic hypochromic anæmia, *viz.*, simple achlorhydric anæmia and the Plummer Vin^{cent} syndrome. (ii) Secondary microcytic hypochromic anæmia, due to starvation, insufficient or defective dietary, *e.g.*, diet low in protein and green vegetables, high carbohydrate diet or milk diet. This may also follow inflammation and catarrh of the stomach and intestines (*vide a, ii*).

II. *Post-hæmorrhagic anæmia*. Acute or chronic, including blood loss from the gastro-intestinal, urogenital, and respiratory tracts.

III. *Hæmolytic anæmias*. (a) From acute, sudden, and severe hæmolysis, with hæmoglobinæmia and hæmoglobinuria, *e.g.*, malaria and blackwater fever, paroxysmal hæmoglobinuria, hæmolytic streptococcal septicæmia, hæmolytic poisons, such as toluylendiamine, snake venom, etc.

(b) From steady and incessant hæmolysis associated with excessive activity of the reticulo-endothelial system, leading to icterus and splenomegaly.

(i) Congenital acholuric jaundice and sickle-celled anæmia. (ii) Acquired hæmolytic jaundice:

1. Causal factor unknown. The condition resembles clinically the congenital type, but fragility is less marked or absent.

2. Associated with profound dyscrasias of the hæmatopoietic and reticulo-endothelial systems, *e.g.*, certain cases of Hodgkin's disease and obscure affections of the liver and spleen.

IV. *Anæmias due to depression of bone-marrow function*. (a) Idiopathic aplastic anæmia and idiopathic agranulocytic anæmia. (b) Aplastic or partially aplastic anæmias secondary to radio-active substances, benzol poisoning, toxæmias and septicæmias, cachectic states, cirrhosis of liver and spleen, metabolic diseases (nephritis), and metallic poisons such as lead and mercury.

It is admitted that no classification is perfect, since several factors may be present in any individual case of anæmia. Thus a case of cancer of the stomach may lose blood by hæmorrhage, may be on a defective milk diet, and may have a depressed condition of the bone marrow secondary to cachexia. Nevertheless, the above classification gives a scheme suitable for diagnosis and treatment.

Thus the anæmias in Group I (a) are all macrocytic hyperchromic diseases requiring the administration of liver, liver extract or ventriculin.

The anæmias in Group I (b) and in Group II are microcytic hypochromic anæmias, and require a well balanced diet with massive doses of iron.

In group III the essential treatment is the removal, where possible of the factor causing hæmolysis, *e.g.*, splenectomy in acholuric jaundice and quinine therapy in malaria.

In group IV the guide to proper treatment is an understanding of the underlying causal factor, *e.g.*, change in occupation of workers with benzol and radioactive substances, splenectomy in splenic

anæmia, etc. In addition, stimulation of the depressed bone marrow by blood transfusion and liver and iron therapy should be carried out.

Hyperchromic anæmia is profoundly related to disturbance of gastric secretion. In primary hyperchromic anæmia there is as a rule a complete disappearance of normal gastric secretion, in other words, a true achylia gastrica is present. No free hydrochloric acid has been found even after an intramuscular injection of 1 c.cm. of 0.1 per cent. solution of histamine.

In the hypochromic anæmias achlorhydria is not absolutely invariable. The amount of pepsin is diminished, but the renine-like ferment, which is absent in the hyperchromic anæmias, can be demonstrated to be still present.

It appears then that many chronic types of anæmias described, may be translated in terms of dysfunction of the stomach and intestines. This explains the curious over-lapping in the blood changes which sometimes occurs. A hypochromic anæmia may eventually become hyperchromic as the secretory function of the stomach gradually fails, whilst the efficient treatment of a hyperchromic anæmia may reveal a hypochromic anæmia.

It was formerly held that life in the tropics favoured the production of anæmia but this idea is no longer tenable. Tropical anæmia is a vague term about which there is very little definite knowledge. This diagnosis should never be made until other causes of anæmia have been excluded; the most important of these are malaria, hook-worm disease, dysentery, kala-azar, etc. Mental and physical weakness, pallor, palpitation, œdema of the feet and emaciation are characteristics of this disease.

Pernicious anæmia. DIAGNOSIS. I. *Blood*—(a) Red blood corpuscles are diminished in number; hæmoglobin per corpuscle is increased. The colour index is therefore high (greater than one). (b) The red cells show anisocytosis, poikilocytosis, polychromatophilia and punctuate basophilia; normoblasts and megaloblasts are present. (c) The platelets are reduced. (d) Reticulocytes are increased to 2 per cent. (e) Slight leucopenia with relative lymphocytosis. (f) The polymorphonuclear leucocytes show a 'shift to the right' in the Arneth count, many having 4 or 5 lobed nuclei. (g) Van den Bergh's reaction (indirect) is often positive. (h) Inequality in the size of the red cells in pernicious anæmia is a characteristic feature of the disease. Price-Jones elaborated a method for graphical demonstration of the size of the red cells. In pernicious anæmia the mean diameter of red cells is 8.24μ . (i) Halometric determination of the size of the red cells can also be conveniently employed. (See technique under blood). Price-Jones claims that the degree of anisocytosis is more important than the mean diameter, and that halometer affords no information as to the amount of anisocytosis.

II. *Urine and fæces* contain excess of urobilin.

III. *Test meal* shows achylia gastrica, no free HCl being secreted after histamine injection. The juice also lacks in pepsin and the 'intrinsic factor' of Castle.

IV. *Clinically*, lemon-tint colour of the skin and absence of wasting are important.

TREATMENT. Recent experimental and chemical studies of anæmias have brought to light many factors which control red cell formation in the bone marrow. A special hæmatinic principle is necessary for the development of the megaloblast to the erythroblast stage. Iron, copper, thyroxin and vitamin C are also needed for satisfactory maturation of red cells.

The state of arrested development in the red marrow is due to the absence of what may be called a mating principle. It is normally formed in the stomach by the interaction of an agent present in gastric juice ('intrinsic factor') with another substance found in the ox muscle and which may be identical with vitamin B₁₂ (extrinsic factor). This principle is mainly stored up in the liver. Absence of the intrinsic or extrinsic factor and failure in the absorption of the hæmatinic principle may lead to a failure in the megaloblastic maturation resulting in anæmia. The principle of treatment of anæmia must therefore be directed towards the supply of the hæmatinic mating principle. In the following lines the different therapeutic agents are discussed.

Liver therapy. The discovery of liver as a therapeutic agent in pernicious anæmia by Minot and Murphy in 1926 is perhaps the greatest advance in medical treatment of anæmia. The specific substance required to enable the bone marrow to function normally as regards the formation and maturation of red cells may be supplied by taking liver by mouth, either raw or cooked. Any mammalian liver is effective. Cooking does not destroy the active substance provided the liver is not subjected to prolonged boiling. The quantity of liver required varies in individual cases, but as a rule $\frac{1}{2}$ lb. daily is needed at the beginning of treatment. The liver extracts, of which there are many preparations on the market, are equally effective but more expensive, and are rarely necessary except perhaps at the beginning of treatment when the patient cannot tolerate the large amount necessary to induce a remission.

Striking blood changes occur with the institution of liver feeding which are especially marked when the patient is very anæmic. Reticulated red cells which in the blood of the untreated patient usually do not exceed 2 to 3 per cent. of the red cells, begin to increase in number within a few days of the beginning of treatment, and by about the 10th day have usually risen to anything between 15 to 40 per cent. Subsequently the percentage of these reticulated cells, or reticulocytes as they are often called, begins to fall and within a few

weeks returns to the normal. With the rise in the percentage of reticulocytes the number of red cells begins to increase and this continues until in the course of four to six months it approximates to normal. There is a coincident rise in the hæmoglobin and the colour index approximates to normal. With the changes in the blood there is a steady improvement in the condition of the patient.

The continuous consumption of large quantities of liver is inconvenient and generally distasteful. It has been shown that the activity is retained by deproteinated aqueous extracts which may be greatly concentrated and which are not disagreeable to take. Liver extract No. 343 is a powdered concentrate of this sort; several other liquid and dry extracts are on the market.

Liver extract No. 343 is a water-soluble nitrogenous, non-protein fraction obtained from fresh mammalian liver. It is supplied in vials containing an amount of powder (3 to 4 gm.) representing 100 gm. of fresh liver. It is administered orally in water, soup, orange juice or other vehicle about an ounce per vial. The initial dose is five to eight vials. When the blood has been brought to normal, the dosage may be reduced to the maintenance level, usually two or three vials per day, controlled by monthly blood examination.

Liver preparations for intravenous and intramuscular injections can be safely administered to patients with satisfactory results. The intramuscular method is almost as rapid in action as the intravenous method and does not produce any reaction; hence it must be considered to be the method of choice. The majority of workers use preparations of a bulk of 5 c.cm. which contain the extract from 100 gm. of liver. *Hepatrat* and *Campolon* are some of these preparations used at present.

One of the causes of failure of liver treatment is the presence of a septic focus, and the commonest infection of any importance is pyelitis. Every patient with pernicious anæmia who fails to respond to injections of liver extract should have a bacteriological examination of a catheter specimen of urine done. Once such urinary focus of infection is cured, liver will exert its usual effect. Hypothyroidism is another common cause. If liver extract has failed to bring the blood to normal, small doses of thyroid extract may be given in addition with encouraging results. Presence of arterio-sclerosis is also a cause of failure, though to a partial extent. This is one of the most troublesome complications and in the absence of efficacious treatment of arterio-sclerosis, larger and larger doses of liver extract is required. In pernicious anæmia blood destruction occurs and it is often assumed that the iron derived from this source will be enough to furnish hæmoglobin for a normal number of corpuscles. But this is not true in every case and it may be necessary in some cases to supplement liver with a course of iron to keep the hæmoglobin and red corpuscles a normal figure.

Stomach preparations. The occurrence of achlorhydria in pernicious anæmia suggests a possibility of causal relationship with gastric functions. The work of Castle showed that meat previously digested in a normal human stomach and then fed to a pernicious anæmia patient is effectual in the treatment of this condition. The use of desiccated pig stomach has also given good results. The therapeutic response is identical with that of the liver extract, quite uniform and even somewhat more prompt.

Ventriculin N. N. R. is prepared by grinding the entire stomach of hogs, drying in vacuum below 66°C. and extracting the fat contents therein. It is standardised by clinical tests, so that 10 gm. of the dried stomach correspond in activity to 300 gm. of the fresh liver. It is taken stirred with water, in which it is insoluble. The daily dose is 10 gm. per million deficit in the cell count. The maintenance dose is 10 gm. per day.

Iron. Iron is seldom required in the treatment of pernicious anæmia. In a small group of cases it is a very important adjuvant to liver therapy.

Hydrochloric acid. It is a valuable drug in the treatment of vomiting and dyspepsia and especially of the diarrhoea which is a common complication of the achlorhydric state; 1 dr. of dilute hydrochloric acid, three times a day, well diluted with water and flavoured with orange juice, often works like a charm. Glycerine of pepsin B. P. may be added to it with advantage.

SUMMARY OF TREATMENT. The present position regarding the treatment of pernicious anæmia may be summarised shortly as follows: The complicated diet, as originally suggested by Minot and Murphy, is now unnecessary, but a liberal well-balanced diet rich in protein is essential. The following is shown by Whipple to be of value in blood regeneration. (1) An adequate daily intake of red meats, green vegetables, and fruits. (2) Liver, either raw pulp or lightly cooked. The amount required for a case of average severity is about half a pound daily. (3) Liver extract derived from 500 gm. of whole liver, or desiccated hog's stomach, 10 gm. for every million red cells deficient, is of particular service during the severe relapsed stage. When nausea and vomiting are prominent features, intramuscular or intravenous liver extract therapy is of particular value. Liver extract or desiccated hog's stomach may be used as a substitute for whole liver during the remission stage, but it should be remembered that whole liver appears to have certain definite advantages over such preparations and therefore should still be considered as the staple article in the maintenance diet. (4) The maintenance dose of effective principle must be taken for life. It varies in individual cases widely as already described, but generally speaking, from one and a half to two pounds of liver per week is sufficient. The only criterion on which to judge the maintenance dose is the blood level. The difficulty in some cases of bringing the blood level

to normal and the dangers consequent on the failure to do so have already been discussed. (5) After preliminary treatment with liver, septic foci, if present, should be adequately dealt with. (6) No drugs are required for routine purposes, but in certain particular conditions hydrochloric acid, iron, and thyroid extract may be of service.

Microcytic hypochromic anæmia. As already indicated in the classification, microcytic anæmia may result from widely different causes, although the blood picture present may be essentially similar. All are agreed that it is wrong to treat such anæmias without diligently hunting for and if possible eradicating the cause. Microcytic hypochromic anæmia results from a deficiency of the hæmoglobin building factors, because of inadequate intake, faulty assimilation, or excessive loss, and the anæmia can be relieved by iron medication, by suitable dietary or by a combination of the two. A brief review of the facts on which our present knowledge regarding the importance of nutrition in the production, prevention, and treatment of microcytic anæmia is based, is, therefore, deemed desirable.

For the maintenance of health an adequate diet is required, which may be summarised briefly as follows. (1) The caloric value should be sufficient to keep the body weight within 10 per cent. of the normal. (2) Protein must be of good quality. Minimum requirement is two-thirds of a gramme per kilo. of body weight. Average amount, 12 to 15 per cent. of the total calories of the diet (from 60 to 120 gm. per day). (3) The carbohydrate must be enough to allow for energy and to avoid ketosis. Average amount is 50 to 55 per cent. of the total calories of the diet (from 200 to 500 gm.). Fat is required for heat and energy, and as a carrier of the fat-soluble vitamins. Average amount 30 to 33 per cent. of total calories of the diet (80 to 120 gm.). (4) There must be a good supply of vitamins A, B, C, D, and E. (5) There should be an adequate amount and a proper balance of the necessary mineral salts :—*Calcium*. Adults require 0.67 gm. (represented by 1 pint milk) and children require 1.2 gm. (represented by 1 quart milk). *Phosphorus* 1.33 gm. *Iron* 0.015 gm. (7) Enough roughage to give a daily bowel movement without aperients. (8) Water, from four to six glasses daily. (9) The food should be properly cooked and attractively served.

TREATMENT. *Iron.* Administration of iron is indicated particularly in those varieties of anæmia in which the hæmoglobin index is low, *i.e.*, in chlorosis, and cases of secondary forms of anæmia, such as are commonly met with in tuberculosis, syphilis, malignant disease and many other conditions. Anæmias, the result of hæmorrhage, chronic poisoning with lead, mercury and arsenic, the presence of parasites in the intestine or presence of malarial organisms in the blood, are also benefited by iron, though special attention must be paid, in these conditions, to removal of the original cause.

Hæmoglobin may be deficient either because of the defective hæmatopoiesis or by reason of excessive hæmolysis. The best results with iron are obtained in cases belonging to the former class.

Iron appears to act by stimulating the blood formation in the bone marrow, although in normal animals, slight increase occurs in the number of red cells circulating and of the fat in the bone marrow, without any increase of cell formation in the marrow. Successful iron therapy in anæmia depends on giving a suitable iron preparation in adequate dosage. The treatment ought to be continued as a rule, for six weeks to two months, in order to procure all its useful effects. As to the dose, iron and ammonium citrate 30 gr. thrice daily or Bland's pill 45 gr. daily are required. Ferrous sulphate tablets (Glaxo) which contain 3 gr. of iron with copper and manganese in minute doses is found to be efficacious. A dose upto 9 gr. thrice daily can be given. It is easy to administer and the cost of treatment is also very low.

Iron therapy is totally ineffective in pernicious anæmia; indeed it appears that the untreated patients have more iron available than can be used in the diminished manufacture of red blood corpuscles; for the colour index is high and the reserve iron of the liver and spleen is considerably increased.

Copper. The role played by copper in the cure of hypochromic anæmias is distinctly a minor one. Whilst certain experimental results suggest that it acts as an adjuvant to iron, the evidence is conflicting. In any case, a well-balanced dietary includes sufficient copper. Copper and ammonia sulphate were empirically tried in doses of 0.03 to 0.12 gm. in the treatment of anæmia that resisted iron, long before recent experiments called attention to its possible value in anæmia. It has been prescribed dissolved in peppermint water sweetened with syrup. Copper acetate, though not an ideal salt for the purpose because of its acetic acid odour and astringent action, might be used in doses from 0.006 to 0.030 gm. Traces of copper which are normally present in food or their addition to artificial diets, aid greatly as a supplement to iron in the formation of hæmoglobin in young animals and in nutritional anæmias.

Radium. The bone marrow, spleen and lymph glands are markedly affected by radiation so that blood picture changes. The hypodermic injection of soluble radium salts produced rapid increase of the red cells, persisting for several weeks. The hæmoglobin did not rise as much. The leucocytes were also increased with small doses.

Arsenic. Small doses of arsenic were found by Stockman to produce hyperæmia of red bone marrow in young animals. Arsenic, however, has a general action in producing dilatation of the capillaries and its action on the red bone marrow may be due to this effect. There is no evidence that arsenic causes any increased formation of

red blood corpuscles in normal animals. Arsenic treatment frequently produces temporary relief, and it is now believed that this effect is due to the arsenic causing the destruction of a certain amount of the patient's liver substance and thus releasing some of the active principles.

Fowler's solution is given orally commencing with 3 min. thrice daily and increasing up to 15 min. The drug is discontinued if there is any symptom of intolerance. Alternately, sodium cacodylate 1 gr. daily may be given intramuscularly. Arsenic may be combined with iron for injection purposes. *Hydrochloric acid* may be used if there is achlorhydria as in primary anaemia.

Splenectomy. Another method of treatment to which much prominence has been given is the excision of the spleen. Splenectomy is done in Banti's disease and in cases of splenomegally of unknown or uncertain origin.

Blood transfusion. The transfusion of 200 to 500 c.cm. of blood from a suitable donor may be of great service when an extreme degree of anaemia is present at the commencement of treatment.

ANGINA PECTORIS. Angina pectoris may be defined as a disturbance of the cardiovascular system with severe substernal pain and generally associated with a sense of oppression or constriction which may reach a high grade of intensity and intolerable anguish. It is associated with other symptoms such as a sense of impending death and an acute misery accompanied by varying vasomotor disorders such as cold sweats and deathly pallor. Angina is common in families associated with an inherited tendency to arterial diseases and hyperpiesia. It is commonly seen in persons of middle age and is commonest in males between the ages of 50 to 70. Good living, lack of sufficient exercise and excessive mental strain are predisposing factors of angina. Diabetes is an important ætiological factor because of the high incidence of generalised arteriosclerosis in such patients, and the increased liability to coronary sclerosis. Syphilis, by causing aortitis, stenosis of the mouths of the coronary vessels and aortic regurgitation, predisposes to anginal attacks. In such syphilitic cases, the capacity of the ventricles is large, the orifice of the coronary vessels is narrowed and the diastolic pressure is low; all these lead to ischaemia of the myocardium. There is special tendency to localized coronary spasm, resulting in angina of the spasmodic type. The essential pathological changes responsible for spasmodic angina are changes in the coronary arteries such as a narrowing of the orifice or lumen of the artery. The pain is really of a physiological nature due to improper nutrition of the heart from organic defect or from temporary spasm. Angina is rarely seen in cases of mitral stenosis and where the auricles are fibrillating. The substernal discomfort or pain is induced by effort and is relieved by rest. The three cardinal symptoms of angina are pain, a fear of impending death and disturbance of respiration. Pain also

has certain lines of radiation the commonest of which is the left arm. Physical examination is generally disappointing in the diagnosis of the condition. A sudden death might ensue from coronary thrombosis. In the hyperpietic group, vascular accidents such as cardiac failure or failure of renal functions may cut life short. The prognosis is grave in families predisposed to angina and essential hyperpiesia.

An electrocardiogram may yield helpful information. A low voltage in all leads, the presence of a branch bundle block, or an abnormal Q R S complex, or evidence of a previous coronary thrombosis, would be an unsatisfactory finding suggesting the presence of myocardial damage and to that extent adding precision to the prognosis.

TREATMENT. Absolute rest is imperative on the slightest sense of substernal discomfort. If the pain does not subside with rest, one or more tablets of trinitrine should be chewed slowly. If this fails to yield relief, the inhalation of amyl nitrite is indicated. If such drugs cannot alleviate the intense pain, morphine may be injected in doses large enough to make the patient comfortable. If, however, the pain proves very resistant and recurs with increasing intensity in spite of rest and opiates, a coronary thrombosis should be suspected. In the less severe attacks, flatulence may be a distressing symptom, and this may be relieved by brandy or a strong carminative draught containing menthol 8 gr., aromatic spirit of ammonia, compound tincture of cardamom and tincture of ginger, each 1 oz.; two teaspoonfuls of this mixture to be given in four tablespoonfuls of water. In cases of frequent recurrent attacks, a mixture containing opium and chloral, given twice daily, may diminish this tendency. In the angina associated with aortic regurgitation, nocturnal attacks are common. In these cases a draught of opium and chloral taken before retiring to bed proves effective. General treatment in these cases is based on the recognition that the circulation through the coronaries is defective and that this defect is permanent and irremediable. Reliance, therefore, must be placed on a change in the mode of life rather than on drugs. A careful investigation should be made not only into the physical condition of the patient, but also into his mode of life and environment, in order to discover the extent of the organic damage. Exercise is advisable to keep the heart muscle fit and walking serves this purpose. As the condition advances, the amount of exercise which can be indulged in with comfort gradually diminishes. Under no circumstances should any sudden or severe physical effort be made. A short rest after even the lightest meal should be insisted upon. With diminution of the cardiac reserve, many patients find comfort and benefit in retiring early to bed at night. Diet is important; meals should be small, the food simple and easily digestible, and a minimum of fluid should be taken with the meal. Obesity should be controlled with strict dietary measures as it often leads to fatty degeneration of the myocardium. Constipation and flatulence should be avoided. In all cases, the examination of

blood for a Wassermann reaction should be a routine procedure, search should be made for all foci of sepsis in the body, and hyperpiesia if present, should be controlled. Large doses of ammonium bromide, 20 gr. twice or thrice daily, are undoubtedly helpful in calming down patients with mental worries. Chloral hydrate 10 gr. twice daily, is also a valuable addition. Luminal $\frac{1}{4}$ gr. or theominal 5 gr. may be administered once or twice daily in restless and eager patients. In syphilitic cases, potassium iodide in full doses should be given and, if possible, mercury by inunction. Large doses of potassium iodide, 30-40 gr. thrice daily, are sometimes very beneficial in diminishing the nocturnal attacks of angina in patients with marked aortic regurgitation. Some authorities prefer intramuscular injections of bismuth preparations to mercury when the Wassermann reaction is positive. Diathermy is said to diminish the number and severity of attacks both in cases of hyperpiesia and in normal pressures. It is best administered with one electrode placed over the sternum and the other between the shoulders. A suitable therapeutic dose is from 800 to 1,500 milliamperes for 20 to 30 minutes twice or thrice a week. Convalescence should be well controlled particularly after toxic illnesses such as influenza. General tonic treatment and hæmatinics are of real value in cases of angina associated with anæmia. Shirley Smith states that he has obtained satisfactory results from the use of insulin and glucose in anginal patients, irrespective of the presence or absence of diabetes.

The principle of surgical treatment consists in cutting off the sensory impulses from the heart and aorta to the nervous system by way of cardiac nerves. The surgical treatment in angina was first adopted by Jonnesco in 1916 who removed the whole sympathetic chain on the left side. Coffey and Brown later suggested a less extensive operation by removing the superior cervical ganglion alone. Eppinger and Hofer found that section of the depressor nerve arising from the vagus and superior laryngeal nerves was beneficial in some cases. Swetlow advocated the paravertebral injection of 5 c.cm. of 85 per cent. alcohol into the upper five intercostal nerves close to the intervertebral foramina. The cessation of pain in such cases may last for several years.

ANTHRAX. See page 1166.

ARTHRITIS. Inflammatory affections of joints are of the most diverse character and are brought about by various factors. Willcox classifies such affections of joints according to ætiological factors as:—

1. **ARTHRITIS OF KNOWN CAUSATION.** (a) *Traumatic arthritis.* A simple trauma, with or without damage to the various structures composing a joint, may bring about inflammatory changes in a joint or it may simply be a predisposing factor to such a change as in subjects with tuberculous diathesis.

(b) *Specific infective arthritis*. Here the exciting cause is generally some organism responsible for systemic diseases, and arthritis develops as a complication in the course of the disease.

Gonococcal arthritis. This is a serious complication in gonorrhœa and usually results from gonococcal septicæmia.

Dysenteric arthritis. It is a common complication in bacillary dysentery and is generally seen after the acute intestinal symptoms have subsided. Such post-dysenteric arthritis is held to be due to secondary infections of the colon with streptococci and other intestinal flora. It is very rare in amœbic dysentery though a few cases are on record.

Pneumococcal arthritis. It occurs in general pneumococcal septicæmia in acute stage of the disease even before the involvement of the lungs.

Tuberculous arthritis. It is generally seen in young patients with a primary tuberculous focus elsewhere in the body.

Scarlatinal arthritis. It is a fairly common occurrence in scarlet fever and varies from mild forms of arthralgia to the severe joint pains.

Malta fever arthritis. Arthralgia, during the initial stage of the disease and effusions into joints, during the relapses, are commonly met with.

Dengue fever arthritis. Effusions into joints accompanied by severe pain in the bones are met with in the course of the disease.

Typhoid arthritis. Arthritis may develop during the later weeks of the acute stage of the disease or a multiple suppurative arthritis may form part of a post-typhoid septicæmia and pyæmia.

Syphilitic arthritis. It is met with both in the congenital and acquired forms of the disease. Effusions into joints in the secondary stage and gummatous thickenings of the structures of joints in the tertiary stage are the common pathological changes in the joints. Relative lack of pain is the essential characteristic of a syphilitic joint.

Arthritis in glanders. The joint is infected with *Bacillus mallei* and arthralgia and suppurative arthritis are the forms seen in the disease.

Septicæmic and pyæmic arthritis. Acute arthritis leading to suppurative changes in the joint is a common complication in septicopyæmic condition of the blood infected with staphylococci, streptococci and other pyogenic organisms.

Filarial arthritis. Among other complications, synovitis, suppurative arthritis and fibrotic ankylosis of joints are seen in the course of the disease.

Arthritis in guinea-worm disease. Sometimes a female dracunculus penetrates a joint and causes synovitis or arthritis.

Arthritis in leprosy. In leprosy, joint involvements present a clinical picture identical with Charcot's joint in tabes dorsalis.

Arthralgia and arthritis are also seen as complications in relapsing fever.

(c) *Arthritis in gout.* The joint never completely recovers after recurrent attacks of arthritis resulting in permanent pathological deformities.

(d) *Arthritis following the injection of animal sera.* Arthritis is a common complication in serum sickness and anaphylactic attacks after serum administration.

(e) *Arthritis of neuropathic type.* Various pathological changes of bones and joints are met with due to trophic changes associated with tabes dorsalis and syringomyelia. Complete absence of pain in the diseased joints is the predominant feature in such cases.

(f) *Arthritis due to abnormal blood conditions.* (i) *Hæmophilia*; Hæmorrhage into joints, with or without an exciting cause, and the resulting arthritis are common in the disease. (ii) *Purpura.* Arthralgia in purpura simplex and arthritis with effusion in joints in purpura rheumatica are the common accompaniments in the disease.

(g) *Arthritis associated with deficiency diseases.* Hæmorrhagic effusions into joints in scurvy and pathological changes of the structures of a joint in rickets are commonly met with.

2. ARTHRITIS OF OBSCURE CAUSATION. (a) *Acute rheumatism.* Here arthritis is one of the diagnostic symptoms in the disease.

(b) *Non-specific infective arthritis.* This includes all the chronic types of arthritis with obscure ætiology, though infection is held to be a factor in its causation and known as rheumatoid arthritis, arthritis deformans, osteo-arthritis and chronic villous arthritis.

The ætiological factors of arthritis of known causation are the same as those causing such diseases, but the factors responsible for the non-specific type are generally obscure. Bad hygienic conditions of living, improper diet, exposure to cold, nervous or emotional shock, a trifling trauma, heredity, all play an important role in the ætiology of the disease. Focal infection, as of the teeth, tonsils, sinuses, genito-urinary passages, is held by the modern school to be a most potent factor in the ætiology of chronic infective arthritis. Cecil (1933) holds that apart from infection, arthritic changes result from many causes more frequently induced by general biologic factors such as chemical, anaphylactic or toxic processes than by infection of the joints. Infections usually remote from the rheumatic joints incite the chemical or toxic processes which cause the change in the joints, yet it is also probably true that other than infectious agents, that is trophic or toxic factors, may produce similar clinical disturbances.

TREATMENT. Burbank (1930), in all cases, suggests a good plan for a thorough investigation of the physical and biochemical conditions of the patient before the rational treatment is commenced. Cultures of organisms, isolated from suspected foci of infections in the system, are made. A complete bacteriological examination of urine and stool, with subsequent identification of all unusual organisms, is undertaken in each case. In every case, blood is taken as for Wasserman's test,

gonococcus fixation and titration against polyvalent antigens of *Streptococcus viridans*, *S. hæmolyticus* and the slow hæmolising type, *Staphylococcus aureus*, *B. coli communis*, and also against thirty-five strains of streptococcus isolated from known active foci in arthritic cases. A blood culture is also done in all cases.

The patient's general health should be kept in the best possible state. A search, to find out the infective foci in the body as in the teeth, tonsils, sinuses, genito-urinary passages, etc., is to be made and prompt measures should be adopted for their eradication. Stasis of food and its subsequent putrefaction in the stomach and the gut are to be avoided. The harbouring of harmful pathological saprophytes in the alimentary canal is best combated by the internal administration of specific drugs against such bacteria. Elimination through the skin, bowels and bladder is to be always encouraged by physical therapy and drugs. Trauma in all forms should be carefully avoided. Complete and perfect rest, both general and local, should be enjoined on the patient in the active stage of the disease. Measures to raise the general resistance of the body, by improved personal hygiene living in a healthy environment, proper dieting with necessary vitamins, increasing the rate of metabolism and stimulating the endocrines of the system should always be advocated. A dry and hot climate is always preferable for arthritic subjects.

Local treatment and physical therapy. Physical methods of treatment in rheumatic and other joint affections have been found to be most effective in general practice and sometimes better results have been obtained than with drug treatment. These methods improve the general health of the patients thus increasing their resisting power both by direct action and indirectly by causing auto-inoculation. In most cases pain is relieved, swelling and stiffness reduced and deformity corrected.

The idea of local treatment is to improve the circulation of the affected part. This is effected by physico-therapeutic measures. Radium, heat, ionisation, massage, exercise, diathermy, heliotherapy—all are invaluable. The affected part should have perfect rest in the acute and subacute stage when active inflammation is present. Resting a joint by splints; elastic bandages and other orthopædic appliances in the acute stage to prevent subsequent deformity should always be borne in mind. The beneficial effects of physiotherapy are due to cutaneous vasodilatation, generalised sweating and pyrexia, whereby the unhealthy state of the skin improves and pain and stiffness of muscles are considerably reduced. Douthwaite (1931) recommends a 'foam bath,' where a patient is placed in water with a temperature of 104°F. and to which a special solution of saponin is added. Air is pumped through and foam envelops the patient. The effect of the 'hot paraffin wax bath' is similar. The profuse sweating after such baths is removed by a hot water douche and the patient is subjected to general massage and muscle kneading. The

most simple and valuable form of thermal treatment consists of the old fashioned hot wet pack, made of blankets wrung out of hot water. A pack is given daily for ten days. No form of thermal treatment is complete unless followed by general deep massage. Local application of heat in form of poultices, hot magnesium sulphate compresses, anti-phlogistin, mud packs, moist heat, exposure to a gas fire containing infra-red rays, a small radiant heat lamp, dry heat in form of electric pads, is beneficial to relieve pain of inflamed joints. Diathermy is a good source of heat whilst if there be much effusion, ionisation with other drugs is useful. Only when the acute stage subsides, gentle massage and graduated exercise to preserve the integrity of blood circulation, electro-therapy in form of Faradism, sinusoidal current or interrupted galvanism, necessary for restoring the function of the part, should be adopted. Any form of exercise which will leave the part painful and tired, half an hour after the cessation of the act, should never be encouraged. Deep X-ray therapy relieves pain in osteo-arthritis.

Diet therapy. The problem of selection of a proper diet for arthritic subjects is a difficult one and is receiving attention every day. Regulation of diet depends on the patient's general condition of health, weight, chemical examination of blood and general clinical progress. The basic diet should be of low caloric value, with low carbohydrate, protein and purine values but of adequate vitamin content. Foods that are not properly digested should be eliminated and easily assimilable, nourishing ones, low in irritants and in carbohydrates (which furnish a good medium for streptococcic growth), substituted.

In the acute stage of the disease, the patient should live on glucose and fruit juice and no liberal diet should be allowed till the acute symptoms subside. Much benefit has been obtained with this, as meanwhile there is generally a marked absorption of pathological exudates in or around the joints, nearly ankylosed by existing fibrous contractions. Persons with atrophic and hypertrophic arthritis have definitely improved on low caloric diets with reduced food intake. Reduction of carbohydrates with adequate substitute of proteins and fats is useful.

Dietetic factors are of great importance, the essential being properly balanced vitamin supply. Deficiency in this induces a lowered state of resistance to rheumatic infection. Many patients with chronic arthritis show an atony and dilatation of the colon and the supply of vitamin B improves such a condition.

About 50 to 100 gm. of raw spleen daily with a salt-free diet have been recommended for tuberculous arthritic subjects. Sometimes about 2 gm. of the pressed juice of raw spleen reaching a maximum of about 30 gm. daily have also been given with benefit.

Non-specific protein therapy. This is of benefit specially in acute poly-arthritis, gonorrheal arthritis and infectious types of chronic arthritis during the period of active inflammation. If the response to such

treatment is prompt and effective, it is continued at an interval of two days, but, if otherwise, the treatment is generally discontinued. The underlying principle of this therapy is to excite a mild inflammatory reaction with leucocytosis and antibody formation. Sometimes marked improvement has been observed in rheumatoid arthritis and arthritis deformans with intramuscular injections of peptone, the dose being 0.2 gm. and repeated weekly. Injections of skimmed milk or its preparations such as Aolan have also been used with some benefit, the dose is 4 to 10 c. cm. injected intramuscularly and generally repeated twice a week. Artificial production of leucocytosis and antibody formation are also facilitated by intramuscular injections of sodium nucleinate, the dose being 0.05 gm., one per cent. sulphur in suspension in olive oil, and the intravenous use of some bacterial emulsions. Yeoman (1926) has used T. A. B. vaccine intravenously and reports rapid improvement in chronic arthritis cases. The initial dose is 50 millions, increased at each subsequent dose by 100 millions and with an interval of 4 days in between the injections. These injections stimulate the defensive mechanism of the body and the ultimate factor in determining a cure may be the response to the antigenic activity of the infecting organism, this response being evoked not directly but indirectly by the protein injected.

Fever-therapy. In chronic types of arthritis this changes the chronic inflammatory processes of the joints into acute ones, with a better healing tendency as a result of the acidosis produced by it which also aids and stimulates the natural defence of the body by stimulating the hæmopoietic system thereby increasing the leucocytic elements. Horn (1933) employed a preparation, consisting of fever-inducing substances from non-pathogenic bacteria and reports much benefit with such therapy in a considerable number of his cases.

Vaccine therapy. This has given encouraging results in the treatment of arthritis. Definite benefit has been obtained in the polyarticular types of cases of quite long duration. Autogenous vaccines prepared from strains of organisms isolated from infective foci of the patient himself are generally preferable. Douthwaite (1931) treated cases of arthritis with stock vaccine freshly prepared from about forty strains of *Streptococcus viridans* isolated from the teeth and tonsils of patients. The initial dose was 5 to 10 millions injected subcutaneously at intervals of 3 to 4 days but sometimes once a week. The reaction was allowed to subside completely before the repetition of a second dose. Generally on an average, about 8 to 12 injections were given and improvements were marked after such treatment.

Hæmotherapy. Copeman (1932) advocates hæmotherapy in the treatment of arthritis. After proper elimination of septic foci in the body, if no improvement in the condition of the patient is marked, blood sedimentation rate is estimated to detect a hidden focus of infection. Two blood transfusions, each of 500 c.cm., are given at an interval

of 8 days and intense physical treatment is undertaken along with it. The patient is next put on an insulin regimen and the weight observed from time to time. Marked improvement was noticed in many cases.

Drug therapy. Sodium salicylate has long enjoyed the reputation of a good anti-rheumatic drug. It is often used in large doses in rheumatic arthritis. Peters (1929) treated cases of rheumatic polyarthritis with marked benefit with large doses of sodium salicylate; 50 c. cm. of a solution containing 30 gm. of sodium salicylate, 60 gm. of sodium bicarbonate, 300 c. cm. of syrup of orange and distilled water added to make it 1000 c. cm. were given ten times daily at two hourly intervals and then at four hourly intervals only when fever and pains had subsided. A quick cure was marked in acute cases and the accompanying endocarditis improved.

Aspirin. The drug has anti-rheumatic properties and is used as a substitute for salicylic acid and its salts. Repeated doses of the drug such as 5 gr. every 6 hours often lessen rheumatic pain and are useful as an analgesic.

Tylcalsin (calcii aceto-salicylas) in doses of 5 to 15 gr. has given excellent results in gonorrhœal arthritis. It is an analgesic, antipyretic, a prompt rheumatic specific and a useful substitute for aspirin. Campbell, Pritchard and Burnford advocate its intravenous use in acute and subacute rheumatism. The usual dose is 0.5 gm. in 10 to 20 c.cm. of distilled water and the concentration should never exceed 5 per cent.

Hexamine. McCarthy Morris (1931) advocates the use of hexamine in rheumatoid arthritis in combination with sodium salicylas. He recommends a prescription consisting of hexamine, sodium salicylate and ammonium benzoate, 1 dr. of each; potassium citrate, 6 dr. and chloroform water to six ounces. Half an ounce of the mixture is to be taken in soda water every morning before breakfast. The treatment is generally a prolonged one.

Amidopyrin has been used in the acute stage of the disease, in doses of 0.3 gm., every two hours and repeated eight times a day. The treatment is continued till the acute symptoms subside and then the dose is gradually decreased. It is better than massive doses of sodium salicylate. Generally, nausea, constipation and headache may appear as after-complications of amidopyrine treatment, but cardiac complications are never observed.

Sodium iodide. A 10 per cent. freshly prepared solution of sodium iodide has been used intravenously in chronic rheumatic arthritis with some benefit. About 10 to 15 injections are given with an interval of two days in between the injection. The treatment should not be given if too much reaction is produced and it should be accompanied by intense physical therapy. Syrup ferri iodide in $\frac{1}{4}$ to 1 dr. doses is beneficial in some cases.

Hæmatinics. As anæmia is an accompaniment of chronic arthritis, iron and arsenic in form of organic preparations are always indicated

to restore the normal level of the blood. Calcium, viosterol and similar other preparations are also useful, as there is generally a drain of calcium from the body in the disease for the elimination of oxalic acid from the system.

Thiosinamin et sodii salicylas is used as an intramuscular injection in rheumatoid arthritis for relaxing scar tissue. One c.cm. contains approximately 0.06 gm. of thiosinamin and 0.09 gm. of sodii salicylas.

Aurotherapy. It was the similarity between tuberculosis and rheumatoid arthritis which led Forestier (1928) to try the effects of gold salts in the latter disease. He used two synthetic preparations of gold.

1. *Allochrysine* (sodium aurothiopropionol sulphonate) is given as an intramuscular injection. A course begins with 3 injections of 0.05 gm. each at intervals of 5 days and if no reaction occurs, further injections of 0.1 gm. each should be continued weekly until a total amount of 1.5 or 2.0 gm. is given. Such a course takes about 3 months and no more than 2.0 gm. should be given in all and the daily dose should never exceed 0.2 gm. After the first course, the patient should rest for 6 to 8 weeks and then a second course should begin. The treatment is then continued by a series of 10 to 20 weekly injections of 0.1 to 0.05 gm. of the drug for one or two years.

2. *Sanocrysin.* (Sodium aurothiosulphate) is administered intravenously. The initial dose is 0.25 or 0.35 gm. The second dose should never exceed 0.65 to 0.75 gm. and is given 6 days after the first dose. The third and the fourth doses being 0.75 gm. each, the former given on the 12th day and the latter on the 19th day after the initial dose.

The patient should be in bed throughout the treatment. Toxic symptoms such as albuminuria due to damage of the kidneys, various cutaneous and ocular affections may appear in the course of the treatment. Slot and Deville (1934) used other organic gold preparations in acute and sub-acute rheumatism and rheumatoid arthritis cases. The preparations are solganal A, containing about 36.5 per cent. of gold and used as an intravenous injection, solganal B and solganal B oleosum, both are used as intramuscular injections; solganal B oleosum being an organic gold compound in an oily base. The use of an oily suspension increases the degree of tolerance resulting in gradual absorption with an even, prolonged effect. Solganal B oleosum was used in the majority of cases with encouraging results. The initial dose of solganal B is 0.01 or 0.05 gm. and is given every 4th day with an increased dose depending on the individual condition.

With solganal B oleosum, increase may be 0.1, 0.2, 0.3, 0.4, and 0.5 gm. respectively provided no reaction occurs. The average total dose is 2.5 gm. per series of injections but generally is between 1.0 to 1.5 gm. The majority of cases improved though pyrexia and jaundice appeared as complications in a few cases. Glucose was given by mouth to avoid toxic symptoms during and even some time after the treatment. The

cases were simultaneously treated with other anti-rheumatic drugs, colonic irrigation with normal saline and diet therapy.

Opoththerapy. The focal toxins have a deleterious effect on the general endocrine system of the body and are responsible for general dysfunctions of the glands. Of all the endocrines, the thyroid suffers most and this is evidenced by symptoms of hypothyroidism in some cases of chronic arthritis. To remedy this, thyroid extract is given by mouth along with measures to eradicate the septic foci. Iodine and its various preparations are also advocated. There are two obvious ways in which iodine may help the rheumatic patients. It may act indirectly by stimulating a defective thyroid and normalising its secretion both qualitatively and quantitatively. Another opportunity is afforded by the local accumulation of iodine near the inflammatory foci. Suitable conditions are thus provided to better the condition not only through the thyroid but by a direct action in the joints and the inflammatory foci themselves, whilst the storage and slow excretion of the drug ensure a steady uniform action throughout the system.

Histamine therapy. Deszo Deutsch (1931) recorded some results obtained by the use of histamine in muscular rheumatism. Compared with gold salts, the remedy is more natural and the action is clearly understood. In any irritation of the skin—chemical, thermal, electrical or mechanical—a substance is liberated which has been named 'H' by Lewis and Dale and it has a histamine-like action, dilating small vessels and thereby increasing the permeability and accelerating the circulation. Similar effects are obtained by physical therapy with massage, hot air baths, diathermy and other applications. But histamine has more powerful effects and these are more lasting ones—it may persist as long as ten hours after application. There are different methods of administration such as by local application or subcutaneous injection. The local form of treatment is favoured by Deutsch who applies blotting paper impregnated with histamine and attaches the anode of a constant current to this, making the patient hold the negative electrode in his hand. There is rapid reddening and heating of the skin under the pad; soon after, little white blebs appear which coalesce to form a patch of oedema. The patch increases in size even when the application is discontinued and disappears at the end of two hours without leaving any trace.

Another method is to apply histamine as a pomade which is massaged into the skin and then removed with ether. If a more intense reaction is desired, the skin is scarified first. Subcutaneous injection (0.5 mg.) of histamine hydrochloride has given good results. After such injections the face is flushed and a mild headache develops. The pain in the muscles and joints diminishes and subsequently the patient can do active and passive movements with greater ease and less pain. Jacchia advocates this method but holds that there is no effect unless the drug enters the circulation.

Histamine is of value only in the treatment of muscular and articular rheumatism, acute or subacute; it has no effect on tuberculous or syphilitic joints or on gouty or suppurative arthritis. Its effects are not in the nature of protein shock, it does not produce local antibodies, it is not an analgesic or sedative in its reaction except in as much as it improves and accelerates the circulation in the affected parts.

Histamine therapy is best avoided in the presence of marked hypotension or cardiac disease. If it is to be given in these cases, it is best given by ionisation, thus avoiding the slight histamine shock produced by the intradermal route. It appears to alleviate the pain of rheumatism. It will not take the place of salicylates, but it may succeed where they fail.

Surgical treatment. No surgical treatment is indicated in acute arthritis cases. Analgesics, local treatment with resting of joints, if necessary, with splints and other orthopaedic appliances are all that are needed at this stage. It is only in chronic cases and where deformities have appeared, surgical intervention is necessary to correct them and if possible to make them useful to patients so far as locomotion is concerned. Various surgical procedures such as synovectomy, arthrodesis, arthroplasty and other orthopaedic operations are necessary to correct such deformities.

ASCITES. Ascites means presence of free fluid in the peritoneal cavity. The peritoneum has remarkable power of absorption. Fluid substances are conveyed by the blood vessels, while insoluble bodies including micro-organisms are taken up by the endothelial cells lining the peritoneum, particularly on the under surface of the diaphragm. Normally the greater omentum secretes a certain amount of fluid in the peritoneal cavity. This is again absorbed. This secretion and absorption are so evenly balanced that there is just enough fluid to keep the serous surfaces moist and free from friction. In morbid conditions this state of equilibrium is disturbed and the amount of fluid may become excessive and this leads to ascites.

Collection of excess of fluid in the peritoneal cavity may depend on the passage of fluid in increased quantities into the sac, the rate of absorption failing to keep pace with this or completely stopping.

Increased secretion depends on changes in the endothelial cells of the peritoneum brought about by poisons; this process occurs in inflammation and is then spoken of as an exudation; or ascites may result from increased venous or lymphatic pressure—passive or mechanical effusion; the process is spoken of as a transudation. These two processes may overlap; thus passive venous engorgement, by interfering with the vitality of the endothelium, will produce changes analogous to those brought about by poisons.

The causes of ascites are:—(1) Backward pressure from tricuspid regurgitation or any other cause, (2) Chronic peritonitis (a) simple,

(b) dysenteric, (c) tuberculous, (d) malignant, etc. (3) Cirrhosis of the liver. (4) Other morbid conditions of the liver—perihepatitis, syphilis, lardaceous liver, malignant disease, lymphadenoma, etc. (5) Thrombosis of the portal vein. (6) Bright's disease. In addition, rupture of hydatid, ovarian or other cysts may give rise to free fluid in the peritoneal cavity. Rupture of lymphatic vessels or lacteals will cause chylous effusion, resembling true chylous ascites in appearance, but differing from it chemically are the two following forms:—(a) the chyloform or fatty, and (b) the milky non-fatty ascites. In chyloform or fatty (adipose) ascites the fat which is present in large globules is due to degenerative changes in cells suspended in ascitic fluid. In the milky (non-fatty) ascites there are a large number of mononuclear leucocytes which probably give rise, as a result of degeneration, to nucleo-albumin or globulin; this causes to the lactescent appearance of the fluid. No fat can be extracted by ether from the ascitic fluid in this form. Hæmorrhagic ascites is sometimes met with. The causes are:—(1) rupture of ectopic gestation, (2) rupture of the spleen, (3) rupture of aneurysm, (4) new growth, (5) result of previous tapping, and (6) tuberculosis.

Characters of ascitic fluid. The characters vary according to the causes at work. Thus, when there is inflammation of the peritoneum (exudates) the specific gravity and amount of contained protein are higher than when ascites is associated with back pressure (transudates). Serous ascitic fluid is clear, transparent and greenish or faintly yellow in colour. The reaction is alkaline, and the specific gravity under 1012 in mechanical effusions or hydroperitoneum and 1018 or higher in exudations in sub-acute or chronic peritonitis. The amount of solids and proteins varies. In simple effusions due to renal disease there may be only 0.3 per cent. or less of protein, while in inflammation the amount may be 4 per cent. In jaundiced patients the fluid contains bile pigment. The cells seen on microscopical examination vary in different kinds of ascites. In ascites due to mechanical causes, *e.g.*, heart disease and hepatic cirrhosis, endothelial cells are predominant, in tuberculous peritonitis small lymphocytes are present in high percentage and this is also found in the ascites due to intra-abdominal syphilis and malignant disease. In inflammatory conditions polymorphonuclear cells predominate in the ascitic fluid.

The ascitic fluid at the first tapping is usually sterile but as a result of paracentesis infection may occur. The colon bacillus and the tubercle bacillus are sometimes present

There may be a positive pressure inside the abdomen. Pitres found that it may vary between 30 and 6 mm. of mercury (average 12 mm.). This positive intra-abdominal pressure varies with respiration and is associated with increased pressure in the portal vein and low arterial pressure (Gilbert and Weil).

TREATMENT. The underlying cause should be looked for and treated adequately. The palliative treatment consists of measures towards removal of fluid. *Paracentesis.* It is indicated in the presence of any distress and pressure symptoms. *Diuretics.* Their use should not be persisted in when there are indications that paracentesis is necessary. They act well after paracentesis, which relieves the pressure on the renal veins. Good results have been obtained by injections of salyrgan intramuscularly or intravenously in conjunction with ammonium chloride and a salt-free diet.

Surgical measures (Talma Morrison's operation) have been advocated.

ASTHMA. The term 'asthma' derived from a Greek word meaning 'panting' is applied to a type of paroxysmal dyspnoea associated with prolonged expiration and wheezing respiration.

For purposes of treatment it can be classified into two main groups:—

1. *Secondary to infection or disease of the respiratory tract, i.e., nose, throat, trachea and bronchi.* This group includes a majority of cases amongst Indians.

(a) *Nasal reflex.* In this type the total leucocyte count is more or less normal, there is no eosinophilia, and the Arneth count is normal. The cases that respond favourably to aspirin will be benefited by a nasal operation. In such cases an examination of the nose and paranasal sinuses is carried out.

(b) *The cases in which the attacks are due to pressure of the enlarged hilus glands on the vagus nerve.* In such cases there is no increase in the number of total leucocytes or eosinophiles and the Arneth count is more or less normal. The X-ray picture will show enlarged hilus glands.

(c) *Bronchial cases due to infection in the bronchi.* These cases are subdivided into two groups. (i) Gram-negative bacilli cases. Total leucocyte count is high, there is marked eosinophilia and a shift in the Arneth count to the left. A smear of the sputum shows Gram-negative bacilli resembling pneumobacilli. The sputum is cultured and non-motile bacilli belonging to the Eberthella group are isolated. A vaccine is made from these organisms and is used for treatment. (ii) Bronchial cases in which the infection is due to the ordinary organisms causing bronchitis. Total leucocyte count may be high or low, there is no eosinophilia, but there is a marked shift in the Arneth count to the left. In such cases cultures from the sputum are made to get the strains for preparations of an autovaccine. An X-ray examination of the chest and a Von Pirquet's test should be done to exclude tuberculosis.

2. *The allergic cases.* These cases may be divided into three groups:

(a) *Local allergy of the mucous membrane to foreign substances such as dust.* These cases may be congenital or may be acquired as a result of the previous disease of the bronchi. The congenital cases are rare amongst Indians but common amongst Europeans. In India the condition is more often acquired as the result of previous bronchitis or may develop during the asthmatic state. This type is common amongst the jute workers and textile workers and in certain occupations where there is a large amount of dust in the atmosphere. The dermal tests are of value in diagnosing these cases. These can be treated with extract made from the dust; the treatment is carried out by giving graduated doses of the sterile dust extract.

(b) *Hereditary allergy, i.e., susceptibility to animal emanations, etc.* These cases are rare in India. Dermal tests are of value in the diagnosis of such cases. The treatment consists in avoiding the excitant or in desensitising against it.

(c) *Allergy due to internal toxins.* This can be subdivided into two groups, firstly it may be due to some rare or common food or foods. Dermal tests are useful in the diagnosis of these cases, but this type is rare amongst Indians. Secondly, allergic symptoms secondary to bowel diseases occur; these are much more common amongst Indians. The dermal tests are of no value, as either all the tests are negative or all the foods tested give positive results. These cases have to be treated along the lines laid down for treatment of allergy of alimentary origin.

There will be a number of cases which do not belong purely to one of the two groups—bronchial and allergic—but which are a mixture of the two types. For example if a case starts as a bronchial case but later the mucous membrane of the bronchi becomes hypersensitive to dust, etc., as a result of the disease, it will present a mixed blood picture, high leucocytosis, high eosinophiles and a marked shift in the Arneth count to the left. Similarly, in a case which starts as an abnormal sensitiveness of the mucous membrane to external stimuli the repeated turgescence of the membrane and its lowered resistance leads to bacterial infection of the mucous membrane and the bronchial glands may become enlarged due to this infection.

DIAGNOSIS. In an acute attack a detailed examination of the patient is hardly needed to make a diagnosis. The characteristic posture and the wheezing respiration are quite typical. The patient sits up with the back hunched, the sternum bulging out and the shoulders raised to the utmost. The skin is usually pale but may be a little cyanotic in patients with emphysema. The mouth is usually kept open to facilitate breathing. All the accessory muscles of respiration are straining to the utmost, and the sterno-mastoids are very prominent and tense. With all these violent efforts at breathing there is only slight movement in the chest. Percussion gives a hyper-resonant note and the area of cardiac dullness is much diminished. On auscultation, the

noisy râles and ronchi drown the respiratory murmur. The expiration is much prolonged and the inspiration is comparatively shortened

Clinically an asthmatic attack may simulate an attack of dyspnoea of cardiac and renal origin. The consideration of a few points will usually make the diagnosis clear. (1) In asthma the time of onset is usually in the early hours of the morning and the attacks are not associated with any physical effort. Cardiac dyspnoea is intimately associated with muscular effort and renal dyspnoea is often a pre-uræmic condition. (2) Difficulty in breathing of asthmatics is expiratory in type, while in cases of cardiac dyspnoea it is mostly inspiratory. (3) Asthmatics have usually got a low blood pressure, while in cases of cardiac and renal dyspnoea the blood pressure is high and there are evidences of heart disease and arteriosclerosis. (4) In renal and some cardiac cases the urine will contain albumin. There are some other conditions to be differentiated from asthma such as retropharyngeal abscess, pulmonary new growths, pathological states of the pleura, foreign body in the lung, aneurism, etc., but these offer no difficulty in diagnosis. In patients of advanced age the low type of pneumonia has to be specially kept in mind.

The personal and family history together with the results of the blood examination will usually enable a case of asthma to be classified into one of these two main groups. An examination of the nose and paranasal sinuses, a skiagram of the chest, Von Pirquet's test and sputum analysis will confirm the diagnosis in the cases in which the attacks are secondary to infection of the respiratory tract. The dermal tests and examination of the stool will help in the diagnosis of the allergic cases.

A history of the case is taken and the following points are carefully elicited. (a) A history of inheritance. This is commonly found in the allergic cases and rarely in the bronchial cases. (b) The pre-asthmatic state. A history of having suffered previously from pneumonia, chronic bronchitis or pleurisy is very suggestive of the bronchial type, while a history of a previous attack of dysentery or of urticaria is rather suggestive of the allergic type. (c) Age of onset, the seasonal variation of the disease and the association of the attacks with a certain place or food eaten are important points. A history of the disease starting after thirty years of age and the attacks coming on during the winter or rainy seasons or being worse at these seasons is characteristic of bronchial cases. In these cases there is no association of the attack with any place or food. The allergic cases usually start early in life, have no seasonal variation and the attacks may show an association with some place or food.

Examination of the blood. Total and differential count of leucocytes are done and the total number of eosinophiles per cubic millimetre of blood is calculated. An Arnetz count is done along with the differential count.

The total number of leucocytes is not of much value owing to various diseases in the tropics, such as malaria and kala-azar, lowering the count. A high count is suggestive of sepsis and is found in bronchial cases, but when the high count is due to an increase in the number of eosinophiles it is found in the allergic and the Gram-negative bacilli cases.

The number of eosinophiles. Sometimes the results are difficult to interpret owing to other causes depressing the bone-marrow such as kala-azar or malaria. A point to realise is that the results expressed as percentages of eosinophiles are not of much value, because a 5 per cent. eosinophilia with a total count of 5,000 leucocytes only means 250 eosinophiles per c.mm., with a count of 10,000 there are 500 eosinophiles per c.mm., and with a count of 20,000 there are 1,000. It is better to express the results in terms of total eosinophiles per cubic millimetre of the blood. Roughly an eosinophile count of over 1,000 per cubic millimetre is suggestive of allergy, but is also seen in the Gram-negative bacilli type.

The Arneth count, which is a count of the polymorphonuclear cells according to their maturity, is of great diagnostic value. The young forms have one-lobed nuclei, and the number of the lobes increases with increasing age of the cells. In bronchial cases where sepsis is present there is an increased demand on the bone-marrow so that young forms are thrown into circulation at a greater speed than normally. The result of this enhanced supply is that when an Arneth count is made the number of cells with one or two-lobed nuclei is found to be greater than normal. This is spoken of as a shift to the left in the Arneth count. The Arneth index, which is the sum of the cells with one and two-lobed nuclei and half the cells with three-lobed nuclei naturally rises with this left-handed shift in the count. An Arneth index above 70 is suggestive of bronchial cases. In the allergic cases there is no sepsis and hence no demand on the bone-marrow for the increased production of the polymorphonuclear cells so that the Arneth count and the Arneth index are more or less normal in these cases. An Arneth index below 70 is suggestive of allergic cases. It is to be noted that in allergic cases with leucocytosis, although the bone-marrow is active, there is no left-handed shift in the Arneth count, because the increase in the number of the leucocytes is due to an increase in the number of eosinophiles and not of the polymorphonuclear cells.

It can be concluded that the bronchial cases usually have an Arneth index above 70 and an eosinophile count below 1,000 and the mixed bronchial and allergic cases have an Arneth index above 70 with usually an eosinophile count of above 1,000. The Gram-negative bacilli cases usually have an Arneth index above 70 with an eosinophile count of above 1,000, while in the allergic cases the Arneth count is almost always below 70 and this is usually associated with an eosinophilia of

above 1,000, but the eosinophile count may be low in some cases when the total count is low.

Analysis of the sputum. A smear made from the purulent portion of the sputum shows the common micro-organisms—pneumococci, streptococci and micrococcus catarrhalis. In about one-fifth of cases in addition to these micro-organisms Gram-negative bacilli resembling *Klebsiella pneumoniae* (Friedlander) are found. Special significance has been attached to the presence of these bacilli in the sputum. Knott and Oriel (1930) obtained a histamine-like effect with extracts of various asthmatic sputa. Referring back to the bacteriology of these particular sputa, they found that many showed numerous Gram-negative bacilli in the bronchial plugs. The broth culture of these bacilli cause a histamine-like effect similar to that obtained from the sputum. They think that the histamine-like substance demonstrable in the plugs has arisen as a result of the growth of these bacilli within the small bronchial tubes. Oriel (1932) considers that the local production of histamine in the bronchi in addition to causing contraction of the plain muscle surrounding the bronchi, would also tend to increase the permeability of the epithelium lining the bronchioles and facilitate the entrance of foreign proteins and possibly bacteria. The Gram-negative bacilli cases constitute a clinical group characterised by a high blood eosinophilia and the presence of pleomorphic Gram-negative bacilli in smears and cultures of the sputum. The benefit derived in these cases from vaccines made from these bacilli is the same as in the other bronchial cases.

The presence or absence of eosinophiles in the sputum is not of any diagnostic value.

Therapeutic test. During the attack of asthma, the effects of atropine, aspirin and adrenalin are tried in turn, beginning with the atropine, then aspirin and finally adrenalin. In some severe cases none of these three drugs gives any relief to the patient and we have to give morphine-atropine injection. *Atropine*—a subcutaneous injection of 1/150th gr. of atropine sulphate is given at the onset of the attack. Atropine paralyses the vagal nerve-endings in the bronchi and if the attack is due to broncho-constriction due to reflex stimulation of the vagus the injection will relieve the patient. On the other hand, if the attack is due to direct chemical stimulation of the bronchial muscles it will have no effect on the attack.

Aspirin is given in form of an A. P. C. powder (aspirin 5 gr., phenacetin 3 gr. and caffeine citrate 5 gr.). In the bronchial cases it is a very effective drug and relieves the spasms. In cases where the broncho-constriction is due to direct chemical stimulation, i.e., in the allergic cases, the drug has no effect.

An injection of 0.3 to 0.5 c. cm. of adrenalin hydrochloride (1 in 1,000 solution) is given subcutaneously at the onset of the disease.

The allergic cases are benefited by this injection more than the bronchial cases. Adrenalin has no action on the vagus nerve-endings and will act best when the broncho-spasm is due to direct chemical stimulation.

The diagnosis can then be further confirmed. In the cases due to infection in the respiratory tract the nose and the paranasal sinuses are examined. A Von Pirquet's test is done and a skiagram of the chest is taken. The Von Pirquet's test and an X-ray picture are of value in excluding tuberculous lesions of the lung.

The diagnosis in the allergic cases is confirmed by the examination of the stools and the results of the dermal tests.

Examination of the stools. The allergic cases secondary to gut infections may show *Entamoeba histolytica* infection or the presence of the ova of various helminths. The McConkey neutral-red lactose agar plate may show various non-lactose-fermenting bacilli causing post-dysenteric lesions. These findings are rather important from the treatment point of view. These cases of gut origin are treated with emetine, carbon tetrachloride or an autogenous vaccine prepared from the pathogenic organisms isolated from the stools depending on whether the case is one of amoebic infection, hookworm disease or some post-dysenteric lesions of the gut. In the ordinary way these infections do not cause asthma, but there may be a lowering of the defence mechanism of the liver caused by amoebic or some other form of hepatitis.

The dermal tests are of value in the following cases. (1) When the respiratory mucous membrane is locally sensitive to dust, such as in case of jute workers. (2) In cases who are sensitive to animal emanations. (3) In cases in whom a single rare food is responsible for the attacks.

In the allergic cases dependent on some pathological condition of the gut the dermal tests are no good; the tests are either negative in all the cases or all the foods tested give a positive result. The dermal tests should be done only when the history is suggestive of some animal emanation or some particular food being responsible for the attacks.

TREATMENT. This can be considered under two general headings—the management of the asthmatic attack and the treatment of the asthmatic state.

Management of the asthmatic attack. Medicinal treatment. Previous experience of the patient is usually sufficient to tell which of the drugs, atropine, A. P. C. powder or adrenalin, will prove most beneficial to him. When none of these acts a morphine-atropine injection is to be given.

A subcutaneous injection of 1/150th gr. of atropine is given at the onset of the attack. The patient will be relieved if the attack is due to a broncho-constriction brought about by reflex stimulation of the vagus. The drug is contra-indicated in the presence of emphysema. The dryness it produces is a drawback, because thereby it may increase the cough.

A powder consisting of aspirin, phenacetin and caffeine citrate effectively controls the attacks in the bronchial cases. Aspirin sensitivity is, however, to be kept in mind, because this is the commonest form of drug hypersensitiveness to be seen amongst the allergics.

Adrenalin must always be given intramuscularly. It is of no value when given orally, because it is inactivated by gastric and intestinal secretions. An intracutaneous injection of adrenalin is very painful and the effects of its intravenous injection are very unpleasant. Violent headaches, severe vertigo, palpitation, tremor, breathlessness, precordial pain, nausea and vomiting may result if adrenalin enters into a vein. Adrenalin acts by stimulating the sympathetic nervous system and by shrinking the oedematous mucous membrane lining the bronchioles. The smallest effective dose of the drug should always be employed so that relief is obtained without unpleasant by-effects. The earlier the injection is given the smaller will be the dose required. Three to six minims given at the beginning of an attack will usually control the symptoms whereas large doses late in the paroxysm may fail to do so. For this reason many workers advocate teaching the patient the use of a hypodermic syringe so that he can get the benefit of small doses of the drug at the outset of the attack. It is quite safe to do this, because adrenalin is not a habit-forming drug. With frequent administrations an increase in dosage may be needed, as there is a rapidly acquired tolerance to the drug.

Hurst advocates a continuous method of adrenalin injection in *status asthmaticus* where severe asthma has continued uninterruptedly for days or weeks. The needle of the syringe is kept constantly in position and after the initial injection of a dose that is known not to cause unpleasant symptoms, one or more minims are injected every fifteen, thirty, or sixty seconds according to the patient's reactions, the rate being varied until it is found how frequently the injection can be made without any unpleasant symptoms arising. The injections are carried on for half an hour or so if necessary. Ephedrine, a drug prepared from the stems of *Ephedra vulgaris*, has the same effect of stimulating the sympathetic nerve-endings as adrenalin. Ephedrine can be used in place of adrenalin, but it is of use only in mild cases or as a preventive. Ephedrine can be given orally and its effect is prolonged for several hours, though it is not so prompt in action as adrenalin. The sulphate and hydrochloride of ephedrine are available. Dosage for an adult is 3/8 to 3/4 gr., 1/8th gr. for a child under one year of age and 1/4th gr. above one year. Ephedrine may also be given subcutaneously, but this has got no advantage over a subcutaneous injection of adrenalin.

Besides ephedrine, pseudo-ephedrine, another alkaloid obtained from ephedra has been used in these conditions. Chopra and his co-workers (1931) state that the broncho-dilator action of the drug appears to be quite as marked as that of ephedrine without the unpleasant side effects of the latter. The alkaloid should be given in doses of 1/2 gr.;

the effect is noticed within fifteen minutes to half an hour of oral administration. A similar dose taken when the premonitions of an attack are felt, generally stops the paroxysm, and it can therefore be used in all cases where ephedrine is employed.

Morphine is a valuable drug for controlling a severe attack when other measures have failed. It should be used only as a last resort in asthma and should be combined with atropine.

A mixture containing potassium iodide and antispasmodics such as lobelia, stramonium, belladonna and kuth is given during and between attacks. Iodides liquefy the bronchial secretions and make the cough more effective.

General treatment of the attack. A good purgative is given in the beginning and then the bowels are kept open by mild saline laxatives. A loaded sluggish bowel tends to retard recovery, hence it is essential that the patient should not be allowed to remain constipated. In patients with a distended stomach an emetic affords great relief. It relieves the stomach distension and loosens the mucus in the lungs. In children emesis may be induced by tickling the throat. Taking a large dose of sodium bicarbonate or ordinary salt in a glass of water also serves the same purpose. Large doses of vinum ipecacuanha or a hypodermic injection of 1/20 to 1/10 gr. apomorphine hydrochloride may have to be used.

No food should be given for twenty-four hours, plenty of water and hot weak tea should be allowed in this period. In cases of exhaustion stimulants are indicated. With the subsidence of symptoms a simple, soft, and easily digested diet should be allowed. The patient should be allowed to choose those simple foods which he has by experience found to be harmless.

Treatment of asthmatic state. Treatment between the attacks has for the most part been indicated while describing the types of asthma. A few additional remarks are however needed. The patient should be thoroughly overhauled and any infective focus found or any endocrine dysfunction discerned should be adequately treated. The results with endocrine therapy are encouraging only in a limited number of cases, still it is worth trying wherever indicated. The suprarenals, the thyroid and the sex glands are most commonly involved. The dessicated glands may be given by mouth. Injections of arsenical preparations such as soamine are used to tone up the endocrine system.

The allergic cases, in which no definite offending cause is found, may be treated by means of non-specific desensitisation as described under treatment of allergy.

(8) Gastric distension commonly precipitates an attack, so that late and heavy meals should be avoided. To avoid flatulent dyspepsia the food should be thoroughly masticated and any errors in gastric secretion should be corrected. For hypochlorhydria administration of hydro-

chloric acid by mouth may suffice or a daily gastric lavage may have to be done to treat the underlying chronic gastritis.

In cases of hypochlorhydria Bray recommends $\frac{1}{2}$ to 2 dr. of dilute hydrochloric acid in a cup of orange or lemon juice three times a day before or with meals. For children he recommends pepsin 1 gr., dilute hydrochloric acid 30 min., pure dextrose 30 gr., syrup of senna 10 min., in two ounces of chloroform water. Two teaspoonfuls of this mixture are to be given in orange or lemon juice three times a day. Constipation should at the same time be well guarded against.

Potassium iodide mixture along with antispasmodics such as lobelia, stramonium, belladonna, tincture ephedra and kuth is regularly given for some time. It is usual to add arsenical solution to the mixture. Arsenic is said to have a favourable influence on bronchitis and asthma when given over long periods. Bray recommends the following mixture for children:—Potassium iodide 2 gr., arsenical solution 1 min., tincture of stramonium 3 min., with 10 min. of syrup. Patients suffering from irritating nocturnal cough derive benefit from a dose of linctus at bedtime; linctus paregoric may be used or the following may be given: tinct. of stramonium 15 min., syrup pruni verg. 1 dr., and syrup codeine phosphate 1 dr.

A passing reference may here be made to asthma powders, cigarettes, sprays, etc. Stramonium leaf is the main constituent of most asthma powders and cigarettes, it is mixed with saltpetre to aid its combustion. In some patients these act as preventives and help to cut short mild attacks, but to many patients the fumes are annoying, irritate the mucous membranes of eyes, nose, and throat and induce severe cough. Most sprays contain either atropine in some form, cocaine or adrenaline, some chronic asthmatics get transitory relief from these sprays. Powders, cigarettes and sprays have no place in the treatment of acute attacks.

Breathing exercises are essential, specially to remedy any deformity of the chest which might have resulted from the repeated attacks. The patient is in the habit of using the upper part of his chest for respiration and the exercises are designed to teach him to use the lower part of his chest and the diaphragm.

BATHS. See page 118.

BED SORES. See page 1499.

BERI-BERI. See page 1018.

BLACKWATER FEVER. (See page 574). *Investigation*:—(1) Repeated examinations of thick and thin films of blood for malarial parasites and culture if possible. (2) Examination of urine for hæmoglobin and methæmoglobin spectroscopically and chemically; also for urobilin, albumin and casts. (3) Van den Bergh test of serum. (4) Determination of the cell volume and size of the red blood cells. (5) Fragility of red blood cells. (6) Blood count.

When it is noted that the patient is suffering from oxyhæmoglobinuria without cyanosis a diagnosis of blackwater fever is probable. When there is methæmoglobinuria with cyanosis, plasmoguin toxicity is suggested.

TREATMENT. Careful nursing and administration of plenty of fluids are important. Urine is measured and its character noted each time.

(1) Pituitrin and adrenalin injections, repeated if necessary after 12 hours in collapsed and exhausted cases. (2) Calcium lactate 10 gr. and parathyroid extract 1/10 gr. twice daily. (3) Alkaline mixture every 4 hours. (4) Intravenous glucose and sodium bicarbonate if there is any tendency towards suppression of urine. (5) Blood transfusion if required. (6) Atebrin, a full course if malarial parasites are found. During convalescence, treat the anæmia with iron, arsenic and in the macrocytic type with liver preparations. For further detail see page 574.

BLOOD IN HEALTH AND DISEASE.

Composition of blood. Blood contains plasma and cellular elements. Plasma includes serum and fibrinogen which yields fibrin on clotting. Serum contains serum albumin, serum globulin, glucose extractions, calcium salts, sodium and potassium chlorides, carbonates, phosphates, etc. The cellular elements consist of red cells, white cells (fibrin ferment), blood platelets, hæmoconin. The red cells contain oxyhæmoglobin, lecithin, and salts. (Webster and Koch).

The blood volume. In adults the blood volume is 5 to 5½ litres (10 to 11 pints) or one-fifteenth to one-thirteenth of the body weight. Blood volume is increased in pregnancy just before term, hypertensive and in anasarca accompanying cardiac insufficiency. Decreased total volume occurs when there is excessive loss of fluid as in polyuria, diarrhoea, profuse sweating, etc. A loss of 350 c.cm. of blood in an adult has no appreciable effect on the blood pressure; with the next 350 c.cm. loss, a slight but definite depressor effect results; if the loss reaches 1,750 c.cm. the fall of blood pressure is very marked.

Viscosity of the blood. The viscosity of blood is compared with that of water on the principle that fluids at equal temperature and pressure passing through tubes of equal calibre vary in their rate of flow in direct proportion to their internal friction. The apparatus of Hess is generally used for determining viscosity of blood. Normal viscosity of blood varies from 4.3 to 5.3 for males and 3.9 to 4.9 for females, and of serum from 1.7 to 2 for both sexes.

* The viscosity of blood depends on : (1) the cell volume; an increased cell volume increases the viscosity and white cells are more viscid than red cells; (2) the hæmoglobin content; an increased hæmoglobin content causes an increase in viscosity; cyanosis increases the viscosity

and venous blood is more viscid than arterial; (3) the protein content; dehydration by increasing the protein content increases viscosity. General oedema or anæmia which lowers the protein content also lowers the viscosity of blood. In profuse perspiration in health, the viscosity of blood is considerably increased. The viscosity is also increased in severe types of pneumonia, in diarrhœas and in some protracted types of vomiting. With an increase of cell content per unit volume of blood, the viscosity of blood is increased and a greater load is thrown on the heart. The cell concentration and viscosity give optimum efficiency with the minimal heart work when the cell volume lies between 40 and 50 per cent. of the blood volume.

PHYSICAL AND CHEMICAL CHARACTER. (Values are in mg. per 100 c.cm. whole blood unless otherwise noted.)

Specific gravity	...	1,056 to 1,066 (1.026 to 1.032 for serum, 1,060 for corpuscles).
Reaction	...	pH 7.3 to 7.4
Total solids	...	19 to 23 per cent.
Hæmoglobin	...	14 per cent. (by weight).
Serum albumin	...	4.6 to 5.3 per cent.
Serum globulin	...	1.8 to 2.7 per cent.
Fibrin	...	0.2 per cent.
Total nitrogen	...	2.6 to 3.5 per cent. (plasma, 0.6 to 1.1)
Nonprotein nitrogen	...	25 to 35 (plasma, 20 to 35)
Urea	...	20 to 40
Urea nitrogen	...	12 to 15 (plasma, 10 to 23)
Amino-acid nitrogen	...	6 to 8 (plasma, 4 to 7)
Ammonia nitrogen	...	about 0.1
Uric acid (Folin-Wu method)	...	2 to 3 (extremes, 1 to 3.5) (plasma, 2.5 to 5)
Creatinine	...	1 to 2 (plasma, 0.8 to 1.5)
Creatine	...	3 to 5 (plasma, 0 to 3.8)
Sugar (Folin-Wu method)	...	90 to 120 (same for plasma)
Chlorides (as NaCl)	...	450 to 500 (plasma, 570 to 620)
Fat (Bloor's fat method)	...	about 600
Cholesterol (Bloor's method)	...	140 to 170
Lecithin (Bloor's method)	...	30 (plasma, 22)
Acetone bodies	...	0 to 4
Bicarbonate (plasma)	...	53 to 77 vol. per cent. CO ₂
Oxygen capacity	...	18.5 vol. per cent.
CO ₂ tension (arterial)	...	about 40 mm. Hg.
Calcium	...	5.3 to 6.8 (serum or plasma, 9.0 to 11.0)
Magnesium	...	2.3 to 4 (serum or plasma, 1.6 to 3.5)
Sodium	...	170 to 225 (serum or plasma, 336)
Potassium	...	153 to 240 (serum or plasma, 18 to 21)
Phosphorus, total (as H ₃ PO ₄)	...	about 120 (plasma 35 to 40)
Phosphates, inorganic (as P)	...	(serum) 3.2 to 4.3
Sulphates (as S)	...	0.5 to 1.0 "
Bilirubin	...	0.1 to 0.25

NORMAL CELLS OF THE BLOOD

WHITE BLOOD CELLS.

Total number	5,500 to 8,500 per c.cm.
Polymorphonuclear				
Neutrophile	60 to 75	per cent.
Eosinophile	...		1 to 7	„ „
Basophile	0 to 1	„ „
Mononuclear				
Monocytes	2 to 7	„ „
Lymphocytes	...		25 to 30	„ „

(1) *The polymorphonuclear leucocyte.* This cell is about 10μ in diameter and has an irregularly shaped and lobed nucleus. The cytoplasm stains a very faint blue and is thickly dusted with fine, faintly pink-staining neutrophile granules.

(2) *The small lymphocyte.* This cell is about the same diameter as the red corpuscle. It has a rounded or spherical nucleus which stains most intense purple and occupies almost the entire cell, leaving around it only a narrow rim of rather deeply blue-staining cytoplasm.

(3) *The large lymphocyte.* This resembles the small lymphocyte but is larger. It has a round or sometimes oval nucleus which stains very deeply and a considerable volume of rather pale blue-staining cytoplasm which frequently shows a few purple-staining granules. The largest of these cells which are up to 12μ in diameter are equal to the polymorphonuclears. This point serves to differentiate them from monocytes which are larger.

(4) *The large hyaline mononuclear leucocyte.* The cell has a diameter of about 14μ and is about one and a half or twice the size of the small lymphocyte. The nucleus is large, oval, eccentric in position in the cell and much looser than the nucleus of the lymphocyte. The nucleus stains much less intensely than does the nucleus of the lymphocyte, and it is indented, notched or partly bilobed. The volume of cytoplasm is considerable and often contains a few scanty azure pink-staining granules.

(5) *The coarsely granular eosinophile leucocyte.* It is about 12μ in diameter, and the nucleus is bilobed, or very occasionally trilobed. Frequently the nucleus consists of two more or less spherical masses of chromatin connected together by a thin strand of chromatin. The cytoplasm of the cell is full of large deeply brick-red-staining granules.

(6) *The transitional mononuclear leucocyte.* The cell resembles the large hyaline mononuclear leucocyte but the nucleus is more indented and not unlike that of the polymorphonuclear leucocyte. The nucleus is horse-shoe-shaped and takes a washed-out violet shade of less intensity than that of the large hyaline mononuclear. For practical purposes the transitional leucocyte may be included with the large hyaline mononuclear leucocyte.

(7) *The finely granular basophile leucocyte.* This is a very rare type of cell. It has a frayed out, bilobed or trilobed nucleus and its cytoplasm is dusted with very small fine granules which take a blue stain.

(8) *The mast cell.* This is coarsely granular basophile cell. It is about the size of a polymorphonuclear leucocyte, and has a bilobed, sometimes trilobed, nucleus. Its cytoplasm contains numerous large granules which stain a deep blue to black colour.

Leucocyte count. Capillary blood from the fingers is generally made use of in the total count of white blood cells. A large drop of blood is required for the purpose. The blood is sucked into the pipette up to the mark 0.5 and the same is diluted with W.B.C. fluid (glacial, acetic acid 38 min., mercuric chloride 1.5 gr., and water to 4 oz.) up to the mark 101. The pipette containing the fluid is shaken well. The Thoma-Zeiss type of counting chamber is used which has a rounded disc on which the ruled lines are cut. This surface is exactly $1/10$ mm. below the general surface and is surrounded by a deep channel. The blood drop should be put over it so as just to cover the ruled area only and it should not flow into the channel around. For a leucocyte count the whole central ruled area containing 1 sq. mm. is used. After placing the drop of blood on the counting chamber, one minute should be allowed to elapse for the cells to settle. All the cells contained in the 16 squares should be counted. The corpuscles touching the upper and left side lines of the squares should be counted while those touching the lower and right sides should not come in the count. Multiply the total of the cells by 312. Repeat the count and take the average of both counts. This is the number of cells per cubic millimeter. The new type of counting chamber with Neubauer ruling has got a distinct advantage over the Thoma-Zeiss type. There is less chance of overflow. This type facilitates the counting of four squares in one preparation. The total count of the cells in the four squares multiplied by 50 gives the number of leucocytes per cubic millimeter.

Oxalated venous blood has a decided advantage where the examination is not done at the bedside, and the blood has to be sent to a distant place. The bottle should be well shaken before counting. The pipette is most easily filled from a large drop put on a glass slide.

Differential count of white blood cells. A small drop of blood from a punctured finger is placed near one end of a glass slide and with another slide or some other spreader it is spread evenly over the glass slide. The smear should not be very thin. *Stains used.* (1) Eosin and hæmatoxylin. The slide is immersed in the vial containing the alcoholic solution of eosin for one to two minutes; this is thoroughly washed with water. The slide is then immersed in the other vial containing hæmatoxylin, for three to five minutes. It is again washed with water and then dried. (2) 'Wrights' or Leishman's stain. About 10 to 15 drops of the stain are put over the glass slide

and kept for two minutes. The stain is then diluted by adding distilled water and is left for 3 to 5 minutes. The whole is then washed off by flooding with water and then dried. The differential count is done under an oil-immersion lens of the microscope, 200 white cells being counted and recorded by a tally system. The percentage of each variety is then calculated.

LEUCOCYTOSIS. Any increase in the leucocyte count to over 10,000 per c.mm. is considered a leucocytosis whether such an increase is due to a physiological or a pathological cause.

I. *Physiologic leucocytosis.* (a) In the new-born the average count is 20,000 per c.mm. and as many as 25,000 per c.mm. are recorded. During the first and second days of life the count falls but again rises by the end of the first week to 10,000. (b) In later weeks of pregnancy and during labour the count rises to over 30,000 per c.mm. (c) After exercise, convulsions or severe massage to about 12,000 per c. mm. (d) Digestive or alimentary leucocytosis. *Hæmoclastic test.* If the proteopexic function of the liver is impaired, a protein meal will be followed by a reduction in the white cell count instead of by the usual digestive leucocytosis. (e) From altered circulation. Slight increase in the leucocyte count results from slowing of the blood stream or stasis. Posture, vasomotor influences and changes in temperature slightly alter the count.

II. *Pathological leucocytosis* is characterised by an altered ratio of all the types. Generally the increased count is due to an increase in the neutrophilic granular leucocytes. Such leucocytosis commonly occurs from infection by pyogenic cocci, as in inflammatory conditions, viz., pneumonia, appendicitis, cellulitis, etc. Pertussis is marked by an increased number of lymphocytes.

Leucocytosis is marked after the use of extracts from highly cellular organs, adrenalin, nuclein, turpentine, camphor, antipyrine, phenacetin, digitalis, pyrogallol, salvarsan, and after long continued chloroform narcosis.

Leucocytosis is also marked in uræmia, eclampsia, acidosis, intestinal obstruction, burns, and occasionally rickets. Even toxic food or excess of alcoholic beverages may cause a temporary increase in the leucocytes. Leucocytosis is also the characteristic feature in leukaemia.

Post-hæmorrhagic leucocytosis is more marked when bleeding occurs in a serous sac or into a joint cavity and as many as 20 to 30 thousand per c.mm. are recorded. In neoplastic conditions, leucocytosis is more marked when metastasis in bone-marrow takes place in cases of sarcoma and carcinoma, and as many as over 40,000 per c. mm. have been recorded.

EOSINOPHILIA. I. *Physiological.* In infancy, up to 10 per cent. (in Indians.)

II. *Allergic.* (a) Bronchial asthma, often slight, occasionally as high as 20 per cent of 20,000. (b) Hay fever, up to 10 per cent. during the

period of symptoms. (c) Migraine, inconstant and slight. (d) Urticaria, eczema and with positive tuberculin reaction.

III. *With parasitic infestations.* (Possibly only another manifestation of allergy). (a) Infection with intestinal tænia (not constant), ankylostomes (up to 15 per cent. of 10,000), ascariis, oxyuris, etc. (far less constant) amoebic dysentery (inconstant). (b) In tissues: trichina; (20 per cent. of 20,000 and higher), echinococcus (50 per cent. of normal total count), coccidioidal granuloma (occasionally high, 12 per cent. of 22,000), filaria (less marked, occasionally 15 per cent.) and bilharzia.

IV. *Familial eosinophilia* is high and persisting but rare.

V. *In skin diseases.* Angioneurotic oedema (variable, up to 85 per cent. of 44,000), pemphigus (up to 60 per cent.), Dühring's disease (up to 40 per cent. of 12,000), scabies (5 to 15 per cent.), herpes zoster (occasionally high), psoriasis, urticaria, eczema (less marked).

VI. *In diseases of the hæmopoietic system.* Myelocytic leukaemia (1 to 5 per cent. of high total count), the so-called "eosinophilic leukaemia" (80 per cent. of 100,000). Hodgkin's disease (usually trifling, occasionally as high as 55 per cent. of 25,000).

VII. *With certain infections.* (a) Cholera (4 to 16 per cent. of normal total count, gonorrhoea (inconstant, may be up to 12 per cent.), scarlet fever (5 to 10 per cent. of 20,000), and active tuberculosis. (b) Post febrile, e.g., after pneumonia (up to 13 per cent.), measles, varicella, rheumatic fever and malaria (only slight).

VIII. *In certain diseases of bone.* Sarcoma, metastatic carcinoma, osteomyelitis, rachitis, osteomalacia, osteitis deformans.

IX. *With various neoplasms.* Rare but reported up to 30 per cent.

X. *In endocrine disorders.* Addison's disease (6 to 10 per cent.), ovarian disease (non-suppurative, non-malignant), also reported with menstruation.

XI. *From certain chemicals, etc.* After administration of uncooked liver (up to 50 per cent.), following camphor, pilocarpin, phosphorus, chronic copper sulphate poisoning, etc.

XII. *After irradiation.* Two to three weeks later (up to 20 per cent.).

XIII. *After splenectomy.* After 1 month (up to 15 per cent. for many months).

LYMPHOCYTOSIS. In children from the first two weeks of life up to five years the lymphocyte percentage is 40 to 70. Conditions usually accompanied by lymphocytosis are:—(1) Pertussis. The average mature lymphocytes often constitute 60 or more per cent. The maximum count is about 80 per cent. during the second week of the disease. (2) Infectious mononucleosis. The average lymphocytic count is about 70 to 80 per cent. of the total count. (3) Malta fever. (4) Chronic lymphocytic leukaemia. The lymphocytes usually constitute from 90 to 99 per cent. of the total count. (5) Certain aleukaemic lymphadenoses. (6) Mycosis fungoides with leukaemic blood changes. (7) Certain disorders of the

ductless glands. (8) Certain neoplasms particularly in connection with growths of lymphatic tissues as lymphosarcoma where as much as 90 per cent. of the total count are lymphocytes. (9) Syphilis. (10) Typhoid fever (relative only). (11) Tuberculosis (relative only). (12) Rickets (relative only).

MONOCYTOSIS. This is marked in infectious mononucleosis, tetrachlorethane poisoning, subacute bacterial endocarditis, some forms of septicæmia, Hodgkin's disease, kala-azar, occasionally in typhoid fever, malaria (in some chronic cases during the afebrile intermissions), during the subsidence of the acute stage of acute infections and in rapidly advancing tuberculosis, syphilis (dementia paralytica), and monocytic leukemia.

POLYMORPHONUCLEAR LEUCOCYTOSIS. Leucocytosis due to polymorphonuclear neutrophil increase is usually due to infection by cocci of some variety. Non-infectious tissue lesions may also cause it.

In bacterial infection over 85 per cent. of polymorphonuclears points to pus formation; 90 per cent., to very severe infection. The resistance is good if the total leucocytes are increased proportionally and poor if they are not increased. There should be

15,000 total with 80 per cent. polymorphonuclears.

20,000 total with 85 " "

25,000 total with 90 " "

Pneumococcal infections give very high figures especially in the total counts.

ARNETH COUNT. Polymorphonuclear leucocytes have a life in the blood stream, of about three weeks. When a cell first enters the circulation its nucleus has only one lobe, but the nucleus gradually becomes more segmented, developing five lobes in the oldest cells. In health the proportion of cells respectively with 1-, 2-, 3-, 4-, and 5-lobed nuclei is fairly constant; a variation occurs in microbic infections when more young cells (1 to 2 lobes) are seen.

ARNETH INDEX. Arneth divided the polymorphonuclears under 5 classes according to the number of nuclei or nuclear fragments.

A polymorph with one nucleus belong to class I.

A " " two nuclei " " " II.

A " " three " " " " III.

A " " four " " " " IV.

A " " five or more nuclei belongs to class V.

The sum total of classes I and II is the Arneth index.

The following are the normal figures:—

Class	I	II	III	IV	V	Index.
	5	35	41	17	2	40

If the index is more than 40 the picture is said to be a "drift or shift to the left"; if less than 40, "shift to the right." A shift to the

left takes place in most of the infections. A shift to the right takes place in leprosy, syphilis, etc.

The index or hæmogram proposed by *Schilling* is simpler and has come into vogue recently. In this classification four types are recognised. 1. *Myelocytes* with single round nucleus. 2. *Young metamyelocytes*, which has a plump nucleus. 3. *Older metamyelocytes* with deeply indented nucleus but no true lobulation. 4. *Polymorphonuclears*. In *Schilling's* method each variety of neutrophilic granular cell is counted separately and expressed as a percentage of the total leucocyte count. According to *Schilling* the following is a normal count: Total leucocytes, 6,000 to 8,000; Neutrophilic granular cells 67 per cent. which are divided as follows:—Polymorphonuclears 63 per cent.; old metamyelocytes 4 per cent.; old metamyelocytes, absent; eosinophiles, 3 per cent.; basophiles 1 per cent., lymphocytes 23 per cent.; monocytes 6 per cent. This method advocated by *Schilling* indicates the age of the cells and there is no difficulty in recognising the various types of cells.

LEUCOPENIA. In disease a count below 5,000 is considered a leucopenia and it occurs in the following conditions. (1) Infections, *e.g.*, typhoid and para-typhoid fevers, and briefly after typhoid vaccination, influenza (except at onset), malaria, kala-azar, measles and rubella, small pox (up to fourth day), dengue, pappataci fever and overwhelming infections. (2) Intoxications, *e.g.*, benzol, arsenic, antimony, lead, irradiation with Roentgen ray and radium, early stage of reaction to parenteral foreign protein, inanition. (3) Diseases of the hæmopoietic system, *e.g.*, aplastic Addisonian anæmia, Banti's disease, primary leucopenia (agranulocytic angina), Gaucher's disease and the aleukæmic stage of leukæmia.

ABNORMAL LEUCOCYTES. The *myeloblasts* are the parent cells of the myelocytes, and are characteristic of the blood in spleno-medullary leukaemia. The size of the cell resembles the large lymphocytes with a round nucleus which stains intensely. The nucleus frequently shows three or four nucleoli within it. The cytoplasm is non-granular and intensely basophile. The *neutrophile myelocyte*, the parent cell of the polymorphonuclear leucocyte, is seen in enormous numbers in blood films from cases of spleno-medullary leukaemia, and occasionally in malarial cachexia. The cell is about 15μ to 20μ in diameter and the nucleus is rounded or may be indented or horse-shoe shaped. The cytoplasm contains tiny neutrophile granules staining a faint pink. The *eosinophile myelocyte* is the parent cell of the coarsely granular eosinophile and is met with in spleno-medullary leukaemia. The nucleus is central in position and rounded and the cytoplasm stuffed with large deeply brick-red-staining granules. The *basophile myelocytes* are believed to have been derived from the connective tissues and not from the bone marrow. The cells contain a relatively small round nucleus and the cytoplasm is stuffed with either coarse deeply blue or black staining granules. *Endothelial cells* are derived from the

endothelial lining of the blood capillaries and appear as flattened cells with a flattened nucleus showing a well marked nuclear network. The *irritation cell of Turck* is derived from the spleen and is frequently encountered in cases of malarial cachexia. The cell generally takes a faint stain and the nucleus is round and placed eccentrically. The cells are about the size of large lymphocytes. *Lymphoblasts* are characteristic of the blood in lymphoid leukaemia. The cells are larger than the large lymphocytes and both the nucleus and cytoplasm take a poor stain. In the forms with a single nucleus a spherical chromatin staining dot is often seen in the cytoplasm of the cell and would appear to be a centrosome. Forms are also encountered in which the nucleus consists of two separate lobes which touch one another at one point—the *Rieder's cell*.

RED BLOOD CELLS.

Total number	5,000,000 to 6,000,000
Hæmoglobin percentage 80 to 100
Colour index 0.75 to 1.0

Normal variations of number of red cells in a cubic millimeter of blood (Normocythemia).

At birth. Average, 5,500,000. Total range, 5,000,000 to 7,000,000.

From one month to sixteen years. Average, 4,500,000. Total range 4,000,000 to 6,000,000.

Adult males aged nineteen to thirty years. Average 4,800,000 per cent., of men 4,700,000 to 6,100,000 Total range of men 4,200,000 to 6,400,000.

Adult females aged nineteen to thirty years. Average, 4,800,000. 90 per cent. of females 4,300,000 to 5,300,000. Total range of females, 4,070,000 to 5,550,000.

RED CELL COUNT. Capillary blood from the fingers is used as in a white cell count. The blood is sucked into the pipette up to the mark 0.5 and is diluted with Hayem's R.B.C. fluid (mercury bichloride 5 gr., sodium chloride 9 gr., sodium sulphate 46 gr. and distilled water to 4 oz.) and drawn in up to the mark 101. The pipette containing the diluted blood is shaken well. Before placing a drop on the counting chamber, a few drops from the pipette should be discarded as in the white cell count. The same precaution is taken while placing a drop over the ruled lines on the counting chamber. All the cells in 5 large squares (each including 16 small squares) should be counted. To obtain a total red cell count per cubic millimeter add four zeroes to the total cells counted. This is the number of cells per cubic millimeter.

1. *Hypochromia* (Anchromia) is the main change in hæmorrhagic or chlorotic anæmia. Red cells show less colour in the centre.

2. *Poikilocytosis* occurs in any moderate or severe anæmia.

3. *Anisocytosis* is most marked in hyperchromic, macrocytic anæmias of the pernicious type and less so in other hæmolytic anæmias. It does occur in hypochromic microcytic anæmias due to hæmorrhage

but not until the hypochromia is very marked. The Price-Jones diameter curve is a precise method of recording this observation. The halometric method is a valuable substitute.

4. *Nucleated red cells* occur in anæmias where the immature cells are called out. The very severe chronic anæmias like pernicious may call out the very primitive megaloblast.

5. *Basophilic stippling* with a red cell count from 3 to 5 million is suggestive of lead poisoning, although it is not present in all cases.

6. *Polychromatophilia* is found in any severe anæmia.

MEASUREMENT OF THE SIZE OF RED CELLS. The diameters of cells are measured by ruled lines in the eyepiece of the microscope and the results of 200 cells noted. The results when plotted in a chart are typical for normal blood, secondary or pernicious anæmias. It is a quantitative measure of anisocytosis

Halometric reading. Parallel rays of white light passing through a grating of red blood cells on a glass slide are broken up into the colours of a concentric spectrum. The size and character of this circular spectrum or halo indicate the average cell diameter and the degree of irregularity in size and shape of at least 1,000,000 cells. The smaller the particles the larger the halo and *vice versa*. The whole examination requires less than five minutes.

HÆMOGLOBIN. 1. *Estimation by the paper scale (Tallquist)* A small drop of blood from a finger prick is put on a piece of absorbent paper and the paper is folded so as to blot the drop at once. This gives a layer of blood having a uniform thickness. Compare the colour immediately with the scale given in the book, using daylight coming from over the shoulder. Normal 80 to 100 per cent. The margin of error is 10 to 20 per cent. depending on the experience and skill of the examiner. It is not possible to detect any hyper-hæmoglobinemia by the paper scale.

2. *By hæmoglobiometer of Sahli.* In the Sahli apparatus a standard hæmatin solution is contained in a sealed narrow glass tube. By means of a fine pipette 20 c.mm. of blood are drawn up from a drop on the finger tip and immediately transferred to a small, calibrated tube. Into this tube has previously been placed a small quantity (up to the mark 10) of 1/10 hydrochloric acid. The mixture is allowed to stand for a few minutes until the red hæmoglobin of the blood has been changed by the hydrochloric acid into brown acid hæmatin. Distilled water is added drop by drop until the colour in the open tube is exactly that of the sealed standard tube. With normal blood the two tubes become equal in colour at a dilution of about 100 while in hæmoglobin-poor specimens this point is reached at a lower dilution. The percentage of hæmoglobin may be read directly from the scale on the side of the tube. The standard tube of the Sahli apparatus fades upon prolonged exposure to light and should, therefore, be calibrated frequently.

3. *By Hellige apparatus.* An improvement on the Sahli principle is incorporated in the Hellige apparatus. It consists of colour prisms which are accurately standardised with the colour of blood and are absolutely independent of outward influences. The procedure is the same as with the Sahli Hæmometer. After having filtered the graduated tube to mark 10 with 1/10 hydrochloric acid, 20 c.mm. of blood is taken from the patient and transferred to the measuring tube. The blood is mixed thoroughly with the hydrochloric acid. Water is slowly added after about one minute and constantly shaken until the mixture matches the colour of the standard prism.

Colour index is a term used to express the average hæmoglobin content of the corpuscles of a given blood. It is obtained by dividing the percentage of hæmoglobin by the percentage of red cells (5 millions per c.mm. being taken as 100 per cent.). Thus a blood with 60 per cent. of hæmoglobin and a red count of 2.5 millions (=50 per cent.) has a colour index $\frac{60}{50}=1.2$. In secondary anæmia the colour index is considerably below 1, in pernicious anæmia it is about 1 or over owing to the presence in the blood of many large red cells.

FRAGILITY OF THE RED CORPUSCLES. Red cells can remain for hours in isotonic salt solution without damage, but in distilled water they are quickly hæmolyzed. The fragility of red cells is determined as follows: A drop of blood is added to a series of tubes, each containing 1 c.cm. of different strengths of hypotonic salt solution varying from 0.25 to 0.7 per cent. Each tube is shaken and allowed to stand for two hours at room temperature. If no hæmolysis occurs, the unchanged corpuscles are found at the bottom of the tube, overlaid with colourless solution. If hæmolysis takes place, a transparent red solution results. Normally hæmolysis begins at 0.45 per cent. and is complete at 0.35 per cent. In acholuric jaundice the corpuscles are excessively fragile, and hæmolysis may begin with as high as 0.7 per cent. and be complete at 0.45 per cent. In most other anæmias, the resistance is increased, depending on the severity of the anæmia where hæmolysis may not begin until 0.36 per cent. and complete before 0.24 per cent. After splenectomy also the resistance of the red cells increases.

ABNORMAL RED CELLS. The red corpuscles may vary in shape, in size, and in their staining reactions. They may be distorted in shape—*poikilocytosis*; or be unduly small—from 1μ to 6μ when they are termed *microcytes*; or unduly large 10μ to 18μ when they are termed *macrocytes*. Where marked variation in size of the red corpuscles is present, the condition is termed *anisocytosis*. Regarding its staining reactions, *achromia* is characterised by pallor of the central portion of the stained red cell and in the fresh blood by a vacuolation in the centre of the cell. Immature red cells frequently show *polychromatophilia*, the stained cells taking on a brownish to a dirty blue tint.

Granular basophile stippling may be present in the form of blue-staining fine dots on the pink background of the stained cell, and such basophile stippling is found in many severe anæmias, in the leukæmias, in malarial cachexia and above all in lead poisoning. The punctate basophilia may coexist with polychromatophilia in the same cell. A cell which is very characteristic of benign tertian malarial infections is the *demicune red cell*. This cell stains very faintly. The red blood corpuscles having been derived from a nucleated parent cell, remains of the nuclear apparatus may occasionally be encountered within them. These may take the form of small irregular fragments of chromatin, or *Howell's bodies*. Howell's bodies are small spherical masses of chromatin of varying size in the cytoplasm taking on the violet stain of the chromatin. *Chromatin dust* may also be present in a red corpuscle in the form of single or double tiny red granules, usually seen at the periphery of the cell and in size smaller than Howell's bodies. *Cabot's rings* are loops, and figures of eight, or irregular lines—apparently in the membrane of the red corpuscle—which take a red stain. They are especially well seen in Giemsa-stained films from cases of severe anæmia.

Normoblasts or nucleated red corpuscles are of the same diameter as the non-nucleated red corpuscles and have large round intensely stained nuclei, which nearly fills the cells and the cytoplasm of the normoblast stains pink or not infrequently shows polychromatophilic staining. The parent red cell or *megaloblast* and the normoblast appear in the blood films in cases of severe anæmia. The megaloblast has a diameter of 10μ . with a nucleus which is irregular in shape. The nucleus is poorer in chromatin than that of the normoblast, stains less intensely and has a less distinct outline.

BLOOD PLATELETS. These were first detected by Bizzozero in 1882 as the third formed element of the blood. They are essential to life and play an important rôle in the physiology of blood. Wright holds that they arise from the giant cells or megakaryocytes of the bone marrow, which are large cells about 40 microns in diameter. Schilling and Watson believed that these were derived from erythrocytes. Brown thought that hyperplastic endothelial cells in the bone marrow and mononuclear cells in the marrow, spleen and blood could also give rise to platelets. Others hold that these are formed from leukocytes. Functionally the thrombocytes are essential to the coagulation of the blood, contributing some substance necessary to the process of coagulation.

The average diameter of a platelet is from 2 to 4μ (from $1/5$ th to $1/2$ the diameter of a red cell). They stain well with Wright's or Giemsa's stain. Their specific gravity is less than any of the other formed elements of the blood and they are pure white in color. They are minute, labile and agglutinable; chemically they contain nitrogen, phosphorus,

glycogen, and lipoids of phosphatid character. For practical purposes a count varying from 150,000 to 500,000 cells per c. mm. may be considered as normal for adults and older children. The count is however very sensitive and widely varies.

They decrease after injections of benzol, calcium, antimony, tissue extract, tuberculin, corpus-luteum extract, peptone, and bacterial toxins, and also after a diet poor in either vitamin A or B. They are artificially increased after splenectomy, blood transfusion, subcutaneous injection of blood and protein shock, physical work, inhalation of carbon dioxide and monoxide and small doses of X-rays or radium.

They decrease in eclampsia, uræmia, kala-azar, malaria (just before rigors) in anaphylactic shock, in aplastic anæmia, acute lymphocytic leukaemia, purpura hæmorrhagica, Addisonian anæmia, during the incubation period of the infectious diseases, (influenza, influenzal pneumonia, epidemic meningitis, in measles (during the period of the rash). They are increased in chronic active tuberculosis, polycythemia, sometimes in hæmophilia, chlorosis and chronic myelocytic leukaemia, in acute rheumatic fever during the febrile period, in Hodgkin's disease, in secondary anæmia after hæmorrhage, post-operative and post-parturition periods, some types of Banti's disease. In the hæmorrhagic diathesis when the platelets fall below the level of 35,000 per c.mm. spontaneous bleeding into the tissues or oozing from the mucous membranes occurs.

The average life of a blood platelet is 3 or 4 days after which it is destroyed by the splenic macrophages and the sinus endothelium of the reticulum. The spleen also seems to act as an emergency reservoir for the thrombocytes. After splenectomy the reticulo-endothelial system takes over the function of destroying the platelets. Leucocytes are also described to take a part in the phagocytosis of the platelets.

Methods for increasing the platelets in thrombocytopenic states are splenectomy, blood transfusions, injection of foreign protein and other products such as corpus luteum extract, repeated injections of adrenalin, the use of ultra-violet rays, living in a high altitude and injection of calcium salts, atophan, peptone, etc.

A number of methods of platelet count have been devised none of which is absolutely accurate. The direct technique similar to that used for red cell count has many objections. The most reliable technique consists of mixing the blood immediately with citrated or oxalated cresyl-blue solution and then counting the relative numbers of platelets and red cells on a slide under the microscope. From the total red cell count the number of platelets may be estimated.

Reticulocytes. At birth 30 to 50 per cent. of the red cells in the circulation are reticulated but their number drops during the first week to 1 per cent. at which it remains through life. Their number is increased whenever red cells are being rapidly manufactured.

Reticulocyte counting is a means of estimating the rate of red cell production. A small drop of fresh blood is mixed with two big drops

of cresyl-blue solution. A drop of diluted blood is transferred to a clean glass slide and covered with a clear cover slip. The margin of the cover slip is smeared with paraffin. It is then examined under the microscope with an oil immersion lens. The number of reticulocytes among 1,000 red cells is counted and then the percentage is calculated.

SEDIMENTATION TEST. In blood containing an anticoagulant, the cells settle down leaving a clear plasma. This sedimentation is more rapid in disease than in health. A measurement of its rate is of value in diagnosis and prognosis in various pathological conditions. In women during menstruation and gestation, sedimentation takes place rapidly. It is accelerated in most acute febrile diseases and in exudative tuberculosis. In anæmia, diabetes and nephrosis it is accelerated; in jaundice and hepatic diseases retarded. There is no adequate explanation of this phenomenon. This test is performed by taking blood in 3 per cent. sodium citrate solution or by adding 2 to 3 mgm. of potassium oxalate per c.cm. of blood and allowing it to stand in a Cutler tube.

Normal. Men 2 to 10 mm. and women 2 to 15 mm. in one hour when the blood column is 50 mm. high. Changes occurring in the first thirty minutes are of greatest importance.

If a patient complains of illness and no pathological lesion can be found, a rapid sedimentation rate will indicate the existence of some obscure, serious disease. It is of value in prognosis. Recovery is well under way when the sedimentation rate approaches normal.

Diseases influencing the sedimentation rate. Pelvic cellulitis, advanced suppurative appendicitis, mastoiditis, suppurative sinusitis, empyema of gall bladder, pneumonia, endocarditis, infectious fevers, active tuberculosis, syphilis, malignancy in all but early stages, pregnancy (after third month).

(1). **AGGLUTINATION REACTIONS.** After inoculation or infection, substances which agglutinate the specific type of invading organism are found in the blood serum. A standard bacterial culture or antigen if agglutinated by a high dilution of the serum from a patient indicates infection or inoculation by that organism. A standard serum containing agglutinating powers for only one type of organism may be used to identify that organism.

(2). **BLEEDING TIME.** Duke's method. Make a deep prick in the lobe of the ear, and at intervals of 30 seconds, take up the drops as they exude with a piece of filter paper, care being exercised to avoid touching the skin. Note the time elapsed when clotting occurs. Normally the continuance of bleeding is not more than two or three minutes. A prolonged bleeding time indicates capillary wall defect due to toxins or lack of nutrition. The bleeding time is greatly increased in thrombocytopenia and in chloroform and phosphorus poisoning. In hæmophilia the bleeding time is usually ~~not~~ prolonged.

(3). **COAGULATION TIME.** There are two methods:—(1) By Wright's coagulometer. This consists of several fine capillary tubes into

which blood is drawn at definite intervals and at varying intervals they are blown out. When the blood cannot be blown out it has coagulated. Note the time in each case. The difference of the time indicates the actual coagulation time of the sample of blood. (2) By a long fine capillary tube into which the blood is drawn and the time noted. A little part of the tube is broken at intervals until a fine thread-like substance is produced in the broken part (fibrin-thread). The time of appearance of the thread is the coagulation time. The average time is about 3 to 4 minutes. Age and sex do not influence the rate.

Coagulation time is increased in hæmophilia, kala-azar, certain cases of pernicious anæmia, jaundice, splenic anæmia, leukæmias, urticaria, etc.

(4). **COMPATIBILITY TEST.** A sample of the patient's blood is mixed with an equal quantity of sodium citrate and to this is added one-fifth of its volume of similarly treated blood from the donor. The proportion of the respective bloods is the same as that in the patient after a large transfusion. The addition of the citrate makes any clumping more apparent. A transfusion should never be given if the donor's and patient's blood are incompatible by this test. (For details see page 54).

(5). **PEROXIDASE REACTION.** This is done in order to differentiate leucocytes of marrow origin from those of lymphatic origin. The granules in the leucocytes of marrow origin take a deep blue stain. Granules of polymorphonuclears and eosinophiles, myelocytes and myeloblasts are stained intense blue. The large mononuclears and transitionals show few black granules.

(6). **ICTERUS INDEX.** By comparing the colour of the blood serum or plasma with fixed standards a definite figure is given for the degree of bile pigment concentration. (1) Normal 4 to 7. (2) Latent icterus 7 to 18. (3) Bile in the urine and jaundice at 18 or more. (4) Secondary anæmia 2 to 4. (5) Pernicious anæmia 7 to 20. (6) Pneumonia and septic infections 4 to 15. (Above 10 in fatal cases.) (7) Chronic heart failure 4 to 15. (Above 6 in passive congestion of the liver.) (8) Cholelithiasis 4 to 7. (9) Cholecystitis 7 to 15. (10) Occlusion and cholangitis of the common bile duct 30 to 150. (11) Arsenical hepatitis from treatment of syphilis 10 to 150. Gastric ulcer, rheumatic fever, syphilis, tuberculosis 4 to 7. Duodenal ulcer 7 to 14. Diabetes 7 to 15.

Techniques for collecting blood. **Venepuncture.** The median basilic vein at the elbow is one of choice in venepuncture in general practice for collecting blood. Absolute asepsis of the overlying skin is of extreme importance in the procedure. This is generally effected with absolute alcohol, or with tincture of iodine. It is always well to ask the patient to lie down to avoid the risk of fainting, particularly in nervous patients. The vein is made prominent by applying

a tourniquet above the elbow and asking the patient to open and close the hand alternately. Immersion of the arm in a hot water bath might also hasten the process. In fat subjects the vein is generally palpated before introducing the needle. A clean, sterile and dry record syringe is generally used to withdraw blood from the vein. As soon as the blood is withdrawn the needle may be taken off from the nozzle of the syringe and the blood transferred to the tube. This procedure best applies to adult patients but infants' blood is usually withdrawn from the external jugular vein or the longitudinal sinus (anterior fontanelle). Sometimes capillary blood, in infants, is also used for the purpose.

Blood from the external jugular vein. A clean, sterile and dry glass syringe with a needle 1 to 1½ inches in length is generally used. The child should be wrapped up in a small sheet. One person should hold the shoulders and the body and another should fix the head, hanging over the edge of a table and turned to one side. After proper sterilisation of the skin of the neck, the needle is pushed into the vein, which often dilates and becomes prominent as the child cries, at an angle of 20 degrees to the skin surface. There is little danger of damage to the underlying vital structures during such procedure. The blood is then transferred to a tube as before.

Blood from the longitudinal sinus. In infants with fat necks, the longitudinal sinus may be used for withdrawal of blood as the anterior fontanelle remains usually open up to the age of eighteen months. With the same aseptic precautions as were adopted for puncture of the external jugular vein and the head being shaved beforehand and held in position by a nurse, the needle of the syringe is inserted at the posterior angle of the fontanelle making an angle of 20 degrees to the skin surface and not more than 1/8 inch deep. Puncturing brain substance, though not fatal always, should always be avoided.

Collection of capillary blood. The blood is collected from the lobule of the ear or the finger. The part should not be cold, oedematous or congested. With proper aseptic precautions, an incision or a stab wound is generally made with a sterile fine-pointed lancet on the back of the second or the third finger, a little behind the nail bed. The depth of the wound should not exceed more than 2 mm. The finger is grasped well and is flexed. Blood wells up in drops. When the lobule of the ear is used its lower border should be used for incision.

Collection of arterial blood. A puncture is generally made where the artery runs a superficial course. Blood is withdrawn from the brachial, the radial or the femoral artery. The overlying skin is thoroughly sterilised and the part is anaesthetised with a local anæsthetic like 2 per cent. novocaine. The needle of the syringe is inserted at an angle of 45 to 60 degrees directing it towards the arterial pulsation and the syringe fills without suction. No untoward results follow such a procedure. After withdrawal of the needle, the punctured spot should,

in all cases, be evenly pressed with firm pressure for some time, to avoid the formation of a local hæmatoma.

Collection of specimens. No special preparation is usually necessary except that the blood should be drawn in the morning before the patient has any food; it is essential however that the specimen is properly labelled and sent to the laboratory immediately after collection.

The following table gives an idea of the approximate quantity of blood required and the method of collection.

Estimation of or Examination for			Quantity of Blood in c.cm.	To be collected in :
Sugar 2	Oxalated tube.
Urea 2	" "
Non-protein nitrogen 5	" "
Cholesterol 3	" "
Calcium 3	Sterile test tube.
Van den Bergh's test 5	" " "
Aldehyde test 2	" " "
Antimony test 2	" " "
Widal reaction 2	" " "
W. R. 3	Clean phial or test tube.
Culture 5	Broth tube.
Grouping 5	2 c.cm. in citrate tube.
				3 c.cm. in test tube.

PARASITES OF THE BLOOD. 1. *Malarial plasmodia*. Three common species (in man)—(a) *Plasmodium vivax* (tertian parasite). (b) *Plasmodium malarie* (quartan parasite). (c) *Plasmodium falciparum* (æstivo autumnal parasite).

Methods of examination of the blood. The blood may be examined for malarial parasites (a) in wet preparation, (b) in stained smears. For identification of different parasites *vide* text.

Provocative methods for increasing the number of plasmodia in the circulating blood in patients where blood contains small numbers of parasites have been advocated. After a subcutaneous injection of 1 c. cm. of adrenalin, the parasites appear in the peripheral blood in about 20 minutes and the maximum number is obtained in about an hour after such injection. Ergotine, strychnine, application of ice, ultraviolet rays or X-rays over the splenic region have also been advocated.

Ross' thick blood film method and methods for culture of plasmodia *in vitro* (Bass and Johns)—*vide* text.

2. *Filaria*. The embryonal or microfilarial form enters the peripheral blood stream and the examination of such blood is undertaken for diagnostic purposes.

Examination of the blood for microfilaria. A small drop of blood is generally placed on a clean glass slide, the surrounding part is smeared with vaseline to prevent rapid drying and the whole is covered by a clean glass slide.

A better method of detecting the parasites in the blood is to add about 0.5 c. cm. of blood to about 9 c. cm. of 2 per cent. acetic acid. After thorough mixing the preparation is centrifuged and the wet preparation is made from the sediment. The blood for examination should usually be taken at midnight when the peripheral blood exhibits the maximum rise. The embryos exceed by a little the red cells diameter while their length is between 130 and 300 microns.

3. *Trichina*. The embryos of *Trichinella spiralis* may be found in the blood in trichiniasis. At birth an embryo measures 0.1 mm. and grows to about 1 mm. when it becomes encysted in the muscle.

4. *The blood flagellates*. Two groups. (A). *Trypanosoma*. (a) *Trypanosoma gambiense*—African sleeping sickness. (b) *Trypanosoma rhodesiense*—Rhodesian (African) sleeping sickness. (c) *Trypanosoma cruzi*—Chagas' disease.

Trypanosoma. *Trypanosoma gambiense* Length from 15 to 30 microns. As they occur sparsely in the blood a method of concentrating them is necessary.

Method of concentration (Craig). Ten c.cm of blood is mixed with 1 c. cm. of 6 per cent. sodium citrate solution; the citrated blood is centrifugalised 3 times; the final deposit contains all the trypanosomes. This is a better method for detecting the parasites than simply wet blood preparations. Auto-agglutination of the red cells should be looked for as this is frequent in infection with *trypanosoma gambiense* and *rhodesiense*. The other type presents similar diagnostic features.

(B). *Leishmania*. (a) *Leishmania donovani*—Kala-azar. (b) *Leishmania tropica*—Oriental sore. (c) *Leishmania braziliensis*—American leishmaniasis.

Leishmania donovani. In blood the L. D. body is seen as a small rounded or oval body, 2 to 4 μ in diameter, within the monocyte or neutrophil. The scarcity of the parasites in the peripheral blood has led to methods for increasing their number. One c.cm. of adrenalin is injected subcutaneously or 0.1 to 0.2 gm. of an organic antimonial intravenously. This produces a splanchnic contraction with the squeezing out of the parasites from the splenic pulp into the peripheral blood. The parasites may also be demonstrated by examination of the material from splenic puncture and culture from the blood.

Leishmania tropica. Successful diagnosis depends on the detection of the parasites by examining material from the lesion of the skin.

5. *Spirochaetes of the blood*. Direct examination of the blood is necessary in (a) relapsing fever, (b) infectious jaundice, to detect the particular parasites. There are two methods for staining films for spirochaetes: (1) Giemsa's rapid method, (2) Fontana's method.

Relapsing fever (Treponema recurrentis). Length of the parasites 10μ to 20μ . Generally found in the blood during fever. The thick drop method is of advantage when parasites are scanty in the blood. The parasites, unlike *T. pallida*, stain easily with Wright's stain.

Infectious jaundice (Leptospira icterohemorrhagica). Length 5 to 25μ . Direct examination of the blood is necessary to detect the parasites. The parasites are found in numbers in the peripheral blood towards the end of the second week.

BACTERIOLOGICAL EXAMINATION OF BLOOD It is often necessary to make a bacteriological examination of blood and it is a safe and sound rule that when a patient has *continuous fever for three days or more and the cause of such fever is unknown a blood culture should be undertaken*. (In health the blood is sterile and the recovery of organisms from it during life is of pathological significance). Bacteria may be found in patients supposed to be suffering from septicæmia or pyæmia. (1. spread from a septic focus—streptococci, staphylococci, anthrax, 2. general infections—typhoid, plague, meningococcal infections, pneumonia, undulant fever and 3. infective endocarditis).

In the Enteric group of fevers blood culture offers the most definite means of diagnosis but it must be carried out early in the disease (it is also positive in relapse). To do a blood culture properly the following method is recommended.

Apparatus, etc. 1. Sterile syringe and needle (a well-made 10 c.c. syringe with a sharp-pointed moderately stout needle).

2. Culture media. (One or more of the following in flasks containing 50 to 100 c.c.). (a) Peptone-water with $\frac{1}{2}$ per cent. sodium taurocholate. (b) Nutrient broth with $\frac{1}{2}$ per cent. sodium taurocholate. (c) Sterile ox-bile. (d) Sodium taurocholate $\frac{1}{2}$ per cent. in distilled water. (This or even distilled water alone may be used in an emergency where other media are not available. Note that the laked blood serves as a nutrient medium. (e) One per cent. glucose broth (f) When anaerobic cultures are also desired appropriate media (such as minced meat-broth) must be arranged for. Remember this is most important in cases suspected of *Br. abortus* infection or anaerobic streptococcal infections.

3. Tourniquet—a piece of stout rubber tubing, 2 feet long (or a bandage).

4. Sterile swabs, towel and tincture iodine.

The actual technique. Sterilise the syringe with the needle. This is best done by drawing up hot olive oil (heated with a spirit lamp to just boiling, $140^{\circ}\text{C}.$). The syringe can be previously sterilized and carried in a large sterilized test tube plugged with cotton wool and the whole covered. (NOTE:—Boiling at 100°C cannot destroy spores) but if the syringe is kept scrupulously clean, boiling for 15 minutes will suffice. After taking all necessary precautions, 10 c. cm. of blood should be withdrawn. Inoculate the appropriate medium. Remember to protect the mouth of the flask from contamination and to

flame the mouth. Collect the last c. cm. or so of blood in a sterile tube for agglutination test.

Incubate at 37°C. for 24 hours and examine flask for growth. If there is evidence of growth in the enrichment broth, inoculate media in plates from the flask, using one plate of MacConkey's neutral-red-lactose-bile salt-agar and a plate of blood agar. If after twenty-four hours incubation these plates show no growth of bacteria incubate them further for forty-eight hours more. In case no growth appears but there is evidence of growth in the broth culture, plate the broth again, keep the original flask for two weeks as growth is sometimes delayed and even if no visible growth be seen in the broth it is advisable to make and examine films and to subculture at intervals of 48 to 72 hours on to solid media. It is advisable not to open the flask too often in order to avoid any risk of contamination. Blood clots from specimens submitted for agglutination test can be utilized for cultural examination if necessary. Do not plate such specimens directly, but break up the clot with sterile forceps and transfer it to a bottle containing some medium (Glucose broth). Then proceed as above. When it is necessary to perform blood culture at a distance from a laboratory and to transmit the specimen by post, the most convenient method is to forward the bile in sterile 25 c. cm. vaccine bottles provided with rubber caps. The blood can be introduced directly through the rubber cap into the bile. The needle puncture sealed and the whole wrapped and sent to the laboratory.

BLOOD PRESSURE. By blood pressure is meant the pressure that the blood exerts against the wall of the vessel in which it is contained. The term, therefore, includes endocardial pressure, arterial pressure, venous pressure and capillary pressure. But clinically, blood pressure usually refers to the tension of the arteries only and depends on the following factors :—(a) The force of contraction of the left ventricle. (b) The volume of blood which the left ventricle propels into the already full arteries. (c) The elasticity of the middle coat of the large arteries. (d) Lastly, the peripheral resistance or the resistance to the outflow offered by the arterioles. These factors are under the control of the vagus and the vasomotor centres and the brain can adjust the blood pressure to suit its needs. The carotid sinus appears to be the most important centre for the control of blood pressure. The activities of the vagus and the vasomotor centres are regulated by reflexes from the carotid sinus. Any rise of pressure in the sinus causes slowing of the heart and dilatation of the arterioles whilst a fall of pressure produces the opposite change. The arterial pressure of the body at rest may be said to be the lowest pressure at which the brain can obtain an adequate blood flow. The blood supply to different organs and tissues of the body depends on the efficient working of the heart and the maintenance of a certain amount of tone in the arterioles supplying blood

to them. The arterioles are richly supplied with vaso-constrictor nerves and always maintain a certain amount of tone, which is constantly regulated by the vasomotor centre in the medulla through the vaso-constrictor nerves. When there is a general rise of pressure, the action of the vasomotor centre is re-inforced by the suprarenal glands which produce an increased output of adrenalin thus causing a further constriction of the vessels and adding to the already existing increased blood pressure. The arteries and arterioles are relatively thick-walled vessels and the blood in them is under considerable pressure and moves with a fair velocity. The blood in the aorta is at a pressure of about 120 mm. Hg. and moves with a velocity between 100 and 200 mm. per second during systole. The velocity and the pressure decrease as the vessels branch and become smaller but both remain considerable as far as the arterioles. The arterioles open into the capillaries where the pressure is only 10 mm. Hg. and the velocity of the blood is about 1 mm. per second.

Essential hypertension may be described as a persistently raised systolic and diastolic blood pressure not due to arterio-capillary, renal, cerebral or other recognizable morbid change. It may, however, cause and be the antecedent stage of cardiovascular changes, renal fibrosis and other pathological conditions. It has often been suggested that high blood pressure is a compensatory adaptation to maintain an efficient circulation through the kidneys, brain and myocardium. Starling suggested arteriolar proliferation in the vasomotor centre as the cause of hypertension. MacWilliam concludes that the hypertensive impulse however caused, emanates from the controlling vasomotor centre in the medulla. Vasomotor instability is present in many cases of hypertension. It is conceivable that a metabolic poison selectively constricts the arterioles of the vasomotor centre and the resulting ischaemia stimulates pressor impulses. Clinical observation shows that arteriosclerosis and high blood pressure, though often associated, occur independently and that long-continued hypertension is more responsible for degenerative arterial changes than *vice versa*. Volhard and Fahr have made a division between benign and malignant hypertension. The malignant form is complicated with diffuse changes in the arterioles. It mainly occurs about the fourth decade and runs a rapid course with very high blood pressure. Death may result from apoplexy or acute functional failure of the brain, myocardium or kidneys. Malignant hypertension thus differs from uncomplicated essential hypertension. Hoyle (1933) showed a pressor substance in the urine of hypertensive subjects (during adolescence) with a physiological action upon the cardio-vascular system similar to that of adrenalin and allied pressor bases. Clifford Allbutt (1895) held that persistent high arterial blood pressure is not secondary to chronic kidney disease and suggested as an alternative the word 'hyperpiesis' and pointed out that persistent high arterial pressure was not confined to the elderly only. He eventually restricted the use of the word 'hyperpiesis' to the high sphygmomanometric reading and employed

the modified title 'hyperpiesia' for the clinical condition. The essential pathological change consists in a hypertrophy of the middle or muscular coat of the arterial wall affecting principally the medium and small sized arteries of the body. Broadbent (1890) applied the term 'virtual tension' to the impression conveyed to the finger by arteries worn out and dilated by old-standing high blood pressure when the heart is failing. Huchard (1893) wrote on 'hypertension' and introduced the word 'presclerosis.' The term 'essential hypertension' is rather confusing and so O'Hare in advocating the heading 'vascular hypertension' points out that it is better to use a simpler term than one, the meaning of which is not at once obvious, though Sir Thomas Lewis in his recent and concise account adopts the title 'essential hypertension.' Rolleston holds that the word 'essential', though probably better than 'idiopathic' is not so good as 'primary.'

ÆTIOLOGY *Predisposing factors.* Heredity has been rightly considered to be a predisposing factor. Weitz concludes that 'genuine or vascular' hypertension is a constitutional disease with dominant Mendelian characters. Males suffer more than females due to stress and strain of life. *Exciting causes.* These are sedentary habits and factors leading to intestinal toxæmia; toxic blood states, renal disease; metabolic diseases like gout and diabetes; psychical causes such as worry, anxiety and prolonged mental strain; plethora; cardiac hypertrophy; neuro-vascular diseases like Raynaud's disease and certain endocrine disorders such as excessive secretion of adrenalin or vasopressin. It has been suggested that hypertension is due to overactivity of the chromaffin system and hyperplasia of the adrenal medulla, though adrenalin has not been found in excess in the blood of hypertensive subjects. MacWilliam holds that deficiency of hypotensive bodies in the circulation is a possible cause of hypertension.

Clinically there may be no symptoms and the discovery of high blood pressure may be purely accidental. Subjective symptoms experienced by the hypertensive subject may be headache, cardiac symptoms such as præcordial pain and palpitations, nocturnal frequency of urine, dizziness, nervousness, fatigue, symptoms of cerebral vascular lesions, ocular symptoms, epistaxis and hæmoptysis.

Methods for determining blood pressure. William Russell (1921) states that the finger is still the main means of estimating blood pressure in clinical work. This view is based on the belief that considerable pressure may be required to obliterate an artery thickened by degenerative changes, or in a state of hypertonus. It is usually thought that the force thus expended in blood pressure determinations is comparatively negligible, but Russell, from experimental observations concludes, that in some instances a pressure of 150 mm. Hg. or more may be required to compress a thick artery.

It is quite impossible to determine, even approximately, the diastolic pressure without instrumental aid. It is important to investigate

it for several reasons. The diastolic pressure may be raised without corresponding increase in the systolic pressure. This involves a continuous increased strain on the vessels. The prognosis with a constant diastolic pressure of 135 mm. Hg. or over is very grave. The diastolic pressure may be abnormally low, although the systolic is raised, this is found typically in aortic regurgitation with a free reflux. It is necessary to determine the diastolic pressure in order to calculate the pulse pressure. An increased pulse pressure is associated with hyperthyroidism. Another example of the value of instruments in taking blood pressure is the fact that the condition of *pulsus alternans* may sometimes be diagnosed by this means, although it is not perceptible to the finger alone.

The chief methods employed for determining the blood pressure may be classified as follows:—Palpatory, vibratory, oscillatory and auscultatory.

Palpatory. Systolic pressure. Von Basch of Vienna in 1876, first devised a clinical method for estimating the systolic blood pressure in man. He employed a pelote consisting of a small glass funnel connected by a rubber tube with a mercury manometer, the open end of the funnel being closed by an elastic membrane. The pelote and tubing were filled with water. The systolic pressure was determined by compressing an artery, such as the radial or temporal, between the pelote and the underlying bone and at the same time feeling the pulse beyond the site of the pressure. The force required to obliterate the pulse could then be calculated by means of the manometer. Potain (1889) modified this instrument, using a rubber pelote communicating by air transmission with a metal manometer. Reading by either of these forms of sphygmomanometers gives figures for the systolic pressure, which are often 50 to 60 mm. (Hg.) higher than the normal.

Riva-Rocci (1890) introduced the method of compressing the artery by means of an armlet encircling the limb, into which air is pumped. His instrument is well known and constitutes the most accurate means of estimating clinically the systolic blood pressure in man. The results obtained are about 7.5 per cent. higher than the true systolic pressure. Care must be taken to determine the residual systolic pressure by making several estimations until a constant reading is obtained. The point at which the pulse disappears on compression should be determined rather than its point of reappearance on decompression. The mean of these two readings is often taken as the systolic pressure.

Diastolic pressure. Strasburger (1904) described a method for determining the diastolic pressure with the Riva-Rocci apparatus. The radial pulse is carefully felt while the armlet is slowly inflated, and a point is noticed at which there first occurs a diminution in the force of the beat. This indicates approximately the diastolic pressure, but the figure obtained is a little high. *Vibratory method.* This is a method for determining the diastolic pressure only. When the pressure is

slowly raised, as in Strasburger's method, just before the pulse becomes perceptibly smaller, the artery suddenly pulsates vigorously, giving a strongly vibrating sensation. This is much more clearly appreciated if the brachial rather than the radial artery be palpated. As the pressure is further raised these forcible vibrations first increase and then decrease in intensity (variations of 5 mm. on the pressure scale), and are then replaced by normal beats which disappear when the systolic pressure is reached. On lowering the pressure the reverse takes place, and the point at which the vibrations disappear on decompression is usually 2 to 3 mm. lower than that at which they are first noted on compression and these are well marked in cases of high blood pressure. The diastolic point is taken as that pressure at which the first normal beat follows a vibrating beat on decompression.

Oscillatory. This is a method for determining both the systolic and diastolic blood pressures. It is found with the aid of Pachon's oscillogram and Erlanger's sphygmomanometer. The former apparatus consists of a rigid metal box, containing a manometric capsule, a pressure manometer and an armlet. The manometric capsule enables the extent of the oscillations to be read at different pressures. It is put into communication with the circuit, consisting of the box, manometer and armlet by means of a screw, and the oscillations read, as the pressure is lowered. Small oscillations are first seen on decompression, which become larger and then decrease in size. The difficulty in interpreting the readings lies essentially in the fact that often there are oscillations at pressures above the systolic figure and below the diastolic. These are called supramaximal and inframinimal oscillations.

The systolic pressure is that pressure at which the first large oscillation occurs on decompression. If there be no supramaximal oscillations present, this is easy to determine; if, however, they occur, the systolic pressure is that point at which the supramaximal oscillations are replaced by larger oscillations. The supramaximal oscillations are due to waves of blood beating against the obstruction caused in the brachial artery by the pressure of the armlet.

Pachon originally said that the point at which the oscillations are greatest was the diastolic pressure. It is however now taken as that point at which the large oscillations undergo a sudden and marked diminution in their size, and become inframinimal. The average diastolic pressure for an adult with the Pachon instrument is about 90 mm. Hg.

Erlanger Apparatus. The oscillations are recorded graphically on a blackened paper travelling with a moving drum. The systolic and diastolic points are as in the Pachon readings, and present the same difficulties of interpretation.

The auscultatory method of Korotkoff is the most practical and widely used. The patient should be comfortably seated with his arm bared to the shoulder and resting on a support so that the muscles

of the arm and the forearms are relaxed. The armlet is applied about an inch above the fold of the elbow. The cuff is inflated by small but rapid compressions of the bulb until the radial pulse becomes imperceptible. The stethoscope is placed over the artery just below the compression cuff, which is then deflated evenly. Five phases in the readings are recognised. The first phase consists of clear-cut snapping sounds. The change to loud rough stenotic sounds is the second phase, which shows partial and at times complete disappearance. Then there is return of the sound similar to phase one, but not so loud, and this is the third phase. The fourth phase is an abrupt dulling of the sound or a change from sharp pistol-shot to dull toneless sound. The disappearance of the sound is the fifth phase. The beginning of the first phase is the systolic pressure and is usually 4 to 6 mm. higher than that estimated by palpation. The true diastolic pressure is the beginning of the fourth phase. In cases of marked aortic regurgitation or vasodilatation the fifth phase may be attended by a dull sound down to zero, then the diastolic pressure must be estimated at the beginning of the fourth phase.

A frequent source of error in cases with raised blood pressure is the 'silent gap' which occurs usually in the second phase. This zone of silence may be absolute or relative, but generally begins 10 to 30 mm. above the diastolic level. It can be produced to a variable degree by obstruction to the peripheral circulation, for example, through venous compression. Its mechanism is unknown, but it is sometimes associated with the shape of the pulse wave, as in the anacrotic or plateau pulse of aortic stenosis.

If several trials are made without completely deflating and waiting for about thirty seconds between readings, there will be venous engorgement with changes in blood pressure, which causes difficulty to identify the phases. A tight roll of clothing at the shoulder may make it impossible to estimate the diastolic level, by causing obstruction sufficient to produce sounds which can be heard to zero and so simulating aortic regurgitation.

The normal pressure varies at different ages, and it may be taken that the average systolic reading for an adult is 100, plus half the age in years, and that in any case a systolic pressure above 150 mm. of Hg. is abnormal. The diastolic pressure is approximately two-thirds that of the systolic up to middle age, but later it may be only half the systolic. A diastolic pressure which is higher than 120 mm. Hg. is of serious significance. In healthy individuals a blood pressure below the average from the standpoint of longevity is an asset. Sir Thomas Lewis says: "The average blood pressure rises with age; this is not to say that rising blood pressure is normal, for many vigorous and long-lived men retain low blood pressure; it is good that an otherwise healthy but aged man should show a pressure below the average for his years." Consequently, there is justification in regarding a blood pressure below

average as the normal. If individuals can perform their daily work with a blood pressure below average they are fortunate as there is less wear and tear upon their tissues, especially their blood vessels and the heart.

The following may be regarded as the normal standard of systolic blood pressure as measured in the brachial artery, while at rest. In children under 10, 100 mm.; in early manhood from 100 to 120 mm.; in middle age from 125 to 135 mm.; above 60 years of age 145 to 150 mm. In the female, the systolic pressure is generally 10 to 20 mm. lower than in the male. The range of diastolic blood pressure, as estimated by the auscultatory method in healthy young adults, is usually accepted as 70 to 90 mm.

There are variations in the blood pressure under physiological conditions, among these being mental states, sensory stimulation, sleep, change of posture, meals and physical exertion. Those of nervous and anxious temperament, as well as those whose mode of life necessitates considerable nervous strain, have a tendency to exhibit higher readings, especially in the later period of life; while in those of an equable and placid temperament, and those whose mode of life is smooth, the opposite is the case. Sensory stimulation often causes a rise in the arterial pressure, especially in the diastolic. In sleep there is a fall of blood pressure. Opinions vary as to the effects of the digestion. It is probable that the change in pressure commences within a quarter of an hour after a meal, the highest reading being reached in about an hour, after which it gradually returns to the normal. During exercise the pressure as well as the pulse rate are raised, returning to normal in half an hour.

The systolic blood pressure shows the greatest variations. It is, usually affected first. Persistent readings of more than 10 mm. above the average are not normal. When hypertension has existed for some time there is enlargement of the heart. The diastolic blood pressure is more stable, and small variations are significant. It is however more difficult to estimate. When over 90 mm. it is suspicious; over 95 it is abnormal; 100 and over is definitely pathological; 110 and over usually means progressive kidney disease or malignant hypertension (Keith). If diastolic pressure is high it means excessive constant strain on the circulation, and if it is abnormally low, it means a serious handicap, because of poor myocardial nutrition. Pulse pressure is a composite of both the systolic and the diastolic. A dropping pulse pressure usually means myocardial failure. Pressure variations from beat to beat may occur with premature beats and in auricular fibrillation. When during normal rhythm, regular variation occurs in alternate beats, one can diagnose *pulsus alternans*. This is one of the most important signs of cardio-vascular failure and is indicated by the sphygmomanometer.

Blood pressure, both high and low, appears to be a familial trait, and has been regarded by some as associated with special constitutions. The characteristic of low blood pressure subjects is a long narrow chest; they are easily affected by cold, easily tired, and of hyposthenic habits. The high blood pressure subjects are broad-shouldered, broad-chested, athletic and are of hypersthenic habits. Constitutional low blood pressure shows no tendency to become progressively lower, but so-called constitutional high blood pressure is liable to become permanently higher.

Hypertension may be divided clinically into three groups according to the order of appearance and seriousness. (I) Both systolic and diastolic pressures are raised with a pulse pressure above normal. Here we have pathological changes in the vascular system, especially the arterics. (II) The diastolic pressure is normal or nearly so, but the systolic is raised and the pulse pressure correspondingly high. This is the so-called stage of 'essential hypertension' or hyperpiesia. (III) The diastolic pressure is high, but the systolic is dropping, giving a low pulse pressure. This is the stage of myocardial failure and may be present for some time without symptoms.

TREATMENT. As normal blood pressure has a wide range of variation in different subjects, before adopting a line of treatment for an individual, inquiries should be made of his previous usual blood pressure, abnormal symptoms if any, the treatment adopted before and the effects following such treatment. The patient should be encouraged to think that a high blood pressure is not so serious if his life is governed by moderation. It is more important to treat the underlying conditions, responsible for the high blood pressure than the pressure itself, when this can be done. A review of the conditions of life is necessary in such a case. Foci of chronic sepsis which may be associated with the teeth, tonsils, nasal sinuses, gall bladder, prostate, etc., should be searched for and eradicated, where possible. Rest should come foremost in the general care of a hypertensive subject. It should be enjoined both mentally and physically. As psychical factors are more important than others in hypertension, absolute mental rest should be aimed at. Halls Dally (1891) advocated the creation of a congenial psychical atmosphere and the cultivation by the patient of an equable, cheerful and balanced temperament. Occupations of steady routine are to be preferred to those that involve constant anxiety and sudden fluctuations. Light reading and similar distractions are useful in getting rid of worries before retiring to rest. He suggests that not less than eight hours be spent in bed, and rest should be enjoined after meals if possible. Holidays should be spent in pleasant surroundings which will give mental relaxation. Sudden exertion, hurry, worry, and straining at stool should always be avoided. When symptoms of hypertension develop, physical rest in bed is imperative and the pressure consequently falls. Myocardial failure also demands absolute rest.

Diet therapy. Diet should be simple, wholesome and small in amount. A tendency to obesity should be controlled and carbohydrate should be restricted if such a tendency exists. Excess of carbohydrates and fats causes flatulent dyspepsia which in turn increases the blood pressure. A high protein diet should never be encouraged as the products arising out of putrefaction of proteins in the intestine are potent causal factors in hypertension. On the other hand, a low protein diet induces anaemia and asthenia and, therefore, moderation in the protein intake should be aimed at. Fresh fruits, vegetables, cereals and fish may form part of the dietary. Eggs, milk and similar products rich in cholesterol should be cut down to the minimum. Drinks like alcohol, tea and coffee should never be freely indulged in. A moderate indulgence in tobacco is probably not harmful while its soothing effects may even be beneficial. Excessive smoking should be forbidden. Ingestion of excessive quantities of fluids is distinctly harmful in hypertensive subjects and it is suggested that one pint of fluid for every five stone of body weight, taken in during the twenty-four hours should be the usual rule. Opinions vary regarding the intake of chlorides. Patients with high blood pressure but presenting no symptoms may be allowed common salt as ordinarily used in the preparation of food, but a strict salt-free diet is desirable in cases where symptoms like palpitation, dyspnoea and oedema have supervened.

Physiotherapy. Exercises, preferably in the open air and only in moderation, may be allowed to hypertensive subjects provided no symptoms of cardiac decompensation appear. Deep breathing exercises, passive movements, general massage are all useful therapeutic adjuncts in lowering high arterial pressure. As regards baths, the value of hot baths is doubtful and cold baths are harmful because they raise the blood pressure; tepid baths (94° to 98°F.) are beneficial. A yearly visit to a spa may be a valuable aid to ordinary treatment. Humphris (1925) refers to the lowering of blood pressure in hyperpiesia by daily application of d'Arsonval electric current. The effect is due to stimulation of metabolism and production of local vasodilatation. High frequency currents lower the pressure for a time. Ultra-violet rays are also stated to have a similar effect. Cyriax (1917) reported good results in cases of moderately high blood pressure, obtained by what he described as 'mobilization of the spinal column' by which he meant active and passive movements of the vertebral joints and passive manipulations, vibrations, petrissage of the erector spinæ muscle. He thought that congestion of these parts led to irritative states of the erector spinæ setting up a series of sensory stimuli to the posterior spinal nerves which in turn gave rise to a series of pressor effects thus raising the blood pressure. Results of treatment were encouraging. Gunewardene modified this method by substituting electrical stimulation of the skeletal muscles.

Drug therapy. Drugs, though of secondary importance, have their place in treatment, more especially in the earlier stages. Later, they are needed to relieve distressing symptoms of cardiac, cerebral and renal origin. No specific drug is known to cure the disease or to alleviate symptoms permanently. A large number of synthetic drugs have been tried but not one is known to have any specific effect in the disease. Treatment with drugs is therefore only symptomatic and emergent and this should go hand in hand with diet and physiotherapy. As constipation and intestinal toxæmia play an important ætiological role in hypertension, purgatives occupy the foremost position in treatment. The daily use of purgatives is obnoxious and it should be noted that slight laxative action of the bowels daily is of greater use than the use of an occasional purge. It is suggested that abdominal massage and bulky carbohydrate foods might help in complete and regular evacuation of the bowels, but this does not suit fat persons who are usually the victims of the condition and are often subjects of flatulent dyspepsia. Carbohydrates increase blood pressure and sometimes give rise to colic and mucous colitis. For regular use, liquid paraffin (1 to 2 oz.) and allied preparations such as petrolagar alone or combined with cascara, serve the purpose best. They all efficiently lubricate the bowels and facilitate the passage of stools. According to some, blue pill overnight followed by a smart saline purge in the morning should be the routine practice of the hypertensive subject at weekly intervals or when subjective symptoms appear. In some individuals a daily dose of saline sufficient to give one or two loose stools keeps the blood pressure down. When actual symptoms of hypertension such as fullness in the head, headache, palpitation, etc., develop, time should not be lost in procuring and maintaining adequate rest and administering depletive remedies such as cholagogue purgatives and the hydragogue cathartics to the patient. Besides the purgatives discussed, a mineral water, where available, such as Hunyadi Janos Friedrichshall, Kissingen, Rubinat or a laxative lithia, along with diet therapy often helps an efficient daily bowel action. In toxæmia resulting from intestinal stasis, rectal injections, every morning for three weeks, of a pint of solution of potassium permanganate (1 gr. to 1 pint of water) is often of great value. Along with such treatment, a simple diuretic mixture with bromides and valerian when the patient is nervous by disposition, is often of much benefit. Sedative drugs are of much benefit in these cases and bromides, chloral hydrate and barbiturates are often prescribed with advantage. One to three tablets of theominal, a combination of theobromine ($4\frac{1}{2}$ gr.) and luminal ($\frac{1}{4}$ gr.) are often beneficial in cases where restlessness is a predominant symptom. Preparations containing valerian are often combined with bromides in neurasthenic cases. For hypertension of menopause in elderly women, bromides with calcium therapy and a polyglandular extract or an extract of ovary, appear to be distinctly valuable. In nervous, excitable and emo-

tional subjects, the use of quinine hydrobromide (3 gr.) or if there be idiosyncrasy the use of ammonium bromide (5 to 10 gr.) has been advocated. Iodides are thought to lower blood pressure by diminishing the viscosity of the blood and also in very minute doses they act as vasodilators. Opinions vary as to the efficacy of iodine preparations in the treatment of hypertension. Potassium iodide in increasing doses has been found of much benefit in persons who have passed middle life; others prefer colloidal iodine, French Codex iodine (5 min. in milk) or a hypodermic injection of an iodine compound such as 'tiodine'. The vasodilators and the hypotensive drugs play an important role in the treatment of hypertension. They are most needed in cases of emergency and though the effects are transient, the use of such drugs is universal. They relieve the heart and blood vessels of excessive stresses, administer rest to the myocardium and are powerful palliatives. These drugs should however be cautiously prescribed as their indiscriminate use might precipitate an apoplectic seizure sometimes. Of the hypotensive drugs, nitrites, mistletoe, preparations of sulphocyanic acid, choline derivatives, veratrum and extracts of certain organs and muscles, deserve special mention. Nitrites are of particular value in relieving symptoms of headache, dizziness and anginal pains. The effects are transient and are of little value in long-standing cases of hypertension. Benzyl benzoate has also been extensively used but this is of disputed value. Good results have been obtained from long-continued use of bismuth subnitrate in the pre-tensive stage of the disease. It is decomposed in the bowel producing nitrate ions which are in their turn, converted into nitrous acid by *Bact. coli* and this maintains continued vaso-relaxation. It is given three times a day in capsules containing 10 gr. of the drug, for several months. Mistletoe is extensively prescribed by French physicians; it contains an alkaloid, a saponin, magnesium and potassium salts and is described as guipsine pills. It has a central action and is not a cardiac depressant; the dose is two pills three times a day. Sodium sulphocyanate is of particular value where organic changes in the arteries are absent. It is prescribed in 1½ gr. doses, three times daily after meals for the first week, twice daily for the second week and once daily for the third week. The drug should be discontinued if a rash appears and it should never be prescribed if the renal functions are impaired. (Elixir sodium sulphocyanate contains sodium sulphocyanate 20 gr. to an ounce.) The choline derivatives act as a specific stimulant of the parasympathetic system and antagonise the action of adrenals. A few of its derivatives are efficient vasodilators of which pacyl (choline content 1½ gr.), acetyl choline and hypotan, deserve a mention. Pacyl and hypotan (methyl acetyl choline bromide) tablets are sold for oral use. The dose of each is 3 to 6 tablets daily. Acetyl choline has a more prolonged action than pacyl or hypotan. It is given as a subcutaneous or an intramuscular

injection and should never be given intravenously. The initial dose is 0.05 gm. increased subsequently to 0.1 gm. daily. The fall of blood pressure is marked and is maintained for some hours. The preparations of *veratrum viride* used in the treatment of hypertension are the tincture of *veratrum* (B. P. 1 dose 5 to 15 min.) and *veratrone*, a synthetic preparation of P. D. & Co. *Veratrone* is injected intramuscularly in doses of $\frac{1}{4}$ c.cm. The drug is of proved value but should be used with caution, as it sometimes produces an alarming fall in blood pressure. Venesection is an efficient hypotensive measure and is particularly useful in congestive cardiac failure in hypertensive cases.

Opothrapy. The extracts of many organs and tissues such as histamine, choline, acetyl choline, adenosine and extracts of liver and brain and internal secretions of the endocrines exert a depressor effect on high blood pressure. *Hepatic extracts.* Anabolin is a hepatic extract and acts by virtue of its histamine content. It is used as daily intramuscular injections, in doses of $\frac{1}{4}$ to 1 c.cm. till the pressure is lowered. Heparhormone (Lily) is claimed to be a better drug than anabolin. It is used in the form of intramuscular injection in doses of 2 to 3 c.cm. and is of particular value in early cases without much arterial or renal damage. *Thyroid extract* is useful in obese menopausal patients. It is given in $\frac{1}{2}$ gr. doses, thrice daily. *Padutin*, a hormone from the pancreas is a useful vasodilator in hyperpiesia. It is used as an intramuscular injection in one unit dose, twice daily for three days and later, in two unit doses for nearly a fortnight. It is also prescribed for oral use in doses of 10 drops, three times a day. Recently, another hormone has been isolated from the pancreas and named *vagotonine*. It is a stimulant of the parasympathetic system and exerts a more depressor effect than other tissue extracts and other hypotensive bodies, as *halkikrein*, another hormone extracted from the pancreas. *Lacarnol*, a nucleoside muscle extract, is an efficient preparation for dilating the coronary arteries and the drug is of proved value in anginal attacks. It is used both as intramuscular injections in doses of 1 c.cm., and orally in doses of 10 to 15 drops, three times a day for many weeks. Opothrapy has no doubt relieved distressing symptoms of hypertension but its value as a cure is open to debate.

A few words are necessary on the treatment of low blood pressure. The common ætiological factors responsible for hypotension include acute cardiac diseases, chronic valvular diseases of the heart, especially the mitral, chronic interstitial myocarditis, myocardial degeneration, endocrine dysfunctions, particularly Addison's disease and early stages of Grave's disease, chronic wasting maladies such as tuberculosis, infectious diseases such as enteric fevers, diphtheria, pneumonia; auto-intoxication from septic tonsils, teeth, colon, genito-urinary tract, etc. Considerable loss of fluid from the body results in marked low blood pressure in cases of cholera, acute diarrhoea, dysentery, vomiting, and severe hæmorrhage. The condition is brought about by a diminution of

ventricular output, lowering of the vasomotor tone due to derangement of the vasomotor centre and splanchnic stasis. The cases frequently show symptoms of asthenia, myasthenia, giddiness, faintness, mental depression, nervous instability, sensitiveness to cold, etc. The treatment of hypotension is essentially a treatment of the primary cause. Eradication of the septic foci in the body when detected is most important. Diet should be a mixed one and may be rich in protein content. Meat extracts, meat soups, eggs and milk should be supplied to the dietary in sufficient quantities. Fluid intake should always be encouraged. In cases where loss of body fluid is marked, to make good the loss sufficient fluid should be supplied to compensate the condition. Massage is held by some to be useful in some cases. Wearing of an abdominal belt is a helpful measure in cases of splanchnic stasis. A few drugs are of reputed value in raising blood pressure in hypotension, of which, adrenalin, ephedrine, pituitary extract and strychnine deserve mention. Strychnine and calcium are very much favoured as drugs of efficacy in acute infectious fevers such as diphtheria, pneumonia, etc., where low blood pressure is frequently marked. Saline infusions, injections of adrenalin, pituitary extract or ephedrine are invaluable in raising the blood pressure in cases of haemorrhage, acute diarrhoea, cholera, etc. In cardiac diseases digitalis and strophanthus are of proved value. A change of climate and tonics such as iron, arsenic and glycerophosphates, are most beneficial in the treatment of prolonged convalescence after acute diseases where the blood pressure is generally low.

BOILS. See page 1161.

BRONCHITIS. The inflammation of the bronchi is a most common malady induced by various agents bacterial, chemical and mechanical. It may be acute or chronic affecting both the larger and the smaller tubes. The acute and chronic types are further classified into catarrhal, suppurative and fibrinous or they may be secondary to other causes. Of the predisposing causes climate and latitude play an important role in the causation of the disease. Besides, a hereditary predisposition, extremes of age, fatigue and privation, deformities of the chest, chronic cardiac and renal diseases and conditions of the respiratory passages deserve mention. The catarrh-producing organisms responsible for the condition are pneumococcus, Friedlander's penumo-bacillus, streptococci, *Micrococcus catarrhalis*, staphylococci, *Micrococcus tetragenus* and sometimes *Bacillus coli communis*. *Spirochæta bronchialis* has also been isolated from the sputa of these cases. In suppurative bronchitis Pfeiffer's bacillus influenzae are found in 90 per cent. of the cases. Secondary bronchitis follows diseases like measles, whooping cough, influenza, fevers of the enteric group, small pox, diphtheria and plague. Other conditions associated with bronchitis are pulmonary tuberculosis, secondary syphilis,

pleurisy and penetrating injuries of the chest. The cause of fibrinous bronchitis is not yet known.

Ordinarily three stages are recognised during the course of the disease and these are, an initial dry stage, the second or mucoid stage and the stage of resolution.

An acute attack is usually characterised by malaise, aching of the limbs, a sense of oppression about the chest, a moderate rise of temperature varying from 99° to 103°F., hurried respirations, a flushed appearance of the patient. The cough is at first dry and hacking and the sputum is scanty and tenacious, later with the onset of expectoration it becomes copious and mucoid in character. The temperature usually abates in a week's time. The physical signs as revealed by auscultation of the lungs include sonorous or sibilant rhonchi in the early stages and bubbling rales later on.

Complications of bronchitis are many, of these broncho-pneumonia, lobar pneumonia, bronchiectasis, chronic bronchitis and even active tuberculosis deserve mention.

TREATMENT. The aim of treatment of a case of acute bronchitis should be to maintain the strength of the patient and especially the strength of his heart, to deplete the tubes and relieve cough by promoting free expectoration.

In all cases of acute bronchitis, the patient should be confined to bed and in cold weather the temperature of the room should be maintained at 65°F. During the febrile stage the diet should be summed up in the words 'hot slops' such as milk, weak tea, gruels, broths and other invalid foods as hot liquids tend to promote bronchial secretion. The air of the room may be moistened by means of a steam kettle in the dry stage only. Medicated inhalations are useful and vapour of compound tincture of benzoin (1 dr. to a pint) is very comforting to the patient in the early stage and later on, a dry inhalation of creosote, terebene and spirit of chloroform is considered to be helpful. Of the drugs, in the early stages, a simple saline diaphoretic mixture with the addition of small doses of tincture of ipecacuanha or wine of antimony may be useful. With the onset of expectoration, stimulating expectorants such as chloride and carbonate of ammonia combined with squill and syrups of tolu and virginian prune, are helpful. In the early stages, Dover's powder is highly recommended. When very distressing cough is present compound tincture of camphor may be advantageously added to the mixture. To reduce cough at night or a dry cough, Samuel Gee's linctus is the best for mild cases. This consists of equal parts of compound tincture of camphor, syrup of tolu and honey of squill. The usual dose is a drachm. Resort may sometimes be made to the use of codeine or heroin. Cardiac stimulants should be administered where necessary.

In subacute cases, an autogenous vaccine, when streptococci predominate, is of greatest value, the dose should be small starting with $\frac{1}{2}$ to $\frac{1}{4}$ of a million.

In chronic bronchitis preventive measures should involve residence in a warm dry climate, the patient's bedroom must be comfortably warm. He should not go out of doors in inclement weather. In fat subjects with bronchitis carbohydrates should be restricted so as to bring down the weight of the patient. In-take of alcohol and smoking should be always forbidden. Stimulating expectorants are the most suitable drugs.

During convalescence, a change of climate, nutritious food and a mixture containing strychnine, iron, glycerophosphate, etc., go a long way to speed up recovery and restore the tone of the patient.

Prophylaxis. The prevention of attacks lies in the problem of aborting the common cold. As suggested by Poulton, the introduction of liquid paraffin in excess into the nasal passages will often abort the condition completely. Ammoniated quinine flavoured with syrup of ginger or lemon and diluted with water is reputed to abort an attack.

BUBO (Climatic bubo). See page 1009.

BURNS. These are common accidents in daily life. From the standpoint of treatment four stages are recognised: (1) shock; (2) acute toxæmia, (3) septic toxæmia, (4) healing.

Stage of shock. This is the first and foremost condition in which there is a general depression of all the vital functions. Small burns are those where 10 per cent. or less of the body surface is involved. Moderate burns are those where 10 to 30 per cent. of the body surface is involved. Severe and generally fatal cases are those where more than half the body surface is involved.

Stage of toxæmia. Here there is a rise of temperature, increased pulse and respiration rates, restlessness, and vomiting. The *stage of healing* is generally protracted.

TREATMENT. *General principles.* (1) *Treat the shock.* (a) Fluids can be administered by intravenous, subcutaneous, rectal and if possible by oral routes. Normal saline combined with glucose forms the best method for such infusion. (b) Relieve the pain and check restlessness of the patient by putting him to bed and injecting morphia $\frac{1}{2}$ gr. (c) Give warmth to the body in the form of an electric bath.

(2) *Tannic acid treatment.* The basis of modern treatment of burns is coagulation of the injured surface by tannic acid. This method has important local and general effects. Locally it is analgesic; pain, discomfort and frequent dressings are avoided on account of the presence of the coagulum. In superficial burns, sepsis is absent and healing is rapid. General effects are that it lessens fluid loss from the body at the burnt area. It probably helps by its analgesic effect to combat shock. It prevents or minimises acute toxæmia.

Aqueous solution of tannic acid 2.5 per cent. is sprayed over the raw surface from an atomizer and dried by a current of hot air or by an electric bath. This is repeated at hourly intervals, 7 to 10 such applications generally suffice. Otherwise a piece of lint soaked in solution, is kept over the areas till the coagulum forms. The lint is then removed and the coagulum dried.

Coagulating solutions used are : 1. (a) Aqueous solution of 2.5 per cent. tannic acid prepared by dissolving 7.5 gm. of tannic acid in 300 c.cm. of warm sterile water. (b) Acriflavine (1 in 1,000) prepared by dissolving 0.3 gm. of acriflavine in 300 c.cm. of warm sterile water. In every case freshly made solutions should be used for spraying.

2. Cleansing. The burnt areas should always be cleansed under general anaesthesia (ether ordinarily preferred). Remove all epithelium which is loose or raised by blistering by cutting with a pair of clean and sterile scissors. Swab the raw surface thus produced gently with ether or alcohol and then with hydrarg. perchlor. solution (1 in 1,000). After cleansing, the coagulating solutions are sprayed over the areas.

3. Treatment of sepsis. This is generally treated as ordinary wounds with fomentations, bath, ointments such as 2½ per cent. tannic acid or ordinary 'Bipp'.

4. Serum treatment. As a routine treatment in all burn cases anti-tetanic serum (1,500 units) is always given as soon as the patient overcomes the shock. During the stage of toxæmia and sepsis when the temperature rises high, anti-streptococcic serum 20 c.cm. should be injected intramuscularly. The repetition of such serum is determined by the reaction and general progress of the patient.

The above treatment applies to all types of thermal injuries and also for electrical burns.

CARBUNCLE. It is an extensive gangrene of the subcutaneous tissue as a result of an acute inflammation due to the invasion of pathogenic microbes, usually the *staphylococcus pyogenes aureus* or *albus*. The condition generally supervenes on slight injuries or as a result of auto-infection in debilitated individuals usually suffering from some chronic disease such as diabetes, albuminuria, nephritis, etc. and in whom the body resistance is low. The sweat glands and the hair follicles of the part are primarily infected with organisms; the blood supply of the subcutaneous tissues is poor and very often predispose to the condition. Though carbuncles may form on any part of the body, the common sites are the nape of the neck, the back and the buttocks. The disease is common in males over forty and appears as a hard painful infiltration of the subcutaneous tissue ; the overlying skin becomes red and oedematous; the swelling increases in size peripherally and the centre becomes soft and boggy. Multiple openings gradually appear on the surface resulting in a cribriform condition of

the cutis. Many of these coalesce producing a central crateriform opening under which the necrotic mass lies. A constitutional disturbance of an asthenic type occurs; the temperature varies with cases and a temporary glycosuria of toxic origin is often present. The prognosis is usually grave in cases of carbuncles of the face and upper lip as the infection may extend and lead to intracranial complications.

TREATMENT. The general treatment of carbuncle is the same as of an acute infection. The treatment of associated primary conditions, namely, diabetes or albuminuria is as important as the disease itself. Septic foci in the body should also be eradicated. In the early stages, Bier's hyperæmic treatment, once a day (the suction cup being applied six times in three quarters of an hour with regular intermission of two or three minutes) may be successful in preventing suppuration. Locally relief is always obtained by applying a hot fomentation over a dressing of perchloride of mercury (1 in 4,000) or magnesium sulphate compresses. A thin paste of magnesium sulphate cream (magnesium sulphate 24 oz., phenol 1 dr., glycerine 12 oz.; heat magnesium sulphate to 100°C, powder while hot and add glycerine and phenol gradually) is applied over the carbuncle. Where the inflammation is spreading without definite localisation of the necrotic mass and in all carbuncles of the face, drastic operative measures should never be encouraged. Operative treatment aims at the total excision of the diseased mass. When gangrene of the part occurs and toxæmia is intense, the dead area should be immediately excised under a general anaesthetic and the cavity curetted till healthy tissue appears. The after care of the wound is the same as that of ordinary surgical wounds. Later on, nutritious food, tonics and a change of climate are advisable to aid a speedy recovery. For vaccine therapy see page 773. Light and Sosman advocate X-rays for the treatment of carbuncles. The benefit lies in a hastened necrosis of the lesion, and a softening or liquefaction of the carbuncle in the indurated stage. Sometimes the spreading tendency of the lesions is checked and healing occurs by drying up and absorption without any extensive drainage of the necrotic materials. X-ray therapy is of benefit following surgical procedures which fail to check the spread of the carbuncle and in these the activity of the infectious process is diminished and the peripheral spread stopped. Relief of pain occurs in cervical carbuncles especially in those of the face.

CEREBROSPINAL FEVER. See page 888.

CEREBROSPINAL FLUID. The cerebrospinal fluid originates from the choroid plexus in the brain. The pressure of the fluid is the same as the venous pressure, but it is considerably less than the intracranial arterial pressure (about one-sixth). The flow of the fluid can be reversed back into the blood stream by increase of the osmotic pressure of the blood as in dehydration or intravenous injection of concentrated salt solution. In meningitis the capillary cells of the plexus are disorgan-

ised and allow the protein constituents to pass into the cerebrospinal fluid. The fluid passes out from the fourth ventricle into the cisterna magna. Here the course of the fluid divides, four-fifths going over to the brain and one-fifth round the spinal cord. Blocking of the fluid produces internal hydrocephalus.

Absorption of the fluid occurs by osmosis through the arachnoid villi. The diffusion into the blood keeps pace with the formation of the fluid because the total content of salts and other electrolytes in the blood is greater than that in the cerebrospinal fluid. In meningitis the absorption is less rapid and the pressure of the spinal fluid is increased. Repeated lumbar punctures and drainage are therefore practised to bring the pressure and amount to normal. Lumbar puncture is nowadays commonly resorted to for ascertaining the character of the cerebrospinal fluid in normal health and disease, for relieving its pressure in cases of increased subdural pressure, for intrathecal administration of drugs in disease and for the collection and subsequent biochemical and pathological examinations of the fluid in the diagnosis of meningitis, intracranial hæmorrhage, convulsions, coma, persistent vomiting and syphilitic lesions of the central nervous system, *e.g.*, tabes, dementia paralytica, cerebrospinal syphilis.

Normal cerebrospinal fluid. (Values are in mgm. per 100 c. cm unless otherwise noted). Total quantity 100 to 150 c.cm.; alkali reserve 58 to 63; specific gravity 1.007 to 1.009; pH (fresh) 7.4, pH (on standing) 8.3, pressure 7 to 9 mm. Hg. or 95 to 120 mm. H_2O , 5 to 7 mm. Hg. in children; serum albumin about 4; serum globulin 20 to 30; urea 15 to 30; creatinine 0.7 to 1.5; dextrose 70 to 100; chlorides 720 to 750. The normal cerebrospinal fluid is as clear as water. Turbidity or colour means abnormal condition. The sugar content is always diminished in all conditions of acute suppurative meningitis; it is also slightly diminished in syphilitic lesions of the central nervous system (Hopkins). It is increased in diabetes mellitus. The chloride content is increased in nephritis and decreased in meningitis, particularly in the tuberculous type (500 mgm. per 100 c.cm. of the fluid or sometimes even less). The non-protein figures are usually high in uræmia and in other nitrogen retention cases (100 mgm. to 500 mgm. per 100 c. cm. of the fluid).

Colloidal gold reaction. Lange noted that the addition of electrolytes such as NaCl to solutions of colloids such as gold effected a precipitation of the colloids, but such precipitation is also avoided by adding certain other colloids to the solution. Normal cerebrospinal fluid possesses this property, but Lange showed that fluids derived from pathological subjects cannot prevent the precipitation on adding an electrolyte. It has also been found that precipitation occurs with fluids derived from cases of general paralysis, general syphilis of the central nervous system and a few cases of meningitis. With proper technique, the three lesions can be individually differentiated.

There are three types of response—the paretic, luetic, and meningitic, varying with dilutions. A paretic response is obtained with general paralysis, and luetic responses with tabes dorsalis and cerebrospinal syphilis, while opinions vary regarding the proper interpretation of meningitic responses.

Globulin test. Normally the cerebrospinal fluid contains only a trace of protein, but the amount increases in certain pathological conditions as in meningitis and cerebrospinal syphilis; such increase, particularly the globulin content, is detected by the following test.

Technique. About one c.cm of cerebrospinal fluid is added very slowly to the same amount of saturated solution of ammonium sulphate and if there is an increase of globulin, a grey ring is formed at the junction of the two. This is the first phase of the reaction. The second phase consists in filtering off the precipitate and adding a drop of 10 per cent. acetic acid, then boiling the mixture. The formation of a precipitate indicates the presence of albumin. This last reaction is of little diagnostic value except in cases of non-syphilitic meningitis.

Loculation syndrome. The chemical changes in the cisternal and lumbar puncture fluid are of diagnostic value and constitute the syndrome. The fluid stagnates below on obstruction in the spinal cord and the following changes are found:—(1) Increase of protein up to 3 or 4 per cent. (normal being 0.02 per cent.). (2) Xanthochromia due to mixture with the fluid of the extravasated blood pigments from the congested meningeal vessels. (3) Spontaneous clotting due to increase of the fibrinogen element in the fluid. The above changes sometimes are known as 'From's syndrome' but From described a pleocytosis in the fluid as a characteristic feature, rather than an increase in the protein. The removal of the cerebrospinal fluid is of greatest value both diagnostically and therapeutically. Lumbar puncture was the only method adopted for the purpose, but now other situations may be utilised also.

VENTRICULAR PUNCTURE. It is a difficult operation for which considerable skill and special knowledge must be available. The main cavity of the lateral ventricle is situated close to the middle line and about 4 or 5 cm. in front of the upper end of the Rolandic fissure. It may be reached by puncturing the skull with a drill and introducing the needle 1 cm. from the middle line, and directing it downwards and slightly outwards.

CISTERNAL PUNCTURE. Theoretically, the ideal place for obtaining cerebrospinal fluid is one or other of the lateral ventricles because there the fluid is formed and is found in the greatest quantity, but to enter the chamber is difficult at an age when the anterior fontanelle has closed. This operation is undertaken in cases of inoperable cerebellar tumours, for the relief of severe headache and vomiting as well as threatening blindness, and injection of drugs and various other substances into the ventricles as for ventriculography. The cisterna magna (cisterna cerebello-medullaris) is the next largest collection of cerebrospinal fluid

and its drainage was first performed by an open operation by Parker in 1893. Cisternal puncture is formed when lumbar puncture is impossible owing to some spinal deformity, when repeated lumbar punctures fail to yield fluid, which may be either due to faulty technique, or occlusion of the subarachnoid space by post-inflammatory adhesions or tumours above the puncture level; when the lumbar puncture fluid is mixed with blood from injury of the venous plexus in the vicinity and where the cerebrospinal fluid is urgently needed for chemical and cytological examination and lastly the operation is helpful in localisation of spinal tumours (myelography). In cases of coma from hypnotic drugs, particularly with the barbituric acid group, Purves-Stewart and Willcox found that while lumbar puncture failed either to reduce the drug-concentration of the fluid or to rouse the patient, cisterna puncture not only reduced the concentration of the drug in the cerebrospinal fluid but also restored the patient to consciousness and brought about a cure. Similar treatment is also indicated in cases of coma due to endogenous toxins as in uræmia and eclampsia. In meningitis, the introduction of sera into the subarachnoid space of the brain through a cisterna puncture is more efficacious than through a lumbar route.

Technique. The patient is either sitting up or lying on one side. The tip of the spinous process of the axis is felt and after sterilizing and anæsthetizing the skin a graduated cisterna puncture needle is inserted in the middle line, just above the tip. It is then pushed forwards and upwards in the direction of the line joining the external auditory meatus with the glabella. A slight increased resistance is felt when the atlanto-occipital ligament is reached at a depth of 4 to 5 cm., and pushing the needle slightly forwards the cisterna cerebello-medullaris is reached. It must be noted that the medulla oblongata is situated about 2.5 to 3 cm. from the atlanto-occipital ligament and there is very little chance of any accident happening if the needle is never pushed beyond the 6 cm. mark.

LUMBAR PUNCTURE. The technique is simple. The skin at the level of the third and fourth lumbar interspace (the spinous process of the fourth vertebra is on a line joining the highest points of the iliac crests) is carefully sterilized. The patient sits up or lies with his body well flexed. A stout lumbar puncture needle is then inserted in the fourth interspace, either in the middle line or one-third of an inch from it; it must be pointed forwards with a slight inclination upwards. If the bone is encountered, the needle must be withdrawn and reinserted at a slightly different angle. In cases of repeated failures, the third interspace may be tried. In the adult the canal is reached at a depth of 2 to 2½ inches and in children 1 to 1½ inches.

Contra-indication for lumbar puncture is tumour at the base of the brain as release of the fluid may result in a sudden pushing down of

the brain on the medulla causing cessation of respiration and other vital functions.

After the puncture the patient should drink sufficient water during the following few hours and remain in a horizontal position for 12 hours. Severe headaches following lumbar puncture are not uncommon; an intramuscular injection of pituitrin by increasing the secretion of the cerebrospinal fluid promptly relieves the headache in most cases; so also intravenous injection of 100 c. cm. of normal saline solution.

LIPIODOL IN SPINAL CORD COMPRESSION. Since lipiodol was introduced in 1921 by Sicoid of Paris, considerable use has been made of it for the localization of the level of subarachnoid block. Although a skilled neurological examination will correctly localise the level of compression, a lipiodol injection would indicate the exact site, which may be important from the point of view of surgical interference. Difficulties may arise in the interpretation of the results and it must be remembered that a false arrest of the lipiodol may occur due to meningeal adhesions.

Indications. The common indications for lipiodol injections are new growths of the vertebræ, new growths of the extra dural space meninges, nerve roots or spinal cord, inflammatory thickenings or cicatrizations resulting from traumatic hæmorrhage, and syphilitic or suppurative meningitis. In fracture dislocation of the spine or spinal caries, however, a lipiodol injection seems hardly necessary, although recommended by some authorities.

Articles required for the technique consists of a lumbar puncture needle, a lipiodol syringe to fit the needle, lipiodol, hypodermic syringe, sterile novocaine solution 2 per cent., iodine and cotton wool.

Lipiodol is a 40 per cent. solution of iodine in poppy oil and is opaque to X-rays. It can be injected by cisternal or lumbar puncture. The latter method is safer and is recommended in preference to the former by Sharp and Peterson. The patient should lie on his left side, with buttocks raised, and head and shoulders depressed. A lumbar puncture is made in the usual way, and 1 c. cm. of lipiodol injected into the theca with a lipiodol syringe. The patient is then tilted so that the heavy lipiodol may gravitate upwards. X-ray photographs are taken immediately after the injection. If the lipiodol be held up by an obstruction, the skiagrams are repeated at the end of six hours, twenty-four hours and a week, to see if the level alters. Lipiodol once introduced remains unabsorbed for a long time. As a rule, it settles down in the caudal region and gives rise to no symptoms. Sicard and Foreste (1923) state that the lipiodol does not adhere, and can be removed by lumbar puncture, if desired, after several days.

CHARACTER OF THE CEREBROSPINAL FLUID IN PATHOLOGICAL CONDITIONS

Type of case	Amount easily removed and pressure in mm. H ₂ O	Cells per c.mm. and type	Total protein per cent.	W. R.	Colloidal gold reaction	Reaction pH	Urea, mgm. per 100 c.cm.	N. P. N., mgm. per 100 c.cm.	Chlorides, mgm. per 100 c.cm.	Sugar, mgm. per 100 c.cm.
Normal	7 to 10 c.cm. (child) 90 mm. (adult) 150 mm.	1 to 5 mononuclears	0.015 to 0.03	-	-	7.45	20	25	730 to 750	100
Meningococcal meningitis	30 to 50 c.cm. 300 to 700 mm.	50 to 3,000 polymorphs	0.05 to 0.5	-	+ Meningitic curve	6	30	35	650 to 700	0 to 30
Acute anterior poliomyelitis	10 to 50 c.cm. 300 mm.	10 to 100 polymorphs, later mononuclears	0.05 to 0.2	-	-	7.45	20	25	720 to 750	100
Tuberculous meningitis	15 to 30 c.cm. 300 to 700 mm.	30 to 400 mononuclears	0.05 to 0.25	-	+ Meningitic curve	7	35	40	500	6 to 40
Loculation syndrome	Varies	Varies with cause	0.1 to 0.4	Varies with cause	Varies with cause	7.45	50	45	680	70 to 100
General paralysis	7 to 20 c.cm. 160 mm.	10 to 50 mononuclears	0.05 to 0.1	+	+ Parietic curve	7.45	20	25	720 to 750	100
Cerebrospinal syphilis	7 to 20 c.cm. 160 mm.	10 to 50 mononuclears	0.05 to 0.08	+	+ Luetic curve	7.45	20	25	720 to 750	100

CHICKEN-POX. It is an acute infectious disease characterised by a rash which appears in successive crops, each lesion passing rapidly through a papular stage to one of superficial vesiculation and subsequently to partial pustulation. The lesions ultimately desiccate with formation of scab.

The disease is of world-wide distribution and affects children mainly though adults may be affected. The incubation period is generally about three weeks. In children, the day of appearance of rash is considered to be the first day of the disease, but in adults prodromal symptoms such as malaise, pains all over the body and slight pyrexia might precede the appearance of the actual rash. The rash appears in crops on successive days; first on the trunk but it soon invades the face, scalp and proximal parts of the limbs, the distribution in case of the limbs being from below upwards, the lesion being sparse and small on distal parts.

The lesions start with macules and successively pass to papules and vesicles and ultimately end in pustules. Slight pyrexia always accompanies the appearance of the rash, though sometimes an apyrexial course is met with.

Complications such as slight bronchitis, arthritis, an acute nephritis (though rare) and nervous symptoms are met with.

TREATMENT. The patient should be always isolated in bed in the pre-eruptive and the early eruptive stage till all scabs have completely separated. An alkaline diaphoretic mixture is given along with administration of copious fluids such as barley water, fruit juice, plain water and glucose during the acute stage of the disease. Regulation of the bowels is necessary. Skin irritation may be allayed by mild dusting powders and the patient should be prevented from scratching the pocks. Hot boric compresses should be applied to inflamed parts. Crusts may be removed by starch poultices and subsequently mercurial ointment may be applied. Gangrenous varicella may be treated by warm baths (containing weak phenol solution) followed by application of lotio hydrarg. perchlor. (1 in 2,000). During convalescence a nutritious but easily assimilable diet and a tonic containing iron, strychnine, phosphates, etc., should be given. A change of climate will be beneficial if the patient can afford it.

CHOLERA. See page 854.

CIRCULATORY FAILURE. This is a state of collapse due to failure of the function of the cardiovascular system resulting in a diminished cardiac output and a fall in blood pressure. Two forms of circulatory failure are recognised, a central cardiac type with impairment of the ventricular propulsive force and a peripheral vascular type where the heart does not receive an adequate venous return. The first type is associated with myocardial damage and in the second type, a distinct lesion must be present in the peripheral vascular system, though one is

dependent on the other. Sudden impairment of the coronary circulation might also precipitate the condition.

Acute cardiac failure. Formerly acute dilatation of the heart was thought to be the chief causal factor in acute cardiac failure but electrocardiographic findings and radiological observations do not support this. Dilatation of the heart is a rather gradual process as a result of chronic continued failure. Intervention of a sudden abnormal rhythm is responsible for impaired functional activities of the ventricles. Ventricular fibrillation in which each muscle fibre is having its own rhythm and in an incoordinated manner, is a potent cause of sudden death as in angina, coronary thrombosis, during chloroform anaesthesia and in digitalis poisoning. Symptoms such as syncope, dyspnoea, cardiac pain, etc., in sudden ventricular failure have led to the recognition of the following clinical types :—(1) *Cardiac syncope.* Abrupt fall in blood pressure leads to cerebral anaemia resulting in loss of consciousness. The condition is also met with in coronary thrombosis and disturbed rhythm of the heart. Syncopal attacks are liable to occur if the ventricular rate falls below twenty a minute. In Stoke-Adams syndrome, a series of symptoms, such as faintness, a giddiness and pallor appear and may even end in complete loss of consciousness. Injection of 0.5 c.cm. of adrenalin (1 in 1000) might cut short such an attack. A long needle is pushed through the fourth intercostal space, keeping the needle close to the sternal border, until the cavity of the right ventricle is reached and a little blood is withdrawn to see that the needle is inside the cavity of the ventricle. The drug is then injected into the cavity of the heart. In sudden stoppage of the heart during chloroform anaesthesia, massage of the heart through an abdominal incision is of great value while artificial respiration is resorted to.

Cardiac failure with pain. Coronary thrombosis is the cause of sudden death in this condition. There is a severe and prolonged seizure with shock, pallor, subnormal blood pressure and temperature. Diagnosis is made by an electrocardiogram. Morphia ($\frac{1}{4}$ gr.) should be injected to relieve the pain and may be repeated if required. Absolute rest, warmth and small doses of brandy should form part of the treatment. Nitrites are useless and strychnine is of little value. Digitalis should be prescribed in cases of congestive failure and in auricular fibrillation. Intravenous administration of glucose helps in the nutrition of the myocardium of the heart. Oxygen therapy is most beneficial in dyspnoea or cyanosis. After the acute stage, rest in bed is imperative.

Acute cardiac dyspnoea. Cardiac dyspnoea is a sign of left ventricular exhaustion in hypertensive heart disease, less often in coronary disease or syphilitic aortitis. Sudden pulmonary engorgement precipitates the attack. Cardiac asthma is usually nocturnal with symptoms of cyanosis, pallor, tachycardia and rapid breathing but without bronchial spasm. Pulmonary embolism also causes sudden dyspnoea, cyanosis and collapse. Injection of morphia ($\frac{1}{4}$ gr.) combined with atropine (1/1000

gr.) is often known to relieve the distressing condition. Withdrawal of 10 to 15 oz. of blood by venesection also improves the condition and particularly in pulmonary oedema. A severe case might necessitate an intravenous injection of strophanthin (1/100 gr.). After the acute stage, prolonged rest in bed and a course of digitalis by mouth are necessary.

Palpitation. Paroxysmal tachycardia may cause faintness, dyspnoea, præcordial pain or even syncope. If the myocardium is badly damaged, acute failure may suddenly develop. The attack can be cut short by inducing vomiting or by pressing over the carotid sheath in the neck. Injection of morphia ($\frac{1}{4}$ gr.) may relieve the condition. If signs of chronic heart failure develop, complete digitalisation of the patient may be necessary. Intravenous strophanthin (1/100 gr.) is of great value in acute failure. If diagnosis of tachycardia of ventricular origin is confirmed by electrocardiogram, quinidine sulphate in 5 gr. doses is given by mouth and the dose is repeated hourly up to a total of 30 gr. or until the attack ceases. In very urgent cases, quinidine has been given intravenously.

Peripheral vascular failure. Paralysis and subsequent dilatation of the peripheral vessels resulting in stasis of the circulating blood in the splanchnic area, is the principal factor in peripheral vascular failure. The heart does not receive an adequate amount of blood to contract upon, the myocardium bears the brunt and the nutrition of the heart suffers. This vascular paralysis may be central in origin or may be due to a direct toxic action of histamine-like bodies on the vessels themselves. It is seen in surgical shock, after severe injuries, hæmorrhage in certain toxæmias and in diabetic coma; the common symptoms are subnormal blood pressure, pallor, cold extremities, sweating, sighing respirations and extreme prostration.

Clinical types. (1) *Fainting.* This is a type of transient vascular failure, the main feature is cerebral anæmia resulting in loss of consciousness. Stimulation of the parasympathetic system predominates in such a condition and the loss of consciousness is gradual. Ultimate recovery is the rule though the blood pressure keeps down for some time. It is met with both in the young healthy individuals as well as in elderly people with organic disease of the heart. Emotional stresses, fatigue, ill health and menstrual periods in women often precipitate attacks. It sets in in persons while standing and never in bed while resting as in epilepsy.

(2) *Vaso-vagal attacks or Gower's syndrome.* The onset of syncope is more gradual and more prolonged preceded by psychical disturbances like epileptic aura. As regards after-effects of the syndrome, prostration is more marked, consciousness is impaired and sometimes syncope recurs. The condition is mostly seen in the middle aged with a nervous disposition. A history of previous attacks and the absence of signs of organic heart lesions confirm the diagnosis.

TREATMENT. *Peripheral failure.* The underlying principles of treatment should be to increase the volume of the circulating blood, to restore vascular tone and to lessen cerebral anæmia. The treatment is the same as for shock; the foot end of the bed should be raised and bandaging the limbs may prevent venous stasis and facilitate venous return to the heart. The patient should be kept warm under blankets or with an electric bath, where available. Fluids, in any form, should be administered orally and parenterally, to increase the blood volume. Normal saline with glucose serves the purpose best. In cases, where hæmorrhage is a causal factor, blood transfusion is imperative. As there is no organic damage of the heart, the digitalis group of drugs are useless. Of the drugs, having a local action on the vessels, adrenalin ($\frac{1}{4}$ to 1 c. cm.) and ephedrine ($\frac{1}{4}$ gr.) occupy foremost position. Injection of strychnine may be tried and injections of postpituitary preparations are of particular value in these cases. Cardiazol-ephedrine in 1 c. cm. doses is also effective. Between the attacks, sedatives like bromides or luminal should be prescribed.

Gradual heart failure. Gradual heart failure is apt to supervene in a case of old-standing valvular or myocardial disease. In the management of such a case, the chief indication is to prevent or delay the onset of failure. In order to prevent breakdown of compensation and heart failure, the patient's mode of life must be regulated. Over-exertion is particularly to be avoided and the patient should not do more than he can do without getting out of breath and this is true for the myocardial cases particularly. At least nine hours a day should be spent in bed. The diet should be one designed to keep down body fat and fluids to a minimum and also to prevent flatulence as far as possible. It should be a dry spare diet from which articles rich in cellulose (vegetables and raw fruits) are eliminated and in which starchy foods are restricted. Crisp toast and rusks should be substituted for bread and potatoes should be taken very sparingly. The chief meal should be in the middle of the day. The most useful drug to obviate failure is digitalis. It is indicated in cases of myocardial degeneration with threatened failure (senile heart in elderly individuals) and also in cases of mitral disease with auricular fibrillation; 10 min. of the tincture of digitalis thrice daily is often effective in senile cases especially. In patients with high blood pressure, potassium iodide may be given combined with digitalis. When compensation has actually broken down and failure has supervened, the indications for treatment are:—to rest the heart by lessening its work, to remove peripheral obstruction to the circulation such as dropsy, to increase the force of the systoles and to prolong the diastoles thus improving the efficiency of the contractions and lengthening the resting time of the heart. Complete rest in bed is imperative. Diet should always be restricted in severe cases of heart failure. In such cases fluids are badly borne and milk about 2 pints a day may be allowed. Digitalis should be given in efficient doses (1 to $1\frac{1}{2}$ dr. of the tincture daily) and if there is

much dropsy, diuretics may be combined with it. The following is a useful prescription in cardiac dropsy :—acetate of potassium 20 gr., tincture of digitalis 15 min., lemon syrup 1 dr. and infusion of scopolarium to 1 oz., make it to 6 oz. and one-twelfth part to be taken with a little water every four hours. The signs and symptoms due to cumulative effects of digitalis should always be watched for in these cases. To relieve congestion of the liver, mercury may be combined with digitalis as powdered digitalis, squill and pill of mercury each 1 gr., one pill to be taken every four to six hours. Diuretin is an effective diuretic in doses of 10 gr., three times a day. Symptomatic treatment is given to allay irritability of the stomach, to promote sleep and to relieve the bowels. Vomiting may be allayed by a bismuth mixture. For the promotion of sleep there is nothing better than morphia and these patients stand morphia well. To promote the action of the bowels a mercurial at night followed by a saline purgative in the morning is very effective, particularly in cases accompanied by dropsy. Mechanical removal of the dropsical fluid by Southey's tubes or by acupuncture has to be resorted to sometimes. In cases of cyanosis, continuous inhalation of oxygen is indicated. If there are signs of engorgement of the right side of the heart, venesection and withdrawal of 15 to 20 oz. of blood should be done.

CLIMATIC BUBO, LYMPHOGANULOMA INGUINALE AND ALLIED CONDITIONS. See page 1009.

COMA. It is a state of unconsciousness from which a patient cannot be roused by ordinary means. The chief causes are head injuries, the effects of drugs like opium and alcohol, diseases such as epilepsy, uræmia, diabetes mellitus, cerebral diseases including vascular lesions, tumours, abscess of brain, meningitis and encephalitis, acidosis, malignant malaria, and terminal stage of many other diseases.

DIAGNOSIS. (1) Inquire into the previous history of the patient particularly with regard to the presence of renal and cardio-vascular disease, diabetes mellitus and epilepsy. (2) Inquire into the habits of the patient regarding alcohol and other drugs. (3) Ascertain the nature of onset of coma whether sudden or gradual, whether associated with injury of the head or convulsions. (4) Examine thoroughly the comatose patient regarding age and general build, general appearance, nature and type of the breathing, abnormal odour in breath, presence of blood on lips, other external signs of injury, condition of the pupils as to size, reaction to light, etc., condition of the cardiovascular system including blood pressure, any evidence of paralysis of the face and limbs. Test the various reflexes. Examine a specimen of urine (catheterise if necessary) for sugar, albumin, casts and ketone bodies. Do a lumbar puncture. Do an ophthalmoscopic examination of the fundus oculi for optic neuritis, albuminuric retinitis and hæmorrhages. Record tempera-

ture and save all vomits. Examine the blood, especially for malarial parasites.

Different types of coma. **ALCOHOLIC COMA.** This coma is rarely deep or complete; pupils are equal or dilated; conjunctival reflex is usually present; breath has alcoholic smell; inco-ordination of movements, but no paralysis.

Treatment. Wash out the stomach and administer stimulants. Treat according to symptoms.

EPILEPTIC COMA. History is very important, as epileptic fit precedes coma. Consciousness is completely lost, pupils are inactive to light and conjunctivæ are insensitive.

Treatment. The immediate treatment consists in loosening the patient's tight clothing, collar, etc., and removing false teeth, if any. It is useless to try and arouse the patient. If there is collapse, stimulants may be given.

URÆMIC COMA. (1) History of previous kidney disease. (2) Prodromal symptoms such as headache, nausea and vomiting. Patient is more drowsy than comatose; there may be convulsions. (3) Respiratory difficulty, breathing may be 'hissing' or Cheyne-Stokes type (Renal asthma). (4) Urine contains albumin and casts and the quantity is scanty. (5) Blood pressure may be high. (6) Blood urea and non-protein nitrogen are high. (7) Examine fundus oculi.

Treatment. Do a venesection and remove as much as 15 to 20 oz. of blood thereby reducing the amount of circulating toxin. Administer intravenously nearly the same amount or a little less of normal sterile saline with glucose to further dilute the circulating toxin. Administer normal saline with sodium bicarbonate and glucose per rectum. Do a lumbar puncture to reduce cerebral oedema. Prescribe compound jalap powder to be followed by a saline purge for free purgation. Hot air bath by electric cage for sufficient diaphoresis is needed. If the patient can swallow, prescribe alkaline mixture with calcium diuretin. Linseed poultice or dry cupping over the lumbar regions, to facilitate the secretion of urine, is useful. To control the spasm during convulsions administer a few whiffs of chloroform. Chloral hydrate and bromides are given to keep the patient quiet; nitrites are given if the blood pressure is high. Morphine should be cautiously administered to check restlessness and delirium and to prevent recurrence of the uræmic fits. Calcium lactate may be given if vomiting and hiccough are present. Diet should be very low in proteins.

DIABETIC COMA. See page 1049.

APOPLECTIC COMA. May be due to (a) cerebral hæmorrhage, (b) cerebral thrombosis, and (c) cerebral embolism.

Cerebral hæmorrhage. Diagnosis. History of the case, age of the patient usually 45 to 65 years. Onset is sudden and the coma is deep and progressive. The blood pressure is high and pulse is full and bounding.

The pupils are unequal and do not respond to light. There is conjugate deviation of eyes. The respiration is hurried, noisy, stertorous and may be of the Cheyne-Stokes type. Paralysis of the face, arm and leg on the side opposite to the lesion. Cerebrospinal fluid comes out under pressure and is mixed with blood.

Cerebral thrombosis. History of the case, onset is gradual, the patient is conscious; the cerebrospinal fluid does not contain blood. Occurs at early age

Cerebral embolism. Diagnosis. History. Onset is sudden; evidence of mitral stenosis, infective endocarditis or any other source of emboli; consciousness usually not lost; occurs in early life.

COMA DUE TO HÆMORRHAGE INTO THE PONS. Crossed paralysis, pin-point pupils and hyperpyrexia are present.

COMA DUE TO MENINGEAL HÆMORRHAGE. History of direct head injury, a latent period and then a coma.

OPIUM POISONING. History of the case, pupils contracted, breathing slow and Cheyne-Stokes type.

Treatment. Wash out stomach and examine contents. (See page 1453).

COMA DUE TO HYPERPYREXIA. This is an important cause in the tropics and commonly occurs in malignant malaria. Examine blood for the presence of the parasites. Coma due to hyperpyrexia after sunstroke is also common in the tropics (See page 218).

COMMON COLD. The catarrh affecting the nasopharynx, the larynx and the bronchial tubes is known as the common cold. One should not suggest a chill to be the exciting cause of the malady as has been very erroneously done by the laity. The inflammatory condition affecting the mucous membrane of the upper respiratory passages is attributed to external irritants and invasion by pathogenic bacteria. Inclement weather such as damp, cold and chill, by lowering the resisting power of the individual, very often predispose to microbic invasion of the parts. In all cases of acute common cold there is an infection by microorganisms such as the *Friedlander's bacillus*, *H. influenza*, *Bacillus septicus*, *Micrococcus catarrhalis* and pneumococcus, which may occur separately or combined. The condition is usually infectious and is very liable to pass from one member of a household to another. The infection induces inflammatory reaction and the catarrh primarily starts in the nose. Deformity and deflection of the nasal septum, the presence of a ridge or spur on the septum are causal factors, as these help in the retention of the secretions which keep up the infection. Recurrent attacks of cold in susceptible individuals render the nasal mucous membrane more susceptible to inflammatory changes. Children are more susceptible to colds than adults on account of variety of predisposing causes. The presence of adenoids is by far the commonest cause of nasal catarrh in children. Children brought up under bad hygienic conditions are predisposed to this malady. Deficient and stagnant ventilation and dusty

atmosphere also contribute a great deal towards the causation of this common disease. Any condition of faulty metabolism predisposes to nasal catarrh, but sufferers from gout, rheumatism, syphilis and diabetes, are very liable to it. In women anæmia and pelvic troubles are important predisposing factors. Neurotic individuals of the vagotonic type supply many cases.

TREATMENT. All nasal abnormalities should be corrected by surgical operation. Adenoids in children should always be removed and such measures often cure the complaint unless chronic catarrhal changes have supervened. General treatment is useless unless such abnormality is properly dealt with. As regards extranasal causes, a careful search should be made into the general health, habits and hygiene of the patient. Clothing should be such as to promote the healthy action of the skin. Some form of exercise should be enjoined by the patient before the morning bath. When the site of infection is within easy reach of drugs, it is easy to abort an early attack. This is done by washing the microbes out of the part with a weak antiseptic lotion or normal saline, which is used both as a gargle and a nasal douche. The antiseptic lotion for the nasal douche should be comfortably warm (100°F.), alkaline in reaction and isotonic with the blood plasma. A useful prescription for this purpose is bicarbonate and baborate of sodium each 4 gr., benzoate of sodium 1/6 gr., oil of eucalyptus 1/12 min., menthol 1/24 gr., and water to 1 oz.; to be mixed with warm water and used as a nasal douche. It can also be used as a gargle. An efficient early treatment will cut short the attack and prevent the spread of the infection. Dobell's solution used as a nasal douche is often reputed to abort early cases of whooping cough. The formula is bicarbonate and baborate of soda each 30 gr., listerine 2 dr., glycerine 6 dr., and water to 1 pint. It is difficult to efficiently sterilise the parts when the catarrh starts lower down in the respiratory passages such as in the larynx. Oils such as eucalyptus, well-vaporized or atomized in a suitable apparatus and inhaled vigorously and frequently both through the mouth and nose are exceedingly useful. The household remedy of Friar's Balsam (1 dr. to a pint of hot water) inhaled from a wide-mouthed jug is very efficacious. A combination is oil of eucalyptus 20 to 40 min., menthol 10 gr. to 1 dr., liquid paraffin to 2 oz. can be used as a spray. Aqueous solutions in the form of sprays may also be used, and the following is a useful prescription:—bicarbonate and baborate of sodium each 5 gr., liquid carbolic acid 1/2 min., glycerine 20 min., and water to 1 oz., this is to be freely sprayed through the nostrils into the throat every four hours through an atomizer. In case of an acute attack rest in bed for a few days is imperative. During this time a mild mercurial purgative such as calomel in divided doses, followed by a saline aperient in the morning is very helpful. When constitutional disturbances such as headache and fever are present, Dover's powder 5 to 15 gr., or preparations of quinine are of special value. Quinine is said to be a general tonic after a cold

and the drug is sometimes taken as an effervescing mixture. A useful formula is: (A) Sulphate of quinine $2\frac{1}{2}$ gr., citric acid 10 gr., water to $\frac{1}{2}$ oz. (B) Bicarbonate of potassium 10 gr., carbonate of ammonia $2\frac{1}{2}$ gr., syrup 1 dr., and water to 1 oz. A tablespoonful of (A) to be added to two tablespoonfuls of (B) and taken while effervescing. Sedative expectorants are most effective during the acute congestive period when the cough is hard and accompanied by slight mucus. It is only when the congestion is relieved and the secretion is free that stimulating expectorant drugs should be prescribed. When the muco-purulent exudation is mainly tracheal cubes are held to be efficacious. The usual dose is 20 gr. of the powder given for the treatment of harassing cough.

As a local measure wool tampons in the nostrils impregnated with menthol and formalin relieve the obstruction and when the secretion is free a nasal douche is advisable. An oily solution containing thymol 3 gr., camphor 4 gr., menthol 10 gr., oil of cinnamon 4 min., liquid paraffin 1 oz. may be used in an atomizer for a spray inside the nasal cavity in case of swelling and irritation of the mucous membrane. A hot bath or a hot wet pack is very useful in the treatment of the common cold. The underlying idea is to induce copious perspiration by such processes. Two or even three of these packs may be given in a week. The diet in the acute stage of the disease should be liquid; an active preparation of vitamins B, and D are useful adjuncts in the dietary. Ultra violet rays have been suggested by some to be efficacious in acute and chronic catarrh both locally and generally. For vaccine therapy see page 773.

Following are useful prescriptions in common cold:—

Chlorine mixture. Chlorate of potassium 50 gr., hydrochloric acid 30 min., syrup $\frac{1}{2}$ oz. and water to 1 oz. Allow the chlorate to stand in contact with the acid in a stoppered bottle for ten minutes and then add some water and shake. The dose is two or three dr. in 1 oz. of water for an adult. It should not be given more than three times a day lest methæmoglobinæmia may supervene.

Coryza mixture. Salicylate of sodium 6 gr., compound tincture of chloroform and morphine 5 min., chloride of ammonia 5 gr., compound tincture of cinchona 1 dr., tincture of catechu 15 min., syrup of tolu 30 min., liquid extract of nux-vomica $\frac{1}{2}$ min., lemon syrup $\frac{1}{2}$ dr., glycerine 15 min., and water to 1 oz. The mixture should be kept in the dark and though the dose is 1 oz. it is better to take $\frac{1}{2}$ doses frequently after a few full ones.

Chloretone nebulant. Chlorbutol 15 gr., camphor 37 gr., menthol 37 gr., cinnamon oil 4 min., light liquid paraffin to 4 oz. To be sprayed frequently with an atomiser.

CONJUNCTIVITIS. Inflammation of the conjunctiva may be acute or chronic. It is due to a variety of causes such as smoke, irritant vapours, trauma, errors of refraction, etc. It also occurs in certain

constitutional diseases, but the most important is one of microbic origin, the common organisms being pneumococcus, gonococcus and certain bacilli. Conjunctivitis should therefore be considered as an infectious disease. The common symptoms are gritty sensations, photophobia, a purulent discharge and sticking of the eyelids in the morning.

TREATMENT. The diseased eye should never be bandaged, as the discharge should have a free drainage. Free lavage of the conjunctival sac should always be encouraged with a bland, non-irritating weak antiseptic lotion. Ordinary sterile, tepid, normal saline serves the purpose best, though boric lotion (10 gr. to an oz.), perchloride of mercury (1 in 5,000), Condy's fluid (1 in 2,000), etc., are also used. Irrigation of the diseased conjunctival sac should be repeated as often as possible, specially where a purulent discharge is present. Of the drugs prescribed as eye lotions zinc sulphate ($\frac{1}{2}$ to 1 per cent. or 2 gr. to an oz., argyrol (20 to 25 per cent.), protargol (2 to 5 per cent.), silver nitrate (1 to 2 per cent.) and tannic acid (1 per cent.) are most commonly used. Some are irritating and the selection of such drugs should be made to suit individual cases. Argyrol is very commonly used nowadays in the treatment of the common forms of conjunctivitis.

A few common types of conjunctivitis. (1) *Acute catarrhal conjunctivitis.* This is a muco-purulent type of conjunctivitis, the exciting cause is the pneumococcus. Argyrol should be prescribed in the form of eye-drops, three times a day early in the affection and later on zinc sulphate is used. If there is sticking of the eyelids on waking in the morning ointments of yellow oxide of mercury ($\frac{1}{2}$ to 1 per cent.), perchloride of mercury (1 in 3,000) or boric acid (B. P.) may be applied to the conjunctiva at bed time. (2) *Gonorrhœal ophthalmia.* The exciting cause of this type of conjunctivitis is the gonococcus and when seen in the new-born it is called *ophthalmia neonatorum*. The routine method of treatment in maternity practice is to instil drops of silver nitrate (1 per cent.) in the eyes of the new-born infant where infection is suspected. Free lavage of the conjunctival sacs with Condy's lotion (1 in 4,000) should be advised. Silver nitrate (2 per cent.) solution should be applied every morning to the everted lids which should be always kept clean and dry. It is highly infectious. (3) *Trachoma.* This is a very chronic form of conjunctivitis. The main treatment consists in the application to the everted lids of 2 per cent. silver nitrate in the early stages and of copper sulphate stick in the later stages of the disease. This should be done three times a week. It is also highly infectious. (4) *Phlyctenular conjunctivitis.* This is seen in debilitated children and the disease often runs a chronic course. Application of yellow oxide of mercury (1 per cent.) as ointment or dusting of calomel powder, once a day to the phlyctenules of the eye, is beneficial. The pupils should always be dilated with atropine ointment (1 per cent.) where the cornea is involved. The general condition of the patient should be improved with fresh air, nutritious and assimilable food, tonics and cod liver oil.

CONSTIPATION. It is essentially a functional disorder of the large gut and so is only a symptom, but the condition is so common that it is almost considered as a disease in itself. The treatment of the condition is more important as it is such an important aetiological factor in the development of so many chronic diseases that may lead to a fatal issue. Chronic intestinal stasis is also held responsible for the development of the symptom complex of auto-intoxication. Before adopting any special method of treatment either with drugs or with other recent physical agents, investigate thoroughly into the causes of the condition. The treatment of constipation properly considered is essentially a treatment of the patient himself rather than that of the disease, so that a careful and close scrutiny has to be made regarding his general habits, the quantity, quality and frequency of meals, any previous intestinal diseases, and the general muscular state and build of the patient. In the case of female patients, in addition to those already mentioned an enquiry should be made into the obstetrical history of the patient along with other associated symptoms.

In diagnosing the definite cause of constipation, the three types of colon with characteristic features have to be considered as the line of treatment differs accordingly.

Spastic colon. This is a vagotonic state of the large gut. The descending colon is hard, rigid, contracted and tender. The part is extremely irritable due to over purgation, faulty dietary, undigested irritating food particles and the spasticity is sometimes secondary to a septic focus elsewhere. Here constipation is irregular and response to purgatives is uncertain. The patient suffers from colicky pains and gaseous distension of the gut. The stools contain an excess of mucus and are sour smelling due to fermentation of food materials. *Atonic colon.* This state of the large bowel is seen in middle-aged people with neglected health. The abdomen is lax and pendulous. The constipation is persistent and motions are offensive due to caecal stasis and putrefaction of the protein portions of the diet. The diet also in these cases consists of a greater percentage of proteins which offer a poor stimulus to the colonic activity. *Dyschezia.* Hurst regards this to be a rectal condition, often associated with atonic colon, due to a failure of response to the desire for defaecation. The rectum is inattentive to the faecal mass and does not, in these cases, exert itself to evacuate its contents. Such a condition is generally associated with muscular damage, abdominal or perineal, or is due to some local conditions such as the presence of haemorrhoids or a growth which render defaecation painful and uncomfortable. Generally women with poorer musculature and sedentary habits suffer more than men. A local examination of the rectum in these cases is most essential before other causes are excluded.

• Radiograms are very helpful in diagnosing these conditions after a barium meal and also detecting other local conditions such as new growths in the colon or rectum.

Acute constipation. In acute obstinate constipation of a few days' duration and in the absence of any mechanical obstruction or inflammation, a pint or two of an ordinary soap-sud enema should in the first instance be always tried and, if no results follow, a compound enema consisting of castor oil, olive oil, tincture asafetida and oil of turpentine, followed again by another soap-sud enema sometimes gives encouraging results. This routine is of particular value where the abdomen is bloated due to gaseous distension of the coils of intestine. Injections of eserine or physostigmine sulphate have also been tried as a last resort in cases of acute constipation due to paralytic ileus and similar conditions. A full dose of castor oil is also worth trying in these cases.

Chronic constipation. In chronic constipation with signs and symptoms of autointoxication due to intestinal stasis, thorough irrigation of the gut is most helpful. Long-continued physical therapy with appropriate medicinal treatment and diet therapy are all that are needed for the treatment of such conditions. Habitual constipation is also a type of chronic constipation and the secret of treatment lies more in correcting personal habits and dietetic errors of the patient than by treating with ordinary purgative drugs. Laxatives like milk of magnesia, senna and liquorice powder at bed time followed by a small dose of an effervescing draught in the morning are helpful in these cases. No purgative drug should be taken for a long time.

In the atonic type of constipation, increase and maintenance of tone and contractility of intestinal muscles should be aimed at. Physical therapy is useful and sinusoidal currents are more beneficial in these cases than the treatment with drugs. A pill consisting of strychnine, aloin and belladonna is often prescribed in these cases. Increase in mass and fluid should precede an actual stimulation of the gut and salines may serve the purpose.

The spastic colon calls for atropine to normalize the function of the gut and the drug should be continued for some time. Vegetable purgatives, asafetida and benzyl-esters are also beneficial in these types.

Mineral oils are of special service when secretions are lacking and are very useful in all cases of stasis whether spastic, atonic or dependent on anatomic fault. In dyschezia, correct all local errors, if any, of the rectum. Of the purgative drugs, liquid paraffin, agar agar, senna, liquorice powder are often prescribed. The former two lubricate and facilitate the passage of the bowel contents and defæcation is no longer painful. Before instituting any line of treatment, a local examination of the rectum is most essential.

DIET THERAPY. Diet is the most important ætiological factor in the causation of constipation and is probably responsible for it in the majority of cases. A correction of dietetic errors with the institution of a proper diet therapy go a long way towards curing the condition,

particularly in chronic habitual constipation. In chronic constipation, physical therapy should go hand in hand with diet therapy and drugs should come in occasionally.

A complete and thorough enquiry is to be made into the food intake of the individual, its frequency, quantity and quality. The prescribing of a proper diet varies with the types of cases and so a case history is most important. In the atonic type, stimulation of the gut is necessary and hence the bulk of meals should be increased. The coarser cereals, brown bread, fresh green vegetables, salads, fresh fruits be taken in abundantly for this purpose. The daily fluid intake should also be large. The protein intake should be reduced, to limit putrefactive processes inside the gut. The supply of vitamin B and its storage inside the body should be freely encouraged in the treatment of these cases. In the spastic type of case, the intake of roughage is unsuitable, as it is not desirable to stimulate any further an already irritated bowel. Tough, stringy meat, coarse vegetables, fruits with pips and skins should always be avoided while the softer forms of meat, simpler fruits and vegetables are allowed in their place. Sugars favouring fermentation should be reduced. Feeds should include a liberal supply of dairy products, milk, citrated if necessary, cream, raw or lightly boiled eggs and butter, the idea being to soothe the bowel.

In dyschezia, increase in mass and quality should be aimed at. Feeds of a soft, oily and lubricant nature, such as butter, cream and fats should be taken abundantly. Proteins should be reduced with a corresponding increase in carbohydrates like cereals, potatoes, bananas and other forms of starch. The idea here is to lubricate the passage during evacuation of the contents of the gut.

PHYSICAL THERAPY. The co-operation of the patient with the practitioner is desirable in correcting the faulty personal habits of the individual. It is not sufficient to cleanse the bowel only once, but it must be kept clean to avoid subsequent complications following intestinal stasis. The necessity of a complete and thorough evacuation of the bowel, daily, cannot be overestimated. Hurries and worries of daily life are direct hindrances to response to the call of nature and these with other factors have sometimes deleterious effects on the intestinal activities of the individual. The intake of a tumblerful of cold water on waking in the morning sets off a gastro-colic reflex necessary for the purpose. The tone of the abdominal muscles should be improved both in young and elderly people with suitable exercises and massage. Sometimes the sitting posture at stool is faulty and this should be corrected. The intestines are slung from the back and a better adjustment and co-ordination of all the forces concerned in the act of defaecation are served only when the body is bent forwards or if possible, when one rests with the elbows on the knees.

The development of physical therapy in diseases is of recent origin and so also its application to the treatment and prevention of constipation. This line of treatment is of particular value in habitual chronic constipation where drugs and other therapy fail to correct the condition. It is also useful to convalescing patients or individuals with lax and pendulous abdomens where muscular effort is much reduced during the act of defæcation. Physical therapy only attains success in the hands of experts.

Massage. Abdominal massage and exercises for abdominal muscles have been practised for years and the technique has been improved and developed in the hands of Ling, the founder of the Swedish system of exercises. Along with massage proper diet therapy should be advised and the correction of other faulty habits of the individual should be aimed at as all these combined go a long way in curing chronic obstinate types of constipation. The massage of the abdominal wall is said to stimulate the sympathetic system and indirectly it promotes the tone of the intestinal muscles. The masseur should also pay some attention to the muscles of the back and pelvis. Results have been encouraging with simple massage of the part not lasting more than a quarter of an hour each time and repeated four times a week.

Special types of massage recommended for the purpose are (a) Colonic self-massage. (b) The folding exercise. (c) The pulling type. Regarding the details of the above types of massage, special treatises dealing with these should be consulted.

Exercise. In the tropics, the enervating influence of the climate makes people more ease-loving and they are quickly fatigued with a less amount of work than people inhabiting countries in the temperate zone. Though Indian types of exercises are varied and interesting, very few take them regularly. As people grow old, they give up all sorts of exercises and settle down to a sedentary life, thereby making a good base on which constipation can develop. They are often obese persons with a lax pendulous abdomen and without power of exerting the abdominal muscles during defæcation. Women folk in the tropics suffer most and of these particularly 'pardaneshin' ladies with sedentary habits. Damages to the perineal muscles and other accessory muscles concerned in defæcation during repeated parturitions are also contributory causes in the later development of constipation in those women. The Western system of exercises including those of Müller and Hornibrook may not suit people in the tropics, but even such simple exercises as walking, running, or swimming are not regularly practised by them. The neuromuscular system is never properly developed and with advancing years this is deranged and refuses to work properly resulting in intestinal stasis and similar functional disorders of the body system.

Electrical therapy. This is of immense value particularly in chronic types of constipation with weak abdominal muscles. Diathermy or artificial sunlight treatment is of real value and serves as a general sedative

tonic where the causal factors of constipation are overwork, worry, fatigue or illness. Regular interrupted faradic stimulation (in the form of Bergonie's chair) of the whole abdomino-perineal musculature is also a very effective form of treatment for chronic constipation. Sinusoidal current also serves the purpose where abdominal muscles have lost their tone. Of other electrical appliances used to strengthen and promote the tone of the abdominal-pelvic genital muscles, the rhythmic myotroph, Mortin Smart or Bristow coil, deserve a mention here. Electrical therapy should go hand in hand with other forms of therapy for the treatment of constipation.

Lavage treatment. Per rectum. The keynote of this particular type of treatment is to give the bowel time to rest after clearing away the stagnant debris. Of the various forms generally practised, the German Suda chair is the best and most effective though the Plombiere's, the American Suda chair and the two way methods with their applicability in different conditions of the gut deserve mention.

Lavage by the mouth or the water regime. The patient is asked to drink two tumblers of cold water on waking in the morning. The water intake may be increased to about a quart and the patient is then asked to lie on his left side for a quarter of an hour followed by five minutes on his right side before getting up. The water may be warmed a little to suit the patient. The patient may be allowed to take the purgative drug he is used to along with it. If during the early part of this treatment, the quantity of urine passed is increased after such water intake he should be advised to lie down on his side for a prolonged period of time. This treatment has given encouraging results though the underlying rational physiological process operating is not clear. This technique of water regime had been practised by physicians in the old days in the indigenous system of medicine and it is well worth reviving in modern times with the advancement of physical therapy.

Medicinal treatment. Drugs. The list of purgatives and the proprietary drugs on the market is enormous and the difficulty and confusion are mostly experienced by practitioners in the selection of the drugs. Attempts will be made to discuss a few important purgative drugs only in the treatment of constipation and only those that are generally prescribed in everyday practice by practitioners will be described.

Paraffin group. The paraffin group of purgative drugs is most extensively used for their harmless action and the absence of after-effects. They can be safely prescribed for the aged and the young alike and even in cases of full-term pregnant women. They are useful in chronic constipation and the action is purely mechanical, as a lubricant facilitating the passage of hard faecal masses. They are never absorbed and so there is no systemic effects. They have a certain amount of antiseptic action on the bacteria of the intestine. Their action is enhanced by combining them with cascara. The disagreeable effects

are leakage of the oil when flatus is passed. Very prolonged use is said to give rise to irritation and decrease of absorption of foodstuffs from the intestine. *Dose*—1 to 2 oz.

Agar agar. It is a colloid laxative acting purely mechanically by increasing the bulk of the contents of the bowel. It is not acted upon by digestive juices and is not absorbed. As it does not actually stimulate the peristaltic activity of the gut it should be combined with other mild laxatives in the atonic type of constipation. Its disadvantages are that it retards absorption of foodstuffs and favours the growth of bacteria.

Glycerine. It is generally used for rectal injections or is used in the form of a suppository. The action is due to irritation of the mucous membrane of the rectum and the drug causes evacuation of the lower bowel. The drug suits infants and young children where oral administration of a purgative is difficult and undesirable.

Castor oil. Of all purgative drugs castor oil is most extensively used and is a common household remedy for constipation. In chronic constipation in entero-intoxication and in diarrhoea due to indigestion and dietetic errors, the drug is most useful and helpful in thoroughly evacuating the bowel of its irritating contents. The oil should not be prescribed for continuous use in habitual constipation. The oil is not generally taken, as such, on account of its nauseating taste but is given as an emulsion flavoured and sweetened with some agent. Infants tolerate the oil better than adults. Castor oil itself is inert but is saponified in the gut by bile and fat-splitting pancreatic ferment to glycerine and fresh fatty acids. The remaining unsaponified oil supports the action mechanically by lubrication. Castor oil is a safe purgative and may be given in large doses since, as soon as a sufficient quantity is hydrolysed, the resulting cathartic action carries away the superfluous oil. The action begins in the duodenum and passes down through the jejunum into the ileum and colon. It produces thorough evacuation of the bowel and is therefore prone to be followed by constipation. *Dose*—1 to 2 oz.

Croton oil. The drug is a purgative of emergency for its prompt action and is of special use in apoplectic coma, in cerebral hæmorrhage and in lead colic when other purgatives fail to act.

Mercurials. Calomel is commonly used as a purgative drug. Because of its cholagogue property, the drug is often the cathartic of choice in an attack of acute indigestion accompanied by constipation with white pasty stools, coated tongue and other signs of biliousness. The drug should always be given in small repeated doses, $\frac{1}{4}$ to $\frac{1}{2}$ gr. every half an hour as it is changed to grey oxide inside the bowel exerting its cathartic effects, but when a large dose is given at a time, a portion of it is only so changed, the rest passing unaltered or being absorbed and exerting toxic effects. Calomel acts mainly on the small intestines, its action on the large gut being mild. It has a certain amount of antiseptic action and putrefaction in the intestine is decreased by its use as shown by decrease in the bacterial content of fæces and sul-

phates in the urine. A saline purgative should always be taken in the morning to ensure evacuation of the large gut. The drug should never be prescribed for habitual constipation for its repeated use might result in pyalism and other signs of mercurial poisoning.

Anthraces. Cascara sagrada is considered to be one of the best intestinal stimulants in the atonic type of constipation. It has the special advantage of maintaining a regular effect even with continuous and prolonged use. The main therapeutic action of the drug lies in improving the tonicity and excitability of the intestinal musculature. Griping after its use is rare and the tendency to after-constipation is slight. The dose can be slowly reduced tailing off finally to cessation. It may be safely prescribed even to pregnant women nearing term. Several palatable preparations are sold to suit the taste of patients and of these cascara evacuant (P. D. & Co.) is well-known. A teaspoonful in the evening produces the desired result in the morning.

Senna. It is a commonly used and useful vegetable cathartic producing copious stools in 8 to 10 hours. In habitual constipation, an infusion of senna pods (6 to 10 pods left overnight in a glassful of cold water) is an effective preparation evacuating the entire bowel without griping. The drug causes griping when prescribed alone and hence it is often prescribed with ginger, cinnamon and similar carminatives to prevent this. Senna mainly acts on the large intestines. Pulv. glycerrhiza compound contains this drug and sulphur and is specially advised for pregnant women and in cases of hæmorrhoids where ordinary defæcation is painful. It is best taken at night to act in the morning.

Rhubarb. The drug is more an astringent, bitter and stomachic tonic than a cathartic. It causes an evacuation of the offending putrefied foodstuffs due to indigestion, from the bowel and later on controls the diarrhoea by its astringency.

Aloes. The drug has limited applications. It should never be given in cases of hæmorrhoids and pregnancy as it produces a congestion of the sigmoid colon, rectum and the pelvic organs in females. It is especially useful in overcoming the constipation of hypochondriasis and melancholia. The action of the drug is slow and it causes griping.

Hydragogues. They are not common remedies against simple constipation. These drugs are particularly useful in general anasarca of the body, in dropsy of cardiac or hepatic origin, in congestive or inflammatory states of the meninges, cerebral congestion and hæmorrhage. Jalap causes griping and has constipating after-effects. The action of these drugs is too severe for them to be given alone and so they are prescribed in conjunction with other purgatives in various cathartic pills.

Salines. Salines are very commonly used in habitual constipation by elderly people in the form of some sort of effervescing drink on

waking early in the morning. These act by altering osmotic tension and increasing fluid retention or reducing its absorption from the gut. Salines should be followed by intake of a copious amount of plain water so as to increase the bulk.

Magnesium sulphate. It is a common household remedy and is an efficient evacuant producing several watery motions without any griping. The drug is of particular value in cleansing the bowel of offensive and poisonous materials, relieving cerebral congestion or general anasarca of the body. It is also used in cases of acute food poisoning, and indigestion. In lead colic, a prescription containing magnesium sulphate 1 oz., morphine sulphate $\frac{1}{4}$ gr., dilute sulphuric acid 30 min., and peppermint water up to 4 oz. is very useful. One tablespoonful of this with an ounce of water to be taken in every hour till free purgation sets in.

Atropine. The drug is most reliable and specially reputed for its specific vagotropic action and is very useful in the relief of spastic states of the intestine where the vagus is overactive. The drug tends to normalize the tone and contractility of the gut and cuts short the irregular spasms of the intestinal muscles. The pure drug is superior to belladonna and the commencing dose should not exceed 1/150 gr. and be repeated three times a day.

The importance of treatment of constipation in the tropics with so many varying ætiological factors cannot be over-emphasized. No hard and fast rules can be laid down for its treatment. The treatment essentially depends on the merits of the case. 'Treat the patient and not the condition' should be the idea of the practitioner. Drugs only help and probably very seldom cure such conditions. Correction of personal habits and the institution of appropriate diet and physical therapy are all that should be aimed at by general practitioners in laying down a general line of treatment of constipation.

Convulsions in children. The causes of convulsions are : (1) violent diarrhoea and vomiting, (2) in any pyrexia and corresponding to what would be a rigor in an adult. Older children are liable to fits at the onset of lobar pneumonia, pyelitis, or tonsillitis; (3) rickets especially between ages of one and a half and three years, (4) teething, phimosia and worms; (5) sometimes in congenital syphilis; (6) convulsions are common in tuberculous or meningococcal meningitis; (7) tetany (note Chvostek's signs) which may be stopped by injection of 1 per cent. calcium chloride solution intravenously. Chloral and bromide will prevent recurrence.

When the child is in a fit : (1) Try to check the convulsions. Put the child in warm bath and sponge its head with cold water and artificial respiration by gently squeezing the chest with the hand should be resorted to. Inhalation of ammonia is also beneficial; (2) prevent recurrence by potassium bromide in plenty of water, and (3) lastly investigate the cause and treat accordingly.

In adults convulsions may or may not be accompanied by loss of consciousness. (A) When consciousness is retained the causes are, (i) poisoning by drugs like strychnine, (ii) Jacksonian epilepsy, (iii) tetanus, and (iv) tetany.

(B) When consciousness is lost the causes of convulsions may be, (a) epilepsy, which may be treated by injection of sodium luminal 5 gr., or apomorphine 1/6 gr.; (b) Stokes Adam's disease, in which case intracardiac injection of 5 min. of adrenalin has given hopeful results, followed by subcutaneous injection of adrenalin four times a day or barium chloride 1 gr. by mouth three times a day to prevent recurrence, (c) poisons other than strychnine such as cocaine, chronic alcoholic poisoning, etc.; (d) cerebral hæmorrhage; (e) uræmia; (f) general paralysis of insane; (g) hypoglycæmic condition due to overdose of insulin (for treatment see page 1049); (h) eclampsia which is treated with chloroform, liquid glucose, etc.

Emergency treatment of fits accompanied by coma. (1) Prevent the patient from hurting himself, (2) do not attempt to hold him down, (3) put something between his teeth so that he may not injure his tongue, (4) loosen clothing and start artificial (Schafer's) respiration, (5) when convulsion ceases give large doses of potassium bromide in water to prevent recurrence of fits.

COUGH. It is one of the cardinal symptoms of the diseases of the respiratory system and is a valuable diagnostic sign of many diseases of grave prognostic importance. The common causes of cough are enlarged tonsils, adenoids and long uvula particularly in children, pharyngitis associated with dyspeptic conditions, laryngitis, and tracheitis. The coughs arising out of conditions affecting the lungs and pleuræ are those of acute and chronic bronchitis, acute pleurisy, pulmonary emphysema, bronchiectasis, pulmonary tuberculosis, fibrosis of the lungs and pulmonary neoplasms. The nature of the cough should always be studied as it gives a clue to the diagnosis of the particular disease, and proper treatment in time may save the patient from long years of suffering. The tonsil and adenoid cough is of a dry nature, the long uvula cough is also of a dry nature and occurs at night when the patient is in bed. The pharyngitis cough due to dyspeptic conditions tends to occur chiefly in the morning and is non-productive. The laryngitis cough is raucous in character, painful and often associated with hoarseness. In tracheitis, the cough is severe and is totally out of proportion to the physical signs found in the chest. The cough of acute bronchitis is painful and non-productive, of chronic bronchitis it is painless and associated with copious expectoration of mucoid and mucopurulent sputum. The cough in acute pleurisy is most painful, short and dry and is particularly common in the early stages of pneumonia when the pleuræ are involved. In pulmonary emphysema it is associated with a marked degree of dyspnoea and is non-productive.

It is paroxysmal and simulates a condition of asthma. The cough of early tuberculosis is dry and non-productive, and the presence of expectoration suggests that ulceration of the lung has taken place. When the tuberculous disease has advanced to the state of cavitation the cough becomes paroxysmal in nature and the patient attempts to empty the cavity. This type of cough is also met with in advanced bronchiectasis. The cough is almost incessant in cases of new growths in the lungs. In the early stages it is dry and hacking and later on associated with hæmorrhagic sputum. In cases of cardiac dilatation, the cough is painful and entails an effort on the part of the patient. The cough in cases of enlarged mediastinal glands, mediastinal neoplasms and aneurysm is paroxysmal in nature and later on it is of a mild type but irritating, persistent and non-productive. The true brassy cough is always a diagnostic feature of severe degrees of pressure. The reflex causes of cough include some local irritation in the ears or teeth, disorder of the gastro-intestinal tract, pericarditis and genito-urinary diseases in women, or after abdominal operations. It is dry, persistent and non-productive. The most important reflex cough in the adult is due to dyspepsia associated with a pharyngitis and it is typically a morning cough and is relieved by a large and copious expectoration. The habit cough of heavy smokers is familiar to all. The nervous cough is usually of a barking nature and is more distressing to others than to the patient. It is non-productive and is generally associated with nervous diseases. The hysterical cough is still more harassing and may be associated with hæmoptysis.

A thorough investigation into the personal and family history of the patient with a careful physical examination of the chest considerably helps the diagnosis. Skiagrams of the chest often detect hidden lesions. A local examination of the oral cavity, throat and the accessible portions of the pharynx and larynx should be made before the treatment is adopted.

TREATMENT. A correct diagnosis of the primary cause should always be aimed at for successful treatment. The indiscriminate use of anti-cough remedies may mask the true cause of the malady, which if early detected would have yielded a better result from the treatment. The treatment is both medical and surgical. The enlarged tonsils, uvula and adenoids should be removed under strict surgical asepsis. In pharyngitis secondary to dyspeptic conditions a correction of diet and avoidance of alcohol and tobacco in excess will do much more than the ordinary cough mixture. Rest in the recumbent position, fresh air, restriction of exercise and avoidance of fatigue should form the fundamentals of treatment. Warming of the bed in cold weather is of particular value in children. In the acute catarrhal stage, diet should always be liquid and warm feeds are better tolerated. Milk, barley, fruit juices and foods rich in vitamin A should be given. Heavy meals should

never be allowed to patients with chronic cough as these add to the distress of the patient during attacks of coughing.

Drugs. In selecting and prescribing proper expectorant drugs, the stage of the disease should be recognised. The drugs are classified as sedatives, stimulants and anodynes. The sedatives are useful in the acute inflammatory stage of the disease while the anodynes are of particular value in incessant cough which is ameliorated by the drugs. Sulphate of codeine ($\frac{1}{4}$ gr.) allays irritable cough from reflex causes. In combination with sedative expectorants, it is useful in excessive dry cough. Ammonium salts such as the chlorides and the carbonates increase the secretion of bronchial mucus. Terpene hydrate (3 to 5 gr.) lessens cough associated with excessive secretion. Tincture of belladonna and sulphate of atropine are useful drugs in whooping cough. Iodide of potassium (5 to 15 gr.), though a useful expectorant, should be prescribed with caution; bromides lessen the cough-reflex and are useful in whooping cough and hysteric cough. As cough is generally a manifestation of some constitutional disease, measures to promote general health should also be resorted to. Sometimes surgical measures to eradicate septic foci such as the removal of septic tonsils, or adenoid growths are of benefit. The following mixture is useful to lessen the congestion of the inflamed mucosa in laryngitis and tracheitis. Bicarbonate of sodium 15 gr., tincture of ipecacuanha 8 min., syrups of tolu and squill each $\frac{1}{4}$ dr., spirit of chloroform 10 min., and infusion of senega to 1 oz., one dose every four hours until the expectoration is free. In these cases compound tincture of benzoin a drachm to a pint of boiling water, to which 3 min. each of menthol and oil of eucalyptus have been added, serves as a useful inhalation. Warm olive oil applied round the neck may relieve the cough of laryngitis and tracheitis. The following mixture is useful in the early stages of bronchitis when the cough is painful and non-productive. Wine of antimony 15 min., chloride of ammonia 10 gr., spirit of chloroform 10 min., syrup of orange 40 min., camphor water to 1 ounce. The mixture should be discontinued as soon as the sputum becomes free. The following alternative mixtures are helpful in the later stages of bronchitis when expectoration is copious. (1) Carbonate of ammonia 5 gr., tincture of nux vomica 8 min., tincture of squill 15 min., and water to 1 oz. (2) Carbonate of ammonia 5 gr., tincture of squill 15 min., compound tincture of opium and camphor 20 min., and infusion of senega to 1 oz. The above mixtures are of the stimulating expectorant type. The following mixture is useful for children suffering from cough and where the expectoration is just beginning. Tincture of ipecacuanha 2 min., compound tincture of opium and camphor 5 min., nitrate of potassium 2 gr., honey 30 min., and water to 2 dr. The sedative drugs prescribed for the dry cough preventing sleep in tuberculosis cases are: (1) Heroin $\frac{1}{12}$ gr., syrups of virginian prunes and of codeine, each 30 min., and water to $\frac{1}{4}$ oz. (2) Heroin $\frac{1}{12}$

gr., codeine $\frac{1}{8}$ gr., dilute sulphuric acid 2 min., glycerine 10 min., syrup of tolu 1 dr. For these cases the useful drugs for inhalation include menthol 40 gr., creosote 40 min., rectified spirit $\frac{1}{2}$ oz.; a few drops of this to be sprinkled on a mask and inhaled for a few minutes. Drugs such as chloride of ammonia and antimony are helpful in loosening the sputum. Cardiac tonics such as digitalis, nux vomica etc., relieve the cough in fibrosis of the lungs associated with dyspnoea caused by failure of the right ventricle of the heart. The following is a useful combination: (1) Tincture of digitalis 5 min., carbonate of ammonia 5 gr., tincture nux vomica 5 min., spirit of chloroform 10 min., and water to 1 oz. Belladonna is invaluable in coughs where an antispasmodic effect is desired. The following is a useful prescription: Tincture of sumbul 15 min., tincture of stramonii 10 min., tincture of belladonna 5 min., spirit of chloroform 15 min., water to $\frac{1}{2}$ oz.

Useful local applications to the throat including the tonsils are: (1) Iodine 5 gr., iodide of potassium 10 gr., liquid carbolic acid 3 min., glycerine up to 1 oz. (2) Resorcin 40 gr., spirit of peppermint 5 min., glycerine up to 1 oz. These are useful for chronic pharyngitis. The paints are to be applied morning and evening daily with a sterile cotton wool swab.

Inhalations. Menthol $\frac{1}{2}$ dr., camphor $\frac{1}{2}$ dr., compound tincture of benzoin up to $1\frac{1}{2}$ oz. A teaspoonful of this mixture is added to a pint of hot steaming water and the vapour arising out of this is inhaled by the patient. A few drops of compound tincture of benzoin only may be added to hot water and the vapour inhaled. The drugs lubricate the respiratory passages and facilitate expectoration.

Sprays. Camphor 4 gr., oil of eucalyptus and peppermint, each 4 dr., paroline up to 4 oz. The mixture is used in a DeVilbiss spray for the nose and throat.

CRAMPS. These are painful spasms of the voluntary muscles resulting in temporary loss of function of the part affected. In most cases it is suggested that the condition is due to a deficient supply of blood which is not in keeping with the amount of work performed by the affected muscle. Such an explanation is applicable to cases such as intermittent claudication or angina cruris, where a spasm of the vessel wall precedes the cramps. The group of muscles affected presents signs of exhaustion and various factors are held to predispose to it. Overwork, cold, unfavourable environment, etc., are a few of the many predisposing causes. Compression of nerves is held to be an exciting cause in cases of cramp such as follows from sitting on the hard, sharp edge of a chair, badly fitting splints and the use of crutches. A very painful form, affecting often the abdominal muscles and lasting for a prolonged period is met with in individuals working in foundries amidst high temperature. In cases where body fluid is enormously drained out as in cholera and severe diarrhoeas, cramps are attributed to defective

circulation consequent upon the enhanced viscosity of the blood. Other common causes of cramp include chronic gout, chronic interstitial nephritis, anaemia, Raynaud's diseases, tetany, tetanus, strychnine poisoning, ergotism and the paraplegias. Cramp is very often met with in occupational neuroses where there is a disturbance of motor function and is particularly seen when some movements are attempted by individuals in the course of their occupations. It is generally associated with neurasthenia though actual neuritis, arterio-sclerosis of the vasa vasorum, etc., are met with in many cases which distinguish them from idiopathic occupation neuroses. The common forms are those of writers, telegraphists, violinists, typists, pianists, cigarette-markers, etc. It is also seen in the leg muscles of turners and lathe-workers, and in the face muscles of players on wind instruments, glass blowers, etc.

TREATMENT. The treatment of cases should aim at treating the primary causes. Rest, hot applications and baths, suitable massage and exercises are effective measures in the treatment. Antipyrin 10 gr., on retiring is often efficacious in troublesome cases. In occupational neuroses prolonged rest of the part is imperative and later on new methods of carrying on such occupations should be cultivated. Drugs are of little value in these cases and local treatment to the fore-arm and hand is often effective. Electrotherapy in the form of galvanic baths or galvano-faradism is often recommended. Hydrotherapy and other general measures should be adopted in neurasthenic cases. Saline infusion is of particular value in all cases of cramps and has been very lately advocated.

DEAFNESS. Of the various factors contributing to the causation of deafness, a large variety of pathological conditions, infective or bacterial in origin, grouped under 'chronic catarrh of the middle ear' is considered to be the most important one. Pathologically the changes include subacute or chronic sero-mucous inflammation of the mucosa of the Eustachian tube and middle ear. The resulting deafness is obstructive and progressive in type. The common causes leading to chronic catarrh of the middle ear are acute and chronic hypertrophic catarrhs of the nose and throat, adenoids, septic tonsils, infectious diseases such as measles, scarlet fever, diphtheria, etc. The condition often recurs and ultimately results in atrophy or in the development of adhesions within the tympanum. The chronic atrophic catarrh of the middle ear is generally ascribed to depressing conditions such as rheumatism, gout, cold, alcoholism and Bright's disease. Sometimes these middle ear changes in adults may be the after-effects of slight acute or subacute catarrhs in infancy and early childhood. Others hold the changes to be due to constitutional toxic processes or these may be secondary to bacterial infection in the sphenoidal and other nasal accessory sinuses. The prominent symptoms are tinnitus and progressive deafness. The tinnitus is continuous and persistent and varies in quality from time

to time. The deafness is obstructive in type and tends to get worse as time advances in defiance of treatment. The younger the patient is when the disease sets in, the more likely it is to end quickly in grave loss of hearing. The tympanic membrane in middle ear deafness is usually retracted, dull, lustreless, opaque and thickened. A similar clinical condition known as otosclerosis, or an ankylosis of the stapedio-vestibular articulation, is also an important cause of deafness. It is commonly known as ear-hardening and the ætiology is obscure. Tinnitus is the most distressing symptom in this condition and it is continuous and high pitched. Chronic middle ear diseases and otosclerosis often affect the internal ear resulting in lesions of the cochlea. Nerve deafness is very often associated with former conditions mentioned and in conjunction with the signs of nerve deafness, signs and symptoms of vestibular involvement are often met with. A long continued painful noise may be followed by deafness and nerve deafness results from prolonged exposure to noise in the course of an individual's occupation. This type of deafness seems to be due to the injurious action of the intense stimulus upon the organ of Corti as signs of degeneration are met with in it. This is an occupational disease met with among individuals working in the navy, artillery, boiler-making, etc. Other causes of deafness are fracture of the base of the skull, syphilis particularly during the secondary stage of the disease and also in the congenital type, epidemic cerebrospinal meningitis, mumps, typhoid fever, myxœdema, old age (senile deafness or presbycusis), drugs such as quinine, salicylates, arsenicals, etc., shell-shock, hysteria and neurasthenia.

TREATMENT. In treating middle ear deafness the primary causes should be treated first. The lesions of the nose and naso-pharynx should be promptly attended to. Adenoids and tonsils if pathological, should be removed, deflected nasal septa rectified, hypertrophied turbinates removed and suppurating nasal sinuses laid open for free drainage. Locally, the ears should be inflated every two or three days with Politzer's bag as this keeps the Eustachian tubes patent and aids in the expulsion of the retained tympanic exudate. After the acute stage has subsided, Eustachian catheterisation may be resorted to and vapourised iodine and camphor at a fairly high temperature may be passed into the tympanum through the catheter. In cold damp weather, the patient should keep himself warm indoors in an equable temperature. The patients' habits and mode of life should be regulated, unfavourable occupations changed and local irritants, such as tobacco and alcohol, should be avoided. Deafness due to fibroid changes in the middle ear and otosclerosis is difficult to cure. The distressing symptom of tinnitus can to some extent be relieved by ionization with silicon and calcium and by administration of parathyroid gland. Administration of iodide of potassium in moderate doses over prolonged periods is said to be an effective therapeutic measure in otosclerosis. Intestinal stasis should be treated on usual lines and iron administered

internally in those cases associated with anæmia, is said to yield hopeful results. Local treatment by catheter and by inflation is of no avail in genuine otosclerosis. The essential treatment in these cases is to re-educate the dormant centre of hearing and the best re-education medium is the human voice. This is carried out by means of a binaural speaking tube into which the patient reads aloud or is spoken to for a ten-minutes' sitting, three times a day. The more intelligent the patient is, the more rapid is the recovery of this power. Deafness is incurable in cases of true degeneration of the auditory nerve. In noise deafness people should plug the meatus with some material relatively impermeable to sound. This gives a partial protection as the sound can even then reach the cochlea through the bones of the body and head. In all cases people sensitive to noise should plug the ears when exposed to it. Concussion deafness and that arising from fracture of the base of the skull are irremediable. In syphilitic deafness, anti-syphilitic remedies, especially mercury and iodide of potassium, are of definite value. Politzer recommends hypodermic injections of a 2 per cent. solution of pilocarpine nitrate for eight to fourteen days in these cases. Pritchard reports great benefit from blistering the mastoid processes in congenital syphilitic deafness.

Prevention. On a review of the ætiology of deafness, it is noticed that, with the exception of congenital deaf-mutism and otosclerosis, it is an acquired condition. The problem of prevention resolves itself mainly into an early detection and correction of predisposing factors. Improper dieting, malnutrition, exposure to damp and cold tell upon the health of the growing child. The presence of adenoids and the germ-choked tonsils subject him to frequent colds and sore-throats and the Eustachian tube is subject to frequent and recurrent inflammations. The exanthemata, whooping cough, influenza, diphtheria and broncho-pneumonia are the most frequent causes in childhood. It is during the course of one of these fevers that the trouble generally arises in the middle ear. If the labyrinth is involved the hearing is completely destroyed. On the other hand, if the inflammation localises itself to the middle ear, a chronic otitis media results. As there is always a tendency for relapse in the catarrhal type of inflammation, children should be watched during the acute attacks of inflammation and measures adopted to bring about a complete resolution. In acute otitis media, myringotomy should not be delayed if the pain is very severe, and the usual conservative treatment affords no immediate relief. Persistent discharge from the ear, and deficient hearing are the most common and obvious indications for the removal of adenoids and tonsils. Nasal accessory-sinus diseases are not uncommon in children and should receive attention. Body resistance must be built up, dietetic errors must be corrected, and the general health improved. Further prophylactic measures lie in educating the general public and the

educational authorities. Preference must be given to hearing tests rather than disciplinary measures at school.

DENGUE. See page 987.

DIABETES. See page 1043.

DIARRHŒA. It is a very common complaint in the tropics. It should be regarded as a symptom, not as a separate disease. The general causes of diarrhœa include all factors which increase the fluid content of the fæces. It may be produced by (a) rapid passage of intestinal contents through the large intestine before the absorption of the fluid has been completed, or (b) by an excessive secretion of the lining membrane of the intestinal tract, or (c) both factors combined, because generally what causes increased peristalsis also stimulates secretion.

The individual causes of diarrhœa are:—(1) Dietetic errors. Ingestion of large quantities of food or fluid may produce diarrhœa from the (i) stimulus due to bulk, (ii) increase of fluid content of the gut, (iii) defective digestion, (iv) excessive fermentation, and (v) irritation.

The inhabitants of the tropics, especially the new-comers, are especially liable to this type of indisposition. Their digestive organs, especially the liver, are continually over-stimulated, producing *tropical liver*, which is characterized by attacks of hepatic congestion and hepatitis. Unsuitable food is a very frequent cause of diarrhœa in children. Milk is often a source of illness, as its supply is not always satisfactory. Too much over-ripe fruit or rich foods cause intestinal disturbance. (2) Specific organisms—dysentery organisms are frequently associated with tropical diarrhœas. The attacks usually alternate between dysentery relapses. Alternate constipation and diarrhœa is a common manifestation of chronic amœbiasis. Chronic Flexner infection often gives rise to protracted diarrhœa. *Bact. pseudocarinatus*, a mutated Flexner type (phage modified), is another cause, organisms of the Morgan group also cause severe diarrhœa; *Ps. pyocyaneus*, *Bact. faecalis alkaligenes* and *B. proteus* and certain types of streptococci may produce similar symptoms.

Outbreaks of diarrhœa due to food poisoning are not uncommon; tinned meats and rotten flesh or fish cause diarrhœa, Gærtner's bacillus being the organism commonly found. Certain helminths, especially schistosomidæ, cause intestinal irritation and diarrhœa. (3) Chemicals or mechanical irritants, e.g., salts arsenic, arsenic, certain waters (they contain salts and suspended particles of clay, mica, vegetable debris or some organic matter). (4) Diarrhœa associated with other diseases, e.g., intestinal disturbances are common in typhoid, undulant fever, kala-azar, relapsing fever and malaria; tuberculosis of the intestines and malignancy of the rectum cause diarrhœa. (5) Diarrhœa of unknown causation, e.g., sprue and hill diarrhœa, are tropical affections of this nature. See page 879.

Predisposing factors. Insanitary surroundings, over-crowding as in large cities, exposure to chill, prevalence of flies, etc., are important predisposing factors; low-lying, damp and badly drained places contribute to the disease. Such conditions together with high temperature, humidity and rainfall are favourable to the production of diarrhœa in endemic form. The morbid appearances depend upon the cause, the severity and the position of the irritative process. There may be (i) no visible lesion or (ii) only simple congestion of the lining layer, or (iii) actual ulceration may be present. In chronic cases the intestinal wall becomes thin and atrophic and the patient becomes emaciated and anæmic.

Symptoms depend on the cause of irritation and the part of the bowel involved. If the upper part of the small intestine only is affected the diarrhœa is not so watery but motions contain undigested food. If the large intestine is affected there is excessive mucus. The stools are greenish when bile is passed out unaltered. They are pale or white if diarrhœa is due to derangement of the liver. If there is excessive fermentation with gas formation stools become frothy and acid. There is inflammation about the anus if the stools are very irritating. In acute cases, fever, vomiting and pain in the abdomen may be troublesome; the patient becomes prostrated from dehydration and toxæmia. Asthenia, anæmia, emaciation, œdema of the feet, purpuric spots are met with in chronic cases.

DIAGNOSIS. It depends on the cause. (1) Repeated examinations of stools, macroscopic, microscopic and bacteriological, are very important. (2) Blood examinations especially in the early stages are advisable. (3) Agglutination of the blood against dysentery bacilli may be positive. (4) Wasserman's reaction if syphilis is suspected. (5) Rectal examination (ulcer, stricture, new growth) should never be missed in a chronic case. (6) Sigmoidoscopy should be done. (7) Barium meal and barium enema may give very useful information.

TREATMENT. (1) Rest in bed if the attack is severe. (2) Diet. No food for the first 12 hours; afterwards give albumin water, barley water, rice water (4 oz. every 2 hours); later milk, arrowroot, sago, and rice may be given. As recovery takes place give fish and eggs; meat and vegetables should be withheld until all traces of irritation have disappeared. In infants, if breast-fed and the milk is well digested, no change is necessary. If bottle-fed or if curds are found in stools, stop milk, keep on water for 24 hours, then give whey, 3 per cent. lactose or 10 per cent. dextrose solution. If there is too much fermentation give Bulgarian sour milk. In chronic cases give raw meat juice in teaspoonful doses; preparations of dried milk may be tried. (3) Drugs. (i) A preliminary purge, viz., castor oil or fractional doses of calomel followed by salts are helpful in early stages; (ii) later bismuth salicylas 10 gr. with Dover's powder 5 gr. or chalk mixture, or osmokaolin may be given to control the diarrhœa and allay pain. (iii) If motions are

acid and irritating apply alkalis and olive oil locally. (iv) For fermentation give salol 5 to 10 gr. or beta-naphthal 2 to 5 gr. (v) For indigestion add pepsin 10 gr. (vi) For vomiting, gastric lavage is useful. (vii) For collapse, warmth, stimulants and saline, preferably hypertonic, should be given. (viii) If diarrhœa is found to be due to a specific cause, treat accordingly.

Prophylaxis. (1) Food should be fresh and well cooked and without any irritants. (2) Milk and water should be pure. (3) Overfeeding and excesses are to be avoided. (4) Regular action of bowels and exercises are important. (5) Avoid chill and exposure to the sun. (6) Supervision of kitchen and servants is essential.

DIETS AND DIETETICS. See page 146.

DIET IN DIARRHŒA. In acute diarrhœa nothing but plain water or barley water is given for a day or so. When the symptoms have somewhat abated, weak decoctions of cereal preparations, *viz.*, arrowroot, sago, *chitra* are given. Milk is gradually added and then other non-irritating preparations.

In cases of chronic diarrhœa diet depends on the cause. If it is due to carbohydrate fermentation (acid stools) milk, casein preparations, soup, fish and meat (specially underdone) suit best. If, on the other hand, there is protein decomposition (alkaline offensive stools) the diet should consist of carbohydrates. If the stools are white, greasy and show fat droplets, fat should be withheld from the diet.

DIET IN DYSENTERY. Diet in infections with *B. Flexner*. For Europeans. Albumin water, whey, milk (citratd or uncitratd), starch-free prepared milk food like Allenbury's No. 1, Glaxo, etc., soup, boiled fish, lightly boiled or poached eggs, minced chicken, *Vita weat* biscuit, etc. For Indians. Indians depend mainly on milk preparations, such as whey, butter-milk, *dahi* and *chhana*. Whole milk (citratd or uncitratd), starch-free prepared milk food, albumin water, lean fish (boiled and flavoured with coriander, cloves and salt). Any article recommended for Europeans may be used by those Indians who prefer a meat diet.

Articles of diet commonly used but contra-indicated. Barley, arrowroot, sago, rice and sugar. Ordinary biscuits and bread are also unsuitable.

DIET IN INFECTIONS WITH B. SHIGA, B. STRONG, AND IN CHOLERA. Starchy protein-free diet, such as barley water, arrowroot water, sago and glucose water.

DIET IN TYPHOID FEVER. In the acute stage 1½ seers of milk is given daily, diluted with barley water or lime water in measured quantities at 2 or 3 hourly intervals. The nutrition value is increased by the addition of glucose, lactose, plasmon, cream, Horlick's, etc., to the milk. Tea and coffee may be allowed in moderation and the monotony of the diet varied by the addition of soup, broths and orange juice.

Plenty of cold plain water is given in between the feeds. Should intestinal discomfort occur or curds appear in the stools milk is citrated or peptonized. Milk is substituted by whey and albumin water if there is much diarrhoea or tympanitis. Such things as lightly cooked eggs, custards, bread-crumbs and milk, etc., may be given, if liked by the patient, in the absence of much toxæmia and complications.

DIET IN CHRONIC INTESTINAL STASIS. A bulky diet that leaves a large amount of residue is recommended. It includes oatmeal, green vegetables, wholemeal bread, fruits (especially prunes, figs, apples, bael), etc. Fats and oils are also increased in the diet. A glass of cold water should be taken early in the morning on rising.

MODIFIED SIPPY DIET The aim is to keep the stomach free from active hydrochloric acid. This is accomplished by giving a quantity of fat in the form of cream and olive oil, big doses of alkalies after and atropine before the feeds. Three ounces of a mixture of milk and cream, which may be citrated, are given every hour from 7 a.m. to 7 p.m. Eggs are added after two or three days, first in the form of egg-flip and later, lightly boiled. Well cooked farinaceous foods are gradually included in the diet after the pain has subsided. The amount given in each feed should not exceed 6 oz. Half an hour after each feed a powder containing sodium bicarbonate 10 gr., heavy magnesia 10 gr., is given alternately with a powder of bismuth carbonate 10 gr., sodium bicarbonate 10 gr. Half an ounce of olive oil is given immediately before alternate feeds, and atropine 1/100 gr., or tincture belladonna 5 min., immediately before the other feeds. The amounts of magnesia and bismuth may be so regulated that neither constipation nor diarrhoea results. Double and triple carbonate powders may be used alternately for this purpose, calcium carbonate being preferred to sodium bicarbonate as the former does not produce an increased secretion of acid in the stomach.

The after-treatment of gastric and duodenal ulceration is important, and certain guiding principles can be laid down.

1. Regular habits should be formed; meals should be small and the interval between them short (not more than 3 hours).

2. The teeth should be put in order and regular visits paid to the dentist. Food should be taken slowly and be well masticated.

3. The bulk of fluid should be taken between meals.

4. Take especially eggs, milk, custards, jellies, cereals, vegetables, bread, butter, cream, soft puddings, fish and biscuits. Take meat once a day, in small amounts, but avoid tough meat, high game, bacon and pork. A little light wine may be taken with food; salt should not be taken in excess. Smoke only in moderation and not before meals. Take the powders thrice daily and once in the night if awake.

5. Avoid highly seasoned food, cooked cheese, lemon juice, marmalade, pickles, spices; vinegar, acid fruits, strong tea, coffee or cocoa;

rough foods, very hot food, especially meat soups and any alcohol on an empty stomach. Starchy articles of diet that have been cooked in fat, e.g., fried potatoes and fried bread, should be avoided.

6. Regular action of the bowels is essential.

KETOGENIC DIET. It has very recently been introduced in medicine as a therapeutic measure in many diseases. It has been used with favourable results in chronic urinary infections, epilepsy, and migraine. The presence of ketone bodies in the urine has an inhibitory action on bacterial growth. The ketogenic diet contains a preponderance of fats over carbohydrates and proteins. When it is necessary to continue this dietary régime for a long time it is of paramount importance that the patient should receive an adequate amount of protein, vitamins and minerals in order to avoid a dietary deficiency syndrome. The proportion of fat to carbohydrate and protein combined is 2 to 1 or even 3 to 1. Such a diet may contain 40 gm. carbohydrate, 50 gm. protein and 180 to 250 gm. fat. The object is to produce a urine, the pH of which is between 5.1 and 4.9. If the diet produces nausea or otherwise disagrees with the patient, a small amount of orange juice and a short period of fasting will usually relieve these symptoms.

The effective bacteriostatic factor in the urine of patients on ketogenic diet is β -hydroxybutyric acid. Fuller has also shown that aceto-acetic acid and acetone have slight bacteriostatic power. Mandelic acid, a hydroxy-acid, is excreted completely unchanged in urine after oral administration and has been used in recent years to replace the ketogenic diet. The routine method adopted has been to give 12 gm. of mandelic acid daily in divided doses whilst the fluid intake is limited to 2 pints. As with ketogenic diet the urinary pH should be controlled.

INVALID FOOD PREPARATION. (1) *Barley water.* Take 2 oz. of pearl barley and wash it well with cold water. Put it up in a saucepan with 1½ pint of water and simmer for about half an hour. Strain, sweeten with sugar and a few drops of lemon juice and serve.

(2) *'Chira' gruel.* A tablespoonful of fresh *chira* (pounded rice), well washed with cold water is made to simmer in a saucepan with a pint of water for 15 to 20 minutes and then strained. It is now flavoured and served.

(3) *Rice gruel.* A tablespoonful of fine and well-seasoned old rice is first washed with water and then boiled in a saucepan with one pint of water for ¾ to 1 hour. This is strained and the gruel so formed is served properly flavoured. This is very suitable for convalescent typhoid patients, preliminary to solid food.

(4) *'Sooji' gruel.* One tablespoonful of *sooji* is added to ¼ to 1 pint of water and is made to simmer in a saucepan till made into a rather thick gruel. It is now served with sugar.

(5) *Lime whey.* Boil ½ pint of milk in a saucepan. When it is bubbling, add sour lime juice drop by drop till the milk curdles. Strain to separate the curds and the light green transparent fluid is the whey.

It should not have a milky appearance and it should not be made too sour.

(6) *Sherry whey*. Boil $\frac{1}{2}$ pint of milk in a saucepan, and 2 oz. of sherry and strain.

(7) *Powdered milk food*. *Plain milk powder* (Lactogen, Glaxo, Allenbury No. 1) or the same mixed with malt (Nestle's, Horlick's, Allenbury No. 2, Milk food), is prepared by first making a paste of the powder with cold water and then slowly adding hot water and thoroughly mixing with a spoon. The quantity of the powder required depends on the thickness of the preparation desired.

(8) *Powdered food, prepared with milk*. Mellin's food (malted carbohydrate). Allenbury's malted food (mixture of wheat flour and malt) or Sanatogen (containing casein glycono-phosphate) is prepared by making a paste of the powder with cold water and then slowly adding hot milk. One or two teaspoonfuls are usually required for a cup of hot milk. Ovaltine (a special variety of cocoa containing malt and milk powder) and Vitavose (containing vitamin B, maltose and dextrin) are also prepared in the same way.

(9) *Peptonising milk*. To $\frac{3}{4}$ pint of boiled cold milk, add $\frac{1}{2}$ pint water and heat the mixture to about 140°F. (just hot enough to be bearable on the skin). Into a saucepan, put either two teaspoonfuls of liquor pancreaticus and $\frac{1}{4}$ a level teaspoonful of sodium bicarbonate or one tube of peptonising powder and make into a paste with cold water. To this the warm milk is now slowly added and thoroughly mixed. This is kept covered in a warm place or in a water-bath for about 10 minutes. The preparation is again brought to boiling point to stop further action of the ferment as overaction makes the preparation bitter. It is now sweetened and served. Milk is often peptonised with Benger's food (containing a mixture of wheat flour and pancreatic extract).

(10) *Junket*. Take lukewarm milk, add sugar to it, put into a deep enamel dish and add essence of rennet or rennet powder in quantity indicated on the label. Keep it undisturbed in a warm place or on a water-bath for 1 to 1½ hours, when it sets. Serve with sugar. It is an easily digestible and palatable convalescent milk food.

(11) *'Dahi.'* May be prepared in the same way as above. Instead of rennet, a teaspoonful of good *dahi* from the bazar is added to a pint of luke-warm milk and put in a warm water-bath till it sets which usually takes 1½ to 2 hours. This should be taken before it turns acid.

(12) *Oatmeal porridge*. Two tablespoonfuls of oatmeal and a pinch of salt are added to one pint of boiling water and slowly cooked, stirring briskly. This is continued for 20 to 30 minutes till it is sufficiently thick. It may be cooked with milk and sugar or these may be added afterwards.

(13) *'Sooji' porridge*. It is prepared in much the same way, milk and sugar being added when the *sooji* is partly boiled, the whole thing being then brought to a semi-solid consistency.

(14) *Typhoid bread*. Take the inside soft pulp of the bread and put it into boiling milk. Make the whole thing into a paste by rubbing down with the back of a spoon. This is strained and sweetened with sugar.

(15) *Albumin water*. Pour into a cup the white of a fresh egg and beat it thoroughly with a spoon and then slowly add water to make it up to 4 oz., and serve adding a pinch of salt and a few drops of flavouring.

(16) *Egg flip*. Beat 1 to 2 fresh eggs in a cup and then slowly add 8 oz. of warm milk and 1 to 2 teaspoonfuls of brandy. Sweeten as required.

(17) *Custard*. Beat up 2 eggs, add $\frac{1}{2}$ pint of milk, sweeten and flavour to taste. The preparation is now baked in a pie dish or steamed in a basin.

(18) *Patent meat-extracts*. Bovril (beef extract) and finely powdered beef fibrin, Brand's meat essences, Valentine's meat juice, Panopepton (beef extract with wheat) are sometimes substituted for fresh meat extracts. These are prepared by adding $\frac{1}{2}$ to 1 oz. of the extract to a teacupful of lukewarm water, if necessary flavoured with a few drops of lemon juice. These do not keep well in hot climates specially when the container is kept open for a few days. Once a tin is opened it should be used up. Virol, Roboleine and Marrow Malt are preparations of bone marrow with calcium, egg and malt.

(19) *Raw meat juice*. Finely mince $\frac{1}{2}$ lb. of lean mutton, put it in a saucepan and add 4 oz. of clean cold water. Allow it to stand in a cool place for an hour and then press the juice out either with a pressing machine or by squeezing through a clean piece of fine linen. One or two ounces of it are to be taken, flavoured with a few drops of lemon juice and a little pepper and salt.

(20) *Raw liver juice*. Prepared in the same way as raw meat juice and served fresh, or a cut piece of liver is taken and gently scraped with a dinner knife. The scrapings are collected in a tea cup, flavoured with orange juice and served.

DIPHTHERIA. DIAGNOSIS. Acute inflammation of the throat with definite membranous exudate, discharge from the nose, especially if unilateral and blood-stained, croup, cervical glandular enlargement, moderate pyrexia and the presence at times of albuminuria are important diagnostic points. Diagnosis should be aided by the bacteriological examination, but the bacteriological report does not exclude the disease if no Klebs-Löffler bacilli (*Corynebacterium diphtheriæ*) are found, and clinical cases should be treated as diphtheria without awaiting bacteriological confirmation.

TREATMENT. *Anti-diphtheritic serum.* To obtain the most successful results, anti-diphtheritic serum should be administered as early as possible (see page 799).

Local treatment. Local applications are of minor importance and if resisted by children it is advisable not to force this treatment and thereby exhaust the patient. In adults a spray of antiserum or the following lotion and hydrogen peroxide gargle will be found useful:—Sodium biborate, sodium bicarbonate, potassium chlorate, sodium chloride—each 7 gr., compound tincture of lavender $\frac{1}{2}$ dr. and water to 1 oz.

General. Absolute rest in bed is of great importance. In mild cases one pillow can be given, but in moderately severe cases the patient should rest without a pillow; in the most severe, not only should the pillow be removed but the foot of the bed should be raised a few inches (not more than 6 inches) to assist the flow of blood to the vital centres in the brain. As the circulation improves the patient should gradually be allowed to assume the normal recumbent position, then given an extra pillow, then allowed to sit up and lastly to get out of bed. He must be kept in bed for 4 to 8 weeks. *Diet.* Fluid diet (milk, barley, glucose, fruit juice, etc.) should be given during the febrile period. If there is difficulty in swallowing, thick Bengers' preparation may be tried. Bowels are best regulated by glycerine enema or mild aperients.

Treatment of complications. (1) For cough give glycerine or honey to sip or compound tincture of camphor, oxymel scillæ each 20 min., mucilage of acacia and syrup, each 1 dr. (2) For the laryngeal type give steam inhalation, atropine injection 1/200 gr. Tracheotomy or intubation is necessary if there is obstructed breathing as shown by increasing restlessness, dyspnoea, suction of the chest wall and cyanosis. (3) Circulatory failure in diphtheria. Diphtheria is attended with a profound toxæmia. The circulatory system is profoundly affected in diphtheria and from the commencement of the disease, a progressive fall in blood pressure is marked. Death takes place during the first ten days from circulatory failure. The general measures in treatment include absolute rest, and under no circumstances should the patient be allowed to sit up. He should be given an enema at regular intervals. Diet should comprise during the first week a bland fluid, beef extract, chicken broth, Benger's food. In all severe cardiac cases a nutrient enema is most beneficial. As the blood pressure attains normal level the patient may be allowed to recline in bed and be given a liberal dietary. Patients should always be kept warm and quiet with elimination of disturbing elements.

Many drugs have been tried but no specific drugs are known. Adrenalin is considered to be an efficient cardiac stimulant but owing to its rapid and transient action, ephedrine is much more preferred in these cases for its prolonged action. Antitoxin therapy can be safely

carried out after a preliminary dose of ephedrine. Ephedrine may be repeated every six hours but the drug does little good in moribund cases. The author has tried a tincture prepared from Indian species of *Ephedra* containing both ephedrine and pseudo-ephedrine with excellent results. In an extremely low condition of the patient, ephedrine may be combined with a maximum dose of pitressin, the blood-pressure-raising element of pituitary, and it should be given at six hourly intervals till the condition improves. The effect of the pituitary extract is absolutely specific in cases of circulatory failure in diphtheria. If the patient approaches an acute cardiac failure, intramuscular injections of pituitary and camphor in oil, which seem to aid the action of the heart, with the foot end of the bed raised, the patient kept very warm and a light linseed meal poultice applied over to cardiac region, are most helpful to tide over the crisis. If the patient is not vomiting a mixture containing spirit of ether, spirit of chloroform, aromatic spirit of ammonia in equal parts; one tea spoonful being given in a little water every four hours is most useful.

Other stimulants such as strychnine, digitalis and atropine appear to be of little use. Oxygen therapy is very useful in cases of cyanosis. All severe cases should receive brandy or alcohol, in some form or other and in maximum nutritional doses. In case of children it is usually administered as white wine which, if carefully prepared, is easily taken. The circulatory failure in diphtheria is due to vasodilatation, weakened cardiac output from the action of the toxin on the heart muscle and damage to the arterial wall, and provided that the antitoxin be given early enough, the blood pressure would not fall sufficiently to cause any serious circulatory failure; but should the antitoxin be given late for any reason or should the blood pressure fall from any of the previously considered factors then the only really effective treatment is in giving the vaso-constrictors.

(4) If toxæmia is severe, intravenous injection of 20 gr. glucose in 40 c.cm. of normal saline with 10 units of insulin hypodermically is of value. An alkaline mixture should also be given. (5) If swelling of the neck is present warm fomentations and local ichthol application are helpful. (6) Serum sickness. Calamine lotion or bicarbonate of soda lotion may be applied locally to relieve itching. Adrenalin and pituitrin in doses of 0.2 c.cm. may be injected intramuscularly. Calcium may be given by mouth. The bowels should be opened well. (7) Paralysis. The affected parts should be rested and strychnine administered followed by massage. If there is regurgitation of food due to paralysis of the soft palate, the patient will have to be fed by a nasal tube. (8) If there is broncho-pneumonia, treat it in the usual way.

DRUNKENNESS. Alcoholic intoxication includes an impairment of the physical and mental faculties to such an extent as to render an individual unable to execute safely his or her occupation. The three

stages of intoxication are exhilaration, in-co-ordination and drowsiness. All kinds of alcoholic beverages produce intoxication when the alcohol content of the blood reaches 0.15 to 0.2 per cent. The medical examination of a person alleged to be intoxicated is undertaken for the purpose of diagnosing conditions which simulate drunkenness such as those arising from the use of drugs. The routine examination consists in an observation of the temperature which is lowered, the pulse which is rapid, full and bounding, the pupils, dilated and sluggish to ordinary light and contracted in a bright light and in alcoholic sleep and the tongue dry and white. The ordinary speech and gait are unimpaired if the faculties are not notably affected. The breath smells of alcohol if it has been taken lately. Examinations for testing the higher psychical functions of the brain should be undertaken, such as questioning the individual as to his whereabouts, etc. The person's manner and appearance should be noted, the individual being often insulting, garrulous or taciturn. Specific tests should be applied to determine the state of the mental faculties by asking him the day of the week or the date of the month. The lack of co-ordination should be observed while walking on a crooked line or following some person two or three yards ahead of him. He may also be asked to touch his nose or pick up a coin from the floor. Reading tests and handwriting tests are also useful and valuable aids. For treatment see page 1452.

DYSENTERY. Dysentery means passage of blood and mucus with stools, often associated with abdominal pain and tenesmus. It is a symptom complex rather than a disease itself. Different types of dysentery are :—I. *Protozoal*—(1) Amœbic dysentery. (2) Flagellate dysentery—*Giardia intestinalis*, *Trichomonas hominis* and *Chilomastix mesnili*. (3) Ciliate dysentery—*Balanitidium coli*. (4) Leishmania dysentery. (5) Malarial dysentery.

II. *Bacterial*—produced by such organisms as Shiga, Flexner, Gærtner, Bact. Pseudocarinus, S. morgani, Pyocyaneus, etc.

III. *Helminthis*. Trematode infection (Schistosomiasis).

Besides these, the following conditions may simulate dysentery. Carcinoma of the rectum, intussusception, polypoid conditions, tuberculous ulceration, piles and fistulae, specific ulcers, poisons, etc.

There may be dysentery infections without any blood and mucus in the stools.

AMŒBIC DYSENTERY. See page 356.

BACILLARY DYSENTERY. There are two main types :

1. *Dysentery due to non-mannite fermenting bacilli of the Shiga-Krause type.* This infection gives rise to marked pyrexia and toxæmia. Stools are 16 or more in number in 24 hours with blood and mucus ; no faecal matter is seen. There may be severe diarrhoea and collapse simulating cholera. In acute gangrenous types with paralysis of the

gut there may be no stools. The Shiga bacilli produce intra- and extra-cellular toxins, and also poisonous pressor bases from animal proteins.

2. *Dysentery due to mannite fermenting bacilli of the Flexner-Strong group.* This infection gives rise to moderate fever and less toxæmia. Stools are less than 16 a day. They contain blood and mucus but may not be visible to the naked eye. The flexner bacilli produce only intracellular toxin and also produce indol from animal proteins and ferment carbohydrates (except lactose).

Character of stools of acute bacillary dysentery. (i) Alkaline reaction, (ii) little or no faecal matter, (iii) bright blood intimately mixed with mucus, (iv) *not offensive*.

Microscopically the following cellular elements are found. (i) Large macrophage cells, (ii) numerous polymorphonuclear leucocytes, (iii) scattered red corpuscles, (iv) numerous desquamated columnar epithelial cells.

N. B.—Specimen of fæces should be examined and cultured as soon as passed (within three hours).

Blood shows leucocytosis. The serum may agglutinate the dysentery bacilli after the tenth day of the disease. With Shiga strains agglutinating power 1 to 50 is usually accepted as evidence of specificity, but for Flexner strains a dilution of 1 to 150 is required.

Treatment of acute bacillary dysentery. See page 842.

Symptomatic treatment. (a) In collapse—intravenous saline, atropine, stimulants and warmth. (b) In severe purging—kaolin mixture as in cholera.

Investigation of chronic cases. (1) Repeated examinations of the stools, (2) agglutination of serum with dysentery bacilli, (3) sigmoidoscopy, and (4) barium enema.

TREATMENT. (1) A course of autovaccine injections with calcium lactate 10 gr. and parathyroid extract 1/10 gr. by mouth. (2) Diet is carefully regulated, carbohydrates are eliminated as far as possible and proteins are given, *viz.*, fish, chickens, eggs, etc. (3) A thorough overhaul of the digestive system is made. (4) Bacteriophage may be tried. It is particularly useful if the organism is lysable by the phage. If necessary bacteriophage can be grown on the causative organism and then administered to the patient. (5) Medicated enemas or bowel washes are sometimes very useful in healing chronic ulcers. (6) Symptomatic treatment.

ELECTROTHERAPY. See page 125.

ENURESIS. This is a fairly common complaint among children and in some the habit may even persist till adult life. Up to the age of a year, children generally exercise no control over the bladder during the waking hours and pass water during sleep till the age of 2 years. In some children full control of the bladder is never attained and the incontinence is referred to a previous accident or an illness. It is

usually during the first half of the night that the incontinence occurs and such trouble may be intermittent. The children are otherwise normal but often they exhibit neuropathic taints such as excitability, timidity or they may be deficient mentally. The habit is also met with in apathetic children with hypertrophied tonsils and adenoids. Of the other factors concerned three diseases in children are associated with the passage of an excessive amount of urine and these are diabetes mellitus and insipidus and chronic nephritis. Diabetes mellitus tends to be acute in children with the usual symptoms of wasting, thirst and polyuria. Diabetes insipidus is rare in children and when present there is copious output of urine of low specific gravity often associated with disordered hypothalamo-pituitary function. Syphilis is suggested to be a common cause in some. Chronic interstitial nephritis may be a congenital condition and in this enuresis may persist from childhood. Some congenital deformity of the urinary tract is also a causal factor. Congenital hypertrophy of the bladder in children may be due to phimosis, a pinhole urinary meatus, or the presence of valves in the posterior urethra obstructing the passage of urine. When these defects are absent, hypertrophy of the bladder is supposed to be due to a neuro-muscular incoordination between the sphincter and detrusor muscle of the bladder. So, as a rule, in every child brought for examination, the hypogastrium should be carefully palpated to exclude a functional cause. Routine examination of the urine should be undertaken in all cases; hyperacidity of the urine when present results in frequency of micturition rather than incontinence. Beside phimosis, other local causes such as the presence of threadworms, carious teeth, etc., should be borne in mind. The possibility of epilepsy should not be lost sight of. Intake of an excess of mustard and pepper has been found responsible for nocturnal incontinence.

Treatment. Before adopting any specific drug treatment, thorough investigation and subsequent correction of all local irritative processes should be undertaken. Worms should be expelled by proper anthelmintics, tonsils and adenoids should be removed under surgical asepsis and an operation of circumcision may be performed in cases where there is much retention of septic materials under a long and tight prepuce. The urine should be rendered alkaline with suitable alkalis where it is hyperacid. Of all the effective measures in controlling the habit, education of the child is thought to be the most important one. The child should be taught to evacuate the bladder at regular intervals particularly during the daytime. At night he should be made to pass water before going to bed and immediately on awakening in the morning. The time of bed wetting should be roughly determined beforehand and the child may be awakened at that hour to pass urine. Such a training should be imparted quite early in the life of the infant, and the child should never be reproached for the act. Punishment often makes the situation worse. With regard to psychotherapeutic

methods, simple suggestion acts best when the removal of the coexisting defects has failed to cure. The diet should be plain, simple and nourishing and free from indigestible coarse materials that are likely to cause irritation of the bowel. The amount of fluid intake should be restricted before the child is put to bed. Belladonna has had the reputation of being a specific in enuresis. The drug in combination with hyoscyamus and bromide may help for a time or even cure the condition. The usual advice is to push the dosage until the child is on the verge of physiological effects such as dryness of the throat. The initial dose suggested is 7 min. of the tincture given thrice daily and the dose should be increased by 2 min. every four or five days until as much as 30 or even 60 drops are being taken at each dose. When the bedwetting diminishes the dose of belladonna may be maintained for two or three weeks and then gradually reduced, the whole course covering a period of about three months. Ergot is similarly reputed to be a valuable drug in the treatment. A favourite prescription for a child of 5 years contains liquid extract of ergot 5 min., liquid extract of glycyrrhiza 2 min., flavoured with a drop of peppermint oil and given thrice daily for nearly a fortnight. Strychnine in the form of tincture of nux vomica is worth trying in combination with the previous drugs. Ephedrine hydrochloride in doses of $\frac{1}{4}$ to $\frac{1}{2}$ gr. has been found effective in cases of functional enuresis, the action of the drug being due to sympathetic stimulation. Deficient thyroid secretion is suggested as a cause of nocturnal enuresis and such children are obese, present cold extremities and are mentally backwards. Thyroid therapy has given encouraging results in some of the dull and apathetic children. In debilitated children the general health should be improved with tonics, suitable exercises and nourishing diet. Electrical therapy in the form of faradic or galvanic current, with one pole applied over the bladder and the other in the perineum is sometimes of service.

EPIDEMIC DROPSY. See page 1023

ERYSEPELAS. See page 1182.

FEVERS IN TROPICS (See page 202). Fever is one of the commonest symptoms for which patients come to a practitioner in the tropics. Investigation of a fever case is very important. To investigate such a case we should have: (A) *History*. The nature of onset, the type of the fever, the duration, etc., greatly help the diagnosis. But an accurate history is hardly obtainable especially from illiterate persons and often it is unreliable. When an accurate history is available, the evidence that fever has already lasted for so many days enables one to exclude at once the exanthemata, if a rash is present, however, it helps greatly to diagnose an eruptive fever. A history of previous similar attacks is also helpful (e.g., in malaria). As far as possible an endeavour should be made to take an accurate history of every febrile case. (B) *Clinical examination*.

This must be thorough and conducted systematically. The patient should be examined from head to foot. Attention should first be directed to any focus of localized infection. For this, particular attention must be paid to the patient's statements as to his chief complaint, his position, appearance and movements. Careful attention should be paid to: (1) Examination of the surface of the body for any rashes, adenitis, lymphangitis. (2) Examination of the throat for any inflammation, patch, etc. (3) Examination of the gums and teeth for pyorrhoea, caries or apical abscess. (4) Examination of the nose, ear and sinuses for any septic focus. (5) Examination of the lungs, which may present physical signs suggesting local infection. In this connection, however, it must be remembered that lung complications are quite common in certain general infections. For instance, friction sounds may be heard over the left lower ribs in connection with a rapid and painful enlargement of the spleen due to malaria. A certain amount of bronchitis is frequently present in enteric fever, undulant fever often causes bronchitis or broncho-pneumonia about the beginning of the third week. Hypostatic congestion is met with in many conditions. Pulmonary congestion and inflammation occur in typhus, plague, influenza, meningitis, hydatid disease of the lung, schistosomiasis and paragonimiasis. (6) Examination of the heart for any lesion, particularly endocarditis. (7) Examination of the abdomen for any disorder of the spleen, liver, gallbladder, appendix and colon. Rectal and vaginal examinations should be made whenever required. Prostatic and cervical smears are to be examined if there is suspicion of any infection. (8) Examination of the joints should be made when patients complain of fever with pain in the joints. They are not always of rheumatic origin. Rheumatic fever should not be diagnosed if only one joint is involved, or suppuration occurs, and the swelling does not subside in a few days (at most 15 days) and if there is no improvement with salicylates. Undulant fever also causes pain in the joints which become swollen, hot, tender and painful. Salicylates have no effect in such cases. Recovery of *Br. melitensis* from blood or urine and agglutination reaction will settle the diagnosis in such a case. Bacillary dysentery may give rise to polyarthritides. Arthritis due to dysentery should be distinguished from acute rheumatism by the mode of onset, lack of redness and heat in the joints, chronic nature, failure of response to salicylates, absence of endocarditis, and evidence of dysentery. Agglutination of the patient's serum against the dysentery group of bacilli may help the diagnosis. Gonorrhoeal arthritis is often monoarticular. Dengue and trench fever may cause much periarticular pain. Filariasis may cause synovitis. Besides, arthritis may complicate cerebro-spinal fever, typhoid, pneumonia, syphilis, yaws, amebiasis and any form of chronic sepsis.

If after a thorough physical examination one fails to detect evidence of localized infection, generalized infection should be suspected:

(1) Fever with gradual onset may be enteric fever, *Bact. coli* infection, liver abscess, undulant fever, kala-azar, syphilis, tuberculosis, bronchial spirochaetosis, etc. (2) Fevers of sudden onset are numerous, *viz.*, malaria, typhus, relapsing fever, trench fever, plague, small-pox, heat-stroke, meningitis, pneumonia, etc. (3) Hyperpyrexia may occur in malaria, heat-stroke, meningitis, cholera (reaction stage), yellow fever, scarlet fever, etc. (4) Fever with pains occurs in dengue, phlebotomus fever, trench fever, yellow fever, relapsing fever, small-pox, typhus, rat-bite fever and plague (hubo). (5) Fever with pink eyes occurs in measles, small-pox, plague, typhus, dengue, influenza, rheumatic fever, etc. (6) Fever with jaundice occurs in malaria (pernicious), relapsing fever, yellow fever, blackwater fever, infectious jaundice, infantile liver, pyæmic abscess, cholecystitis and pneumonia. (7) Fever with œdema occurs in hookworm infection, nephritis, oroya fever, etc. (8) Fever with relatively slow pulse occurs in enteric fever, undulant fever, dengue, phlebotomus fever, trench fever, cerebro-spinal fever, yellow fever (2nd day) and schistosomiasis. (9) Fever with rapid pulse occurs in tuberculosis, trypanosomiasis and many of the infectious diseases. In this connection other common causes of tachycardia should be borne in mind, *viz.*, exophthalmic goitre, nervousness, excitement, tobacco, myocarditis, pneumogastric irritation and administration of drugs like thyroid, belladonna, etc. (10) Fever with leucopœnia occurs in enteric fever, kala-azar, undulant fever, tropical splenomegaly, splenic anæmia, acute miliary tuberculosis. (11) Fever with leucocytosis occurs in leukæmia, suppurative processes, pneumonia, meningitis, plague, relapsing fever, typhus, etc.

(C) *Laboratory investigations.* (1) First examine the blood films for malarial parasites, leishmania, the spironema of relapsing fever, micro-filiariæ, and trypanosomes. The smear also helps the diagnosis of leukæmia and anæmia. A differential count may show eosinophilia which occurs in asthma, skin diseases and helminthic infections. Increase of large mononuclear leucocytes occurs in malaria, dengue, yellow-fever and trypanosomiasis. Lymphocytes are increased in kala-azar and tuberculosis. A total blood count is also very helpful. (2) If the clinical examination suggests infection with organisms of the enteric group, septicæmia, plague, undulant fever, etc., early blood culture may settle the diagnosis. (3) If the smear examination and culture of blood fail to detect any organism, the blood is tested for specific agglutinins during the 2nd week as the case proceeds. It is well, however, that agglutination tests be performed as early as possible for, in persons protected by prophylactic inoculation, an increasing titre is the only evidence that these antibodies are the result of infection causing fever. For this, several estimations must be made. The test is of value in the diagnosis of enteric fever and undulant fever. Agglutinins for the various dysenteric bacilli appear too late to be of value in the early febrile stage. The Weil-Felix reaction is

done in typhus, but it is not exactly an estimation of agglutinins. Complement deviation tests should be done in all prolonged cases even in absence of clinical evidence of syphilis. (4) Stool examination is of great value especially in dysentery, cholera, enteric, helminthic and other infections. (5) Urine is examined as a routine in every case. If necessary, it may be cultured. In blackwater fever it is tested for hæmoglobinuria. Hæmaturia may occur in severe infections like plague, yellow fever, small-pox, etc. (6) Sputum is examined in pneumonia, tuberculosis and other pulmonary affections. (7) Cerebro-spinal fluid is examined in meningitis and trypanosomiasis. (8) Gland puncture is made for diagnosis of bubonic plague, trypanosomiasis, filariasis or syphilis. (9) Spleen and liver punctures are made for the diagnosis of kala-azar. (10) Aldehyde and antimony tests are done for the diagnosis of kala-azar.

FUNCTIONAL TESTS. RENAL FUNCTION. The efficient working of the kidneys is known by the following tests: (1) Detection of abnormal constituents in urine such as protein, casts, etc. (2) Alteration of the physiological balance between the blood and urine and the demonstration of substances in altered proportions either in the blood or in the urine. (3) The eliminating power of the kidney as tested after administration of:—(a) Some natural substances such as water, urea, test meals; (b) some foreign substances such as dyes like phenolsulphone-phthalein or indigo-carmin.

I. DETECTION OF ABNORMAL CONSTITUENTS OF URINE BY CHEMICAL TEST.
Proteins: (a) *albumin*, (b) *globulin*. It has been found that the albumin-globulin ratio is usually found to be above 10 in cases of nephrosis and between 5 and 10 in acute nephritis. The ratio is low during the early stages of acute nephritis and it rises as recovery takes place. A ratio of below 5 indicates an advanced state of glomerulo-nephritis with urea retention and impaired renal function. Lawson found that a just perceptible trace by the boiling test corresponds to 0.1 gm. per litre, a distinct cloud corresponds to 0.5 gm. per litre and a heavy cloud indicates 2.0 gm. per litre or over. The presence of casts, blood, pus, etc., signifies a renal lesion.

II. ALTERATION OF PHYSIOLOGICAL BALANCE BETWEEN THE BLOOD AND URINE.

The blood urea clearance test. It is claimed to be the most sensitive test of renal efficiency at present available. When urine volume is large the rate of urea excretion is directly proportional to the blood urea content. Expressed in other words, the urea excretion per minute equals the urea contained in a constant volume of the blood; this volume in a normal individual is 75 c.cm. The direct ratio between the blood urea content and the urea excretion rate holds only when

the urine volume is about 2 c.cm. per minute in adults. When the urine volume falls below this limit, the urea excretion also falls and on the average in proportion to the square-root of the volume. These data led to the development of the urea clearance test. Two modes of clearance are recognised. The maximum clearance occurs when the flow of urine is above 2 c.cm. per minute and the standard clearance when the flow is below 2 c.cm. per minute. These two being calculated, the normal percentage is also determined.

No special precaution is necessary, the test being performed between breakfast and lunch. The patient is put to bed, a glass of water is given at the beginning of the test. (1) Blood for urea estimation is drawn a few minutes before the end of the first hour. (2) The total volume of urine secreted is accurately measured. The urine is collected at the end of one hour and again at the end of two hours and the concentration of urea is determined. The standard or the maximum clearance is then calculated in each hourly specimen. The normal clearance is next determined. The normal range is from about 70 per cent. upwards. In terminal stages of hæmorrhagic nephritis the urea clearance is below 20 per cent. of the normal. Uræmia is uniformly present if the urea clearance falls below 5 per cent. and is uniformly absent with figures above 10 per cent. In some cases of nephritis, values between 20 to 40 per cent. may be seen with a normal blood urea content, thus demonstrating the superiority of this test over the simple blood urea estimation.

Urea and non-protein nitrogen contents of the blood are held by most authorities to yield the most reliable information. In certain forms of nephritis as in the azotæmic type, in prolonged vomiting, intestinal obstruction and acute abdominal lesions, there is an increase in the non-protein nitrogen content of over 40 mgm. per 100 c.cm. of blood. A creatinin content constantly over 1.5 mgm. per 100 c.cm. of blood indicates permanent renal damage. With nitrogen retention, in cases of acute nephritis, the blood calcium falls as low as 6 mgm. per 100 c.cm. of blood or sometimes lower and the phosphorus content rises to 5 mgm. per 100 c.cm. of blood. Marked nitrogen retention occurs in chronic interstitial nephritis and little or no retention is found in chronic nephritis with œdema and lipoid nephrosis. Blood cholesterol is markedly increased (as much as 0.3 per cent. or over) in lipoid nephrosis and other conditions such as cholelithiasis.

In chronic nephritis with œdema and in lipoid nephrosis, the albumin falls to 2.5 per cent., globulin to 1.7 per cent. and the total protein to 4 per cent.

- *Volume and specific gravity.* The normal urine volume is 1,500 c.cm., Sp. Gr. 1,015 to 1,025. In acute nephritis the volume is 200 to 500 c.cm., Sp. Gr. 1,025 to 1,035. In chronic interstitial nephritis the volume is 2,000 c.cm. or over, Sp. Gr. 1,005 to 1,012. In lipoid nephrosis the volume is 600 to 900 c.cm., Sp. Gr. 1,020 to 1,025.

III. TESTS DEPENDING ON THE ELIMINATION OF SOME SUBSTANCE ADMINISTERED TO THE BODY.

1. *Water test* (Straus-Graunwald method) A pint of water is given to a starving patient and urine is collected at hourly intervals. Normally, the sum of the first three hours' specimen should be equal to the quantity of fluid administered, but if the quantity is less, it signifies a renal lesion.

2. *MacLean's urea concentration test.* Fifteen gm. of urea dissolved in about 5 oz. of water flavoured with tincture of orange are given to a patient who has had nothing to drink for some hours and after emptying the bladder The urine is passed in each of the subsequent three hours and urea concentration estimated. In the case of normal healthy kidneys the concentration in the second and third hours is usually over 2.5 per cent. and almost invariably over 2 per cent. With moderate damage of the organs, concentration from 1.5 to 2.5 per cent. may be met with and with severe lesion under 1.5 per cent.

Like all tests in which absorption of substances from the alimentary canal plays a part, it suffers from certain disadvantages. The urinary excretion of urea depends in this case not only upon the concentrating power of the kidney but also upon the rate of absorption which is controlled by the emptying time of the stomach since urea is absorbed from the intestines. The urea clearance test has largely replaced this urea concentration test.

3. *Renal test meal* Mosenthal employs a standard diet and collects two-hourly specimens of urine throughout the day. The specimens are examined for volume, specific gravity, urea and salt concentration. The following signs indicate renal lesion. (1) Fixed or low specific gravity. (2) Lowered output of salts and nitrogen. (3) Tendency to polyuria. (4) Loss of concentration in the night urine associated with low specific gravity and nitrogen content.

4. *Dye tests.* (a) *Indigo carmine test.* Ureteric catheters are introduced and 0.1 gm. of the dye is injected intramuscularly. The urine is tested in six to eight minutes. The intensity of the colour indicates roughly how much of the dye is excreted and any delay signifies renal inefficiency This test can detect a unilateral renal lesion and is useful in surgical cases. (b) *Phenolsulphone-phthalein test.* In order to secure a good flow of urine, the patient is given 300 c.cm. of water to drink and the bladder is emptied twenty minutes after and 6 mgm. of the dye in 1 c.cm. of sterile saline are injected intramuscularly. The dye generally appears in urine within ten minutes of the injection. The bladder is emptied after an hour exactly and again after two hours and the two specimens are preserved for the estimation of the dye colorimetrically in each. By the first hour 50 per cent and by the second hour 70 per cent. of the dye should be excreted. Anything below this points to renal inefficiency. By

ureteric catheterisation, the test can be applied to detect a lesion of each kidney separately.

5. *Pyclography*. See page 66.

HEPATIC FUNCTIONS. (A) *Investigation of the pigmentary functions*. A positive reaction of the blood to bile indicates a derangement of the hepatic function.

Van den Bergh reaction. McNee recommends the following classification of jaundice:—(1) Obstructive hepatic jaundice. Here bilirubin is reabsorbed into the blood and is subsequently excreted into the urine. (2) Haemolytic jaundice. Here more pigments are offered than the polygonal cells of the liver can actually dispose of resulting in their transference from the Kupffer cells to the blood stream again. (3) Toxic and infective hepatic jaundice. This is really a combination of these two conditions. Van den Bergh's reaction distinguishes between these varieties of bilirubin and indicates the type of jaundice. An immediate direct reaction indicates obstructive jaundice, a delayed direct reaction points to a haemolytic or non-obstructive type. The biphasic reaction is seen in cases of toxic and infective jaundice. The bilirubin content of normal serum is 0.2 to 0.5 units. Bile does not appear in urine until 4 units are present in the blood, but in haemolytic jaundice there is no bile in the urine though 5 to 18 units are present in the blood.

(B) *Investigation of the metabolic functions*. (a) *Nitrogen partition method*. Urinary nitrogen coefficient = $\frac{\text{Urea nitrogen}}{\text{Total nitrogen}}$. Normally the value of this coefficient is between 85 and 90, whilst in hepatic inefficiency it falls to 40 or 50, indicating a disease in the uricogenetic function. The values for amino-acids and the non-protein nitrogen in the blood increase in such cases.

(b) *Lævulose tolerance test*. By mouth 100 gm. of lævulose are given and during the following twenty-four hours specimens of urine are collected. If lævulose appears in urine about an hour after the administration of the sugar, there is hepatic inefficiency. Specimens of blood are also taken at half hour intervals and tested for sugar; a rise in sugar above 140 mgm. per 100 c.cm. of blood points to hepatic inefficiency. *Galactose tolerance test*. Normally the ingestion of 40 gm. of galactose causes no appreciable increase of blood sugar, but a hyperglycaemia is marked in cases of hepatic lesions as in catarrhal jaundice, cirrhosis, atrophy and neoplasms. *Sugar tolerance test*. This is useful in diabetic cases. The patient is not given an evening meal on the day preceding the test; 50 gm. of glucose (1.5 gm. of glucose per kilo. body weight) dissolved in about 400 c.cm. of water and flavoured with syrup of orange are given to the patient. Blood sugar per 100 c.cm. and urine sugar per cent. are determined at intervals $\frac{1}{2}$, 1, 2 and 3 hours. The normal blood sugar before the test is 80 to 120 mgm. per 100 c.cm. of blood. Within an hour after taking

glucose the blood sugar rises to 130 to 180 mgm. per 100 c.cm. representing the highest figure. Blood generally returns to normal within two to two and a half hours. Urine should not give any reaction for sugar.

In mild diabetic cases, the resting blood sugar is higher and after the administration of glucose, the content rises above the threshold value of the kidneys. In renal glycosuria the blood sugar content is always below the normal level.

(C) *Investigation of the hæmopoietic functions.* (a) The coagulation time of the blood is said to be increased in hepatic derangements. The fibrinogen content of the blood is decreased in hepatic inefficiency.

(b) *Widal's test.* Generally a meal is followed by leucocytosis and this reaction depends on the functional integrity of the liver. In deranged hepatic functions, the reaction is either a leucopænia or there is no rise in the content.

(D) *Investigation of the global capacity.*

Phenoltetrachlorphthalein test. The dye which is obtained in ampoules is injected intravenously, 5 mgm. per kilo., in about 250 to 300 c.cm. of normal saline. Exactly after a quarter of an hour, and again at the end of one hour, 5 c.cm. of blood is drawn out. The amount of dye present in each specimen of serum is determined colorimetrically. In normal persons from 2 to 6 per cent. of the dye remains in the circulation after 15 minutes and nothing remains at the end of one hour. In hepatic disorders there is an appreciable amount retained in the blood after one hour.

(E) *Investigation of the duodenal contents.* Lyon has devised a method by which the functional integrity of the biliary passages can be tested. A fasting patient is made to swallow a duodenal tube and bile is aspirated at intervals before and after injecting in the tube 50 to 100 c.cm. of 25 per cent. magnesium sulphate solution which causes the gall bladder to contract and empty itself. Bacteriological and cytological examinations of the samples of bile aspirated give reliable information as to the inflammatory and infective conditions of the various parts of the biliary tract.

(F) *Cholecystography.* See page 66.

PANCREATIC FUNCTIONS. Derangement of pancreatic function is accompanied by disturbances of carbohydrate metabolism and definite alterations in the digestive and absorptive processes of the body. Diminished or absent external secretion of the organ is marked by the presence of undigested protein, excessive quantities of fat and free starch in the fæces. Microscopical and chemical tests are resorted to to detect these substances in the fæces and to test the efficient working of the organ.

Loewi's test is a clinical test to detect a lesion of the pancreas. This is due to disturbance in the normal antagonism between the suprarenals and the pancreas. The disordered^{pan} pancreas excites the sympathetic and the dilatation of the pupil occurs in response to the

local action of adrenalin. Two drops of adrenalin chloride are instilled into the conjunctiva and dilatation of the pupil is noticed within a short time. This is characteristic of a pancreatic lesion and is not seen in normal subjects.

Diastase test. The normal diastatic index of urine is between 6.6 and 30. A fluctuation of the figure provides a very useful guide to diagnosis. Pancreatic lesions are always accompanied by an increased diastatic index of urine. Acute inflammatory conditions of the organ (acute hæmorrhagic pancreatitis) show a considerable increase of the figure to 100, 200 or sometimes even higher. The figure may or may not be affected in chronic pancreatitis, and varies between 10 to 50. In cases of neoplastic conditions of the pancreas, it is 30 to 100.

Besides the tests mentioned, certain clinical signs and symptoms are characteristics of pancreatic lesions depending on the involvement of the anatomical structures around the organ. A tumour in the head of the pancreas compresses the common bile duct and gives rise to obstructive jaundice. Irritation of the adjacent solar plexus in acute pancreatitis gives rise to pain in the epigastrium and back, vomiting and shock.

GASTRIC FUNCTION. TEST MEALS. One of the methods of investigating the gastric function is by studying the response of the stomach to test meals. The common ones are, one hour method (Ewald), and fractional method (Rehfuess).

Ewald's method. The examination is conducted in the morning, the patient having fasted from 9 p.m. the night before the examination. The test meal which consists of a pint of tea and a small piece of toast (about $\frac{1}{2}$ oz.) is given at 7 a.m.; at 10 a.m. a gastric tube is passed and as much fluid as possible is aspirated from the stomach. The total quantity of the aspirated fluid is measured, its general appearance is studied and noted and then the fluid is sent to the laboratory for qualitative and quantitative examination for the detection and estimation of the presence of (1) free HCl, (2) organic acids, e.g., lactic acid, acetic acid, butyric acid, (3) blood, and (4) total acidity.

The composition of the gastric content after a test meal depends upon the volume and nature of fluid in the stomach at the time of giving the meal, volume and nature of the meal, rate of gastric secretion and its amount and lastly the condition of the pylorus. All these factors vary and it is impossible to obtain anything like comparable results with this method at the end of one hour. Ewald's method, therefore, has now been replaced by the other method which aims at giving a true estimate of gastric function.

Rehfuess method. The patient is given a light supper (a glass of milk and a charcoal biscuit) the night before. The following morning before any food is taken, the patient is made to swallow a Ryle's tube. The tube is marked by one transverse line at 40 cm. to indicate the cardiac orifice and by three transverse lines at 57 cm. to indicate the

pylorus. The tube is swallowed till the pyloric mark almost touches the teeth, the fasting stomach contents are then aspirated through the tube with a 20 c. cm. record syringe till the stomach is completely emptied. The quantity of the resting juice is measured and noted. If the volume aspirated be less than 20 c. cm., it is likely that the total fluid has not been recovered. The injection of a syringe of air in many cases will lead to a more complete evacuation. The test meal is made by boiling one ounce of oatmeal in a quart of water until the bulk is reduced to one pint. The preparation is then strained and may be flavoured with little salt. Immediately after emptying the stomach, one pint of the test meal is given to the patient to drink; 15 c. cm. specimens are aspirated every 15 minutes for 2½ hours or until nothing further can be aspirated. The specimens are collected in separate clean test tubes which are duly labelled and serially numbered 1st, 2nd, 3rd, etc., and then all the tubes including that containing the fasting juice are sent for analysis. Each specimen is examined for the presence of blood, bile, mucus, starch, free HCl; and estimation of free HCl and total acidity is carried out. The emptying of the gruel meal is indicated by the absence of reaction for starch in the specimen.

Fractional test meal interpretation. Normal resting juice. No charcoal, free HCl is very low (from 0 to 20)—volume varies between 10 and 150 c. cm. with average of about 54 c. cm. *Later specimens.* *Acidity.* The first specimen after the test meal shows very low HCl (lower than that in resting juice), then there is a gradual increase in concentration up to the 5th or 6th specimen (1½ to 1¾ hour after meal) rarely going above 40. After this, there is a gradual diminution in the HCl content. This fall is frequently shown by the appearance of bile in the specimen. *Total acidity* is usually 10 to 25 c. cm. N/10 per cent. higher than the free HCl and consists mainly of organic acids such as lactic and butyric. *Blood and mucus*—nil. *Motility.* The usual emptying time of the gruel is from 1½ to 2½ hours.

In gastro-duodenal ulcer the typical climbing curve is seen. The fasting stomach may contain about 30 c. cm. of juice, may be slightly bilestained, with no food remnants or charcoal. Free HCl is in high concentration. Later specimens show diminution of free HCl and total acidity. Afterwards both increase steadily and go considerably above normal even up to 70 or 80 on an average. The bile is absent owing to absence of regurgitation; there is no blood nor mucus.

In chronic cicatrising gastric ulcer with pyloric obstruction, the fasting stomach may contain about 70 c. cm. of the fluid; traces of bile and charcoal are seen from the previous day; free HCl is moderate, but total acidity is rather high. *Later specimens.* *Acidity.* Free HCl climbs to a continued plateau of moderate concentration. Total acid is proportionately rather high; bile is present in traces or absent in later specimens; blood is absent; mucus is normal. *Motility.* As much as 170 c. cm. of fluid containing much gruel may be present even 3½ hours

after the meal showing obvious pyloric obstruction. Ulcers in other parts of the stomach do not give such typical pictures.

Duodenal ulcers may cause very little abnormality in the curve, frequently, however, there is a high concentration of HCl with a rapid emptying time of the stomach.

Carcinoma of the stomach. The fasting stomach contains about 40 c.cm. of fluid which is very foul smelling, dark coloured and contains altered blood; mucus and charcoal are present from the previous night. No free HCl. Total acid is relatively high. *Later specimens.* *Acidity.* Free HCl and total acid are rather above average concentration or kept at a uniform low level with free HCl absent throughout; bile is absent, mucus is normal, and blood is present. The meal leaves the stomach rather rapidly.

Achylia gastrica or achlorhydria. Fasting stomach contains only a few c.cm. of the juice, a trace of bile and no free HCl. The total acid is very low. Later specimens show complete absence of HCl; total acidity is also very low. Bile is present in later specimens, mucus is absent and blood is absent. The whole meal leaves the stomach very quickly, i.e., in about an hour. The graph is represented by a straight line.

FURUNCULOSIS. Boils or furuncles are acute circumscribed staphylococcal infections about one or more hair follicles. The infecting organisms are generally *staphylococcus pyogenes aureus* but in some cases these are *staphylococcus pyogenes albus*. The condition may start as impetigo and infection subsequently takes place along the hair follicles. Crops of boils appear when the body resistance is considerably lowered to staphylococcal infections. The glycosuric soil affords a suitable medium for staphylococci and a gouty seborrhœic acid soil or a diathesis of a sluggish metabolism is also a very fertile one for boils to grow. Of the predisposing factors, faulty dietetics with an avitaminous regime and intake of excess of carbohydrates, excessive tobacco smoking and a mode of life with insufficient muscular exercise, deserve mention. Alcoholic drinks especially champagne, due to some deleterious by-products of partial fermentation, often favour the infection. Besides, anæmia, renal disease, debility and chronic constipation predispose to furunculosis. General debility may be theoretically regarded as an invitation to staphylococci though boils are generally met with in over-fed bulky persons. Psychic states such as anger, emotion, irritation, etc., play an important ætiological role. In these states, both adrenalin and sugar are poured into the blood stream and as these are not utilized, they favour the growth of the bacteria. Chronic intestinal toxæmia and hidden septic foci in the body also favour infection. Endocrine dysfunctions and calcium deficiency are also potent ætiological factors. A boil appears as a hard, tender, circumscribed mass which later suppurates and discharges pus

leaving a central necrotic core. The axillæ, forearms, glutei and face are the sites of selection. Boils on the face and particularly over the upper lip might sometimes precipitate a secondary cerebral infection which generally proves fatal.

TREATMENT. A thorough search should be made for septic foci which when found should be eradicated. Diabetes, albuminuria and chronic constipation should be treated on the usual lines. Flushing of the intestinal canal and subsequent starvation lessens toxæmia and is often successful in aborting an attack. A cautious dietary with abundance of vitamins and restricted intake of meat and sugar, considerably helps the treatment. Fresh yeast, a tea-spoonful, thrice daily, often acts well in furunculosis but this should not be given during vaccine therapy. A mixture of dilute sulphuric acid 5 min., with sulphate of magnesia 1 dr. is often efficacious. Sublimed sulphur in $\frac{1}{2}$ to 1 dr. doses or fresh calcium sulphide in $\frac{1}{2}$ gr. doses, may also be prescribed. The affected region should be frequently washed with weak solution of perchloride of mercury 1 in 2000, or 2 per cent boric lotion to prevent an auto-inoculation. During the early stages before suppuration takes place boric fomentations, compresses of glycerine and ichthylol or glycerine of carbolic are very effective in alleviating the acute throbbing pain. A boil may often be aborted by the application of a mercury and carbolic plaster with a small hole in the centre. In all cases, squeezing is not only a bad but a dangerous practice, as this often helps the dissemination of the organisms into the blood by breaking the protective loculi in the region where the cocci are lodged. This also adds to the inflammatory mischief in the tissues. When the boil is mature and the pus is ready to escape, under proper aseptic precautions, evacuation of the septic materials may be effected with a knife. Correction of faulty metabolism and calcium and endocrine therapy is also useful in the treatment. Intramuscular injections of colloidal manganese $\frac{1}{2}$ to 1 c.cm., twice a week, help the retrogression of furuncles. Stannoxylin tablets, one tablet thrice daily, are also prescribed in some cases. Ultra-violet therapy, baths, etc., are also of proved value in the treatment of furunculosis.

Vaccine therapy (see page 773) has given encouraging results in the treatment of furunculosis, the autogenous type being generally better than stock vaccine. A single dose of vaccine if administered early, tends to abort an acute boil. The dose should be 1000 million of mixed staphylococci. An average initial dose, in ordinary cases should be 100 millions of *Staphylococcus aureus*, gradually increased to 250 millions at intervals of a week. To prevent a relapse, it is advisable to prolong the vaccine therapy for some time after apparent cure.

It is suggested that there is some connection between the oxidising action of potassium permanganate and the thyroid in that they act by tending to sway the pH of the blood. It appears that boils occur in those parts of the body where there is likelihood of local

acidosis. Ball, with his favourite prescription for boils containing sulphate of iron 3 gr., sulphate of magnesium $\frac{1}{2}$ dr., dilute sulphuric acid 10 min., solution of hydrochloride of arsenic 2 min., chloroform water to $\frac{1}{2}$ oz., advocates a tabloid containing thyroid $\frac{1}{2}$ gr. and potassium permanganate $\frac{1}{8}$ gr., in cases of intractable boils. The mixture and the tablets are given three times a day. He reports considerable success with these drugs.

Oxygen injections (Salzmann) have given very gratifying results in cases of furuncles and paronychia. The oxygen, under high pressure $\frac{1}{2}$ to 1 atmosphere, is introduced into the centre of the furuncle through a sterile glass cannula or a fine injection needle. In the course of a day, 5 to 10 such injections may be given, as needed. The tissue of the furuncle softens with astonishing rapidity, so that the furuncle is emptied spontaneously within 24 to 48 hours. Furuncles of the nose and upper lip especially may be similarly treated and leave no disagreeable complications.

GASTRIC AND DUODENAL ULCERS. During the last twenty-five years ideas on the subject of gastric and duodenal ulcerations have been radically revised mainly as a result of the progress of abdominal surgery and modern X-ray methods of diagnosis. Clinicians now realise how unreliable were the signs and symptoms on which they had to base their opinions. Radiology has enabled a diagnosis of ulcer to be made in many cases which previously might have been termed gastritis. Ulceration is sometimes seen not only without pain but actually without any sign of indigestion.

The incidence of peptic ulcer, under which term are included both the gastric and the duodenal forms, has been recently studied in many series of cases. Duodenal ulcer is very much more common than gastric ulcer and occurs more frequently in males than in females. The disease may occur at any age, though cases under twenty years of age are very uncommon. Patients have often suffered from abdominal symptoms for many years before coming under treatment, and it is therefore difficult to be certain when the disease really started.

In spite of the large amount of experimental work that has been carried out in recent years on the pathology of peptic ulcer, it must be admitted that the cause of the condition is still undecided.

Various factors have been thought to be responsible for the causation of the ulcer. The gastric juice or perhaps its hydrochloric acid content may in some way be responsible as ulcers occur in such situations as are exposed to its action, e.g., the stomach, the first part of the duodenum, and last part of the oesophagus and in the jejunum of cases where gastro-jejunostomy has been performed. Interesting experimental work by Bolton confirms the fact that the acidity of gastric juice and pyloric obstruction are factors in the production of peptic ulcers.

Of recent years great stress has been laid on the importance of focal infection as a cause of peptic ulcer. The experimental work of Rosenow in America lends support to this. By inoculation of streptococci obtained from infected teeth of ulcer patients, he claims to have produced gastric ulceration in animals. Although this is not absolutely convincing it is reasonable to suppose that chronic sepsis such as may occur around the apex of a tooth or in a chronically inflamed appendix or gall bladder may play a part in the establishment of gastric or duodenal ulcer. The work of Bolton has demonstrated in animals that the introduction of septic materials into the stomach is followed by the formation of ulcer. Alvarez (1932) is not satisfied with any of the theories of causation of ulcer and particularly with the infection theory. He suggests that the importance of psychical factors has been overlooked and that ulcer commonly appears in persons who live under nervous tension.

Sometimes the ulcer results from auto-digestion of a portion of the stomach wall from which the blood supply has been cut off by a minute embolus lodging in an artery. The presence of a foreign body in the stomach, erosion of the gastric mucosa by strong acids and alkalies are also important ætiological factors. Anæmia, chlorosis, chronic colitis and gastritis associated with hyperchlorhydria are important predisposing factors. Besides there may be gastric ulcer diathesis, as gastric ulcers tend to run in some families and duodenal ulcers in others.

Ulcers may be acute or chronic and the symptoms of the two conditions are different. Acute ulcers are generally multiple, small and superficial. Hæmorrhage is common but rarely fatal. A chronic ulcer is usually single and irregular in shape with an indurated edge. It is usually found near the pylorus on the lesser curvature towards the posterior surface of the stomach and the symptoms are periodic and intermittent, the chief being pain, vomiting, and hæmatemesis. The pain is characteristic, its onset is most punctual in the same patient after the same meals and it appears with the most exact regularity after the same interval of comfort. The periodicity of pain is altered by variation in the quantity and quality of the food and by irregularity of meals. It is complained of in the epigastrium coming on within half an hour to an hour after food and relieved by vomiting. The nearer the ulcer is to the pylorus the lower down is the pain and longer its interval after a meal. In cases of duodenal ulcer, the pain continues until food is taken to relieve the pain. The definite relationship of pain to food intake has been described by Moynihan as follows: "In case of gastric ulcer, the pain which, after an interval, follows the taking of a meal, gradually disappears before the next meal. In cases of duodenal ulcer, the pain continues until the next meal, or until food is taken to give ease to a wearisome pain. The rhythm of gastric ulcer is 'food, comfort, pain, comfort,' and then again 'food,

comfort, pain, comfort'; of duodenal ulcer it is 'food, comfort, pain' and then again 'food, comfort, pain'; a quadruple rhythm in the former disease, a triple rhythm in the latter. The pain may be slight or intense and may radiate to other regions of the body. The actual cause of pain is uncertain. Some believe it to be due to the spasm of the muscles of the stomach. According to Hurst, tension is the cause of pain. Diffuse tenderness over the abdomen is present with a little rigidity of both the upper recti muscles. An area of cutaneous hyperæsthesia can be demonstrated in many cases. When the pain is delayed from one to two hours after food, the ulcer is probably a prepyloric one. If the delay is more than two hours, the ulcer is likely to be duodenal; it lasts till the next meal which usually gives relief for a definite period. When complications such as pyloric stenosis or perigastric inflammation, etc., set in, the pain becomes more continuous and the regularity of its onset in relation to food becomes lost. Vomiting directly after food is unusual in gastric ulcer. It sometimes comes on shortly after taking food and a definite interval elapses which may be longer or shorter according to the position of the ulcer. Hæmatemesis and tarry stools (melæna) may supervene as complications. Hæmatemesis may be absent in duodenal ulcer and altered blood may be passed as tarry stools (melæna). Of the other less important symptoms, secondary anæmia, the feeling of a definite tumour or thickening in the epigastrium, constipation, etc., deserve mention.

Apart from clinical study, the following methods are available for the investigation and diagnosis of gastro-duodenal ulcers:—(1) Ewald's test meal (see page 1357). (2) Fractional test meal (see page 1358). (3) Occult blood in fæces (see page 1477). (4) Radiography Examination of the stomach and duodenum by means of the X-rays after the ingestion of an opaque meal is very useful in the diagnosis of ulcers of these organs. Investigations should be made both under the screen and with photographs. The opaque meal used in the screen examination usually consists of 3 oz. of barium sulphate in half to one pint of milk. By this means the shape of the stomach and its filling properties can be investigated. The motor activity however and rate of stomach emptying are better studied with a more solid meal, such as porridge, or bread and milk containing barium sulphate. There should be no residue of such a meal in the stomach after six hours. Persistent deformity in the outline of the stomach or duodenum is the most reliable evidence in the X-ray diagnosis of ulcer. Thus in gastric ulcer the barium may be seen filling a niche in the wall of the stomach or there may be definite organic hour-glass appearance. In the duodenum a persistent alteration in the shape of the duodenal cap may be seen; X-ray examination will also reveal pyloric obstruction.

Variations in tone or in position of the stomach are not diagnostic of ulceration. Subsequent examination after administration of belladonna

is of value in distinguishing between constriction of the stomach due to spasm and that due to cicatrization.

TREATMENT. The treatment of uncomplicated gastric ulcers should always be medical. Before medical treatment is started, all sources of infection in the body so far as practicable should be eradicated. The teeth, throat and naso-pharyngeal regions should be thoroughly examined and proper treatment instituted. The difficulty lies with the intra-abdominal sources of infection which are not commonly discovered and the treatment is therefore greatly handicapped. The general principle of treatment of all ulcer cases includes complete rest in bed, careful dieting and the use of suitable antacids. In all cases the treatment is a prolonged one and requires the patient to be in bed from four to six weeks. A modified Sippy diet (see page 1340) is advisable with an alkaline powder after feeds, and olive oil, belladonna or atropin before the feeds. During the first two weeks feeds are given every two hours and consist of citrated milk (3 gr. of sodium citrate to an ounce of milk) or peptonised milk, Horlick's milk or Benger's food. The quantity should be small and should not exceed five ounces. The quantity and quality of the feeds are altered and improved during the subsequent weeks and are as follows. During the third week raw eggs, thin bread, butter and cream may be added to the previous diet and are given every two hours as before. During the fourth week the feeds are given every two and half hours and consist of five ounces of citrated milk alternated with feeds composed of potato soup, arrow-root or milk pudding. During the fifth week the milk feeds are reduced and additions are made to the dietary in the form of pounded fish 2 oz., lightly boiled egg and crisp toast with butter. The feeds are allowed every 2½ hours. The same regime is carried on up to the 8th week. With these feeds measures are adopted to diminish the secretion and the strength of the resting gastric juice. Immediately before the three feeds ½ an oz. of olive oil is given and directly before three other feeds, tincture of belladonna 5 to 10 min. with chloroform water ½ oz. or sulphate of atropine 1/200 gr. in 1 dr of water is given to the patient.

In cases of acute ulceration associated with hyperchlorhydria, attempts should be made to neutralise as far as possible this acidity. Alkalies should be chosen which will do this without causing a secondary secretion. It has been found that sodium bicarbonate is a strong agent in producing a secondary flow of hydrochloric acid. It is therefore physiologically wrong and even harmful to employ this drug in attempting to give rest to the ulcer from the effects of the acid. A good combination consists of carbonates of calcium, magnesium and bismuth each 20 gr.; 1 dr. of this powder in a little water is taken by the patient 1 hour after each feed during the day and two teaspoonfuls, the last thing at night. During the third and fourth weeks a teaspoonful of this powder is taken three times a day after

feeds, and two teaspoonfuls at night. During the 5th to 8th weeks a teaspoonful of powder is taken twice a day after feeds and 2 teaspoonfuls at night. The mouth should be well cleansed with some alkaline water after each feed. During such treatment tobacco, alcohol, tea and coffee should never be indulged in. When the radiogram indicates that the ulcer has healed after the treatment, the pain and other clinical symptoms have subsided and the occult blood test (stool) is negative, the patient is allowed up for gradually increasing periods and more additions are made to the dietary. Besides those contained in the previous diets, eggs, honey, apple-jelly, fresh fish (boiled or steamed), chicken or mutton, custard pudding, are added. The feeds are given every 2½ hours and one teaspoonful of the alkaline powder is taken after breakfast and 2 teaspoonfuls last thing at night and the olive oil or belladonna before breakfast, lunch and dinner. In the tropics the main ulcer diet should consist of soft rice and milk. After this the diet should be liberal and vegetables, fish, minced mutton, boiled or roast chicken and sweets may be added to the dietary. The breakfast, lunch and dinner should be small meals, well chewed and eaten slowly. The patient should always rest for some time after meals.

Rich condiments should never be added to the dietaries, which should always be unstimulating so as not to invoke gastric secretion. The food should be poor in protein and rich in carbohydrates and fats, of sufficient caloric value and served as small feeds so as not to overdistend the stomach.

Lenhartz diet. Lenhartz advocates 8 oz. of milk mixed with one egg for the first 24 hours after which the quantity is increased daily by 3½ oz. of milk and 1 egg until 2 pints of milk and about 8 eggs are reached. From about the third to the eighth day, raw minced meat starting with 1 oz. in divided doses is given. If well borne, boiled rice, pounded fish or chicken are later allowed and the number of eggs are reduced. At first feeds are given at hourly intervals and complete rest is allowed at night. Both the eggs and milk are iced and the eggs beaten up whole. By the end of the fourth week the patient is put on a mixed diet containing the common foodstuffs avoiding indigestible ones. While carrying out the Sippy treatment, the precipitation of alkalosis should always be borne in mind. The common symptoms are headache, giddiness, nausea, vomiting, drowsiness, tetany or coma; the pulse is rapid and respirations are slow. Alkalies should be stopped, sufficient glucose should be taken by mouth or 1 oz. of glucose in 8 oz. of normal saline should be administered per rectum six hourly. Intravenous injections of calcium are also advocated in these cases.

Protein therapy. The injections of protein preparations were begun after dietetic treatment had failed. The injections were made intravenously, beginning with doses of from 0.2 to 0.4 c.cm. and gradually increasing to 1 or 2 c.cm. The injections are given at intervals of

3 to 4 days. A series consisted of from 4 to 8 and rarely 12 injections. A slight increase in temperature resulted in some cases, but no local reactions such as gastric pains and hæmorrhage were observed. The results obtained with this form of treatment are very favourable.

Indications for surgical treatment. (1) If symptoms persist after prolonged medical treatment and frequent relapses occur after apparent cure as in chronic ulcers. It is stated by Leube that if there be no relief of symptoms four to five weeks after medical treatment, surgical aid should be sought. (2) If profuse hæmatemesis sets in. (3) If acute perforation with general peritonitis supervenes and the pain is persistent due to perigastric adhesions, hour-glass stomach, stenosis of the cardiac or pyloric orifice and gastric dilatation.

After treatment. The patients with gastroduodenal ulcers must observe certain dietetic rules for at least six months, preferably one year and some care in diet is to be taken for the rest of his life.

The following rules are to be observed:—

1. Avoid longer intervals than two to two and a half hours without some form of food, *e.g.*, milk, eat slowly, bite and chew all the food thoroughly. Try to be free from anxiety during the meals.

2. Avoid highly seasoned food, cooked cheese, lemon juice, lemon peel (marmalade), pickles, spices, vinegar, acid fruits, strong tea, coffee or cocoa, rough foods specially celery, raisins and coarse vegetables, very hot food, specially meat soups, fruit with pips, *e.g.*, currants, figs, raisins, lettuce, raw apples, and any alcohol on an empty stomach.

3. Take specially raw or very lightly boiled eggs, milk, custards, jellies, sieved vegetables, bread, butter, cream, soft puddings, fish (not very salted), plain biscuits, cake, toast, rusks (not new or wholemeal bread).

4. Take fish or meat only once a day, in small amounts, and preferably veal, lamb, rabbit or chicken, but avoid tough meat, 'high' game, bacon and pork. Light wine with food is allowable. Salt should not be taken in excess but is allowable in moderation. Smoke only in moderation and not before meals. Take pulv. triple carb. (Maclean) one teaspoonful three times a day twenty minutes after meals and once in the night if awake.

5. Avoid constipation and indiscretions in diet.

GLUCOSE THERAPY. (See page 46). Glucose is extensively used nowadays in therapy for its beneficial effects in many diseases. It is the best nutrition for the tissues and is a food for the vital organs of the body especially the liver and cardiac muscle and its administration adds to the daily caloric intake in the body. It improves the quality of the pulse by improving the ventricular filling of the heart, also raises the systolic blood pressure and thus enhances the peripheral circulation, promotes diuresis and combats acidosis and lately it is said to increase the protective powers of the blood. The various routes resorted to for

the administration of glucose are oral, rectal, subcutaneous, intramuscular, intravenous and pediatric practice even advocates a peritoneal usage. Regardless of the method of administration, glucose undergoes identical metabolic processes in the body and entails very little work on the digestive apparatus. Althausen asserts that the human body usually requires 8 gm. of glucose per kilo. body weight to meet the carbohydrate demand of the body. It is suggested that hypoglycæmia below 30 mgm. per cent. is generally incompatible with life. Besides its storage in the liver and muscles, glucose is also said to be stored in the skin. During prolonged strain and starvation the glycogen reserve of the liver may be completely exhausted though blood sugar and muscle glycogen remain practically constant. Lesions causing starvation states tend to depress the power of the body to utilise glucose. Regarding the strength of the solution to be used intravenously it has been suggested that a 4.9 per cent. solution in water has the same osmotic pressure as 0.85 per cent. sodium chloride solution and is therefore isotonic with the blood and tissue fluids. Hæmolysis of red blood cells was marked when a concentration below $3\frac{1}{2}$ per cent. was used. A 25 per cent. solution is used for intravenous administration, a 10 to 15 per cent. solution is advocated for intramuscular use and a 5 per cent. solution has been injected intraperitoneally. A 20 per cent. solution when injected intramuscularly causes a local reaction. When glucose is injected into the tissues, absorption is marked in an hour's time. Authorities differ on the absorption of glucose from the rectum though it is often administered as such. A 10 per cent. solution has been found to be absorbed from the colon a little faster than an isotonic 5 per cent. solution.

Though deaths are rare, severe reactions are sometimes seen to follow the intravenous administration of glucose. The syndrome of nausea, restlessness, muscle tremors, rigors, convulsions, collapse, stupor and coma, described by Rowntree, is supposed to follow the administration of large quantities of the solution. The rate of intravenous injection should not exceed 4 c.cm. per minute of a 25 per cent. solution lest it produces an overstimulation of the endogenous insulin causing a hypoglycæmia. Reactions are seen to occur after the lapse of variable periods regardless of the dosage or the percentage of the solution used. Other untoward symptoms met with are acute cardiac dilatation from injecting a considerable amount of fluid at a time, apnoea, vomiting and diarrhoea and a few deaths have been recorded from pulmonary emboli. Technical errors and chemical impurities taken up by the solution from the rubber tubing during administration are claimed to be potent causes resulting in such reactions. Nitrogenous bacterial toxins called 'pyrogen' generated by bacteria present in insufficiently distilled water are held to be another cause. The water used for dilution of glucose solution should always be sterile and double-distilled. The reaction due to the rubber tubing can be overcome by soaking it in

soap and water for an hour, washing well with water and lastly soaking it again for four hours in 4 per cent. solution of sodium hydroxide and again washing the whole in distilled water.

THERAPEUTIC USES. Glucose is always indicated and extensively used before all operations particularly where the hepatic functions are deranged, the metabolic rate is high and the patient is undernourished. Glucose is of particular value where a blood transfusion is impossible. It has marked beneficial effects in cases of shock. Glucose should not be given in the early hours of the morning when the liver activity regarding the metabolism of glycogen is at its height. The best time for the administration of glucose is in the afternoon when the blood sugar level is at its lowest. During the rigid dieting regime in *obesity*, glucose should be freely given by mouth, to supply the necessary energy to the body. It is strongly indicated in cases of *ketosis* or *acidosis* and *hypoglycæmia* especially after overdosage with insulin. During prolonged *high febrile states* accompanied with tissue destruction a free intake of glucose with a sparing one of protein is advisable. In *toxæmias of pregnancy* such as *hyperemesis gravidarum* and *eclampsia* glucose therapy is most useful. In *cyclic vomiting* in children glucose with insulin overcomes the accompanying acidosis. The distressing symptoms of *sea-sickness* are very often relieved by glucose. It serves as an emergent food in *physical exhaustion*. Glucose combined with insulin is invaluable in *diabetic coma* where ketone bodies are excessively formed due to defective fat metabolism. In *toxæmias of acute infective fevers* such as *pneumonia*, *diphtheria*, etc *sepsis* and *severe burns*, glucose is said to dilute and neutralise the toxins. Glucose should always be administered in cases where the liver is liable to be damaged by toxins and after prolonged *anæsthesia*.

HÆMORRHAGE. Hæmorrhage denotes an escape of blood from the blood vessels of the body. It may be arterial, venous or capillary. When the blood is escaping from an artery, it is bright red in colour and escapes from the wounded artery in a series of jerks, synchronous with the heart beats. The loss of blood is considerable and rapid and the force and character of the hæmorrhage change with the fall of blood pressure. In hæmorrhage from veins, the blood is dark red or purple in colour and generally escapes in a smooth even stream, uninfluenced by the heart beats. In capillary hæmorrhage, there is a continuous oozing of dark blood from a cut raw surface which coming in contact with the oxygen of the air becomes bright red. Hæmorrhage may be external, when blood escapes from the body and internal or concealed, when the bleeding is proceeding from some region of the body in which it is not often easily detected. The bleeding in primary hæmorrhage occurs immediately after the division of a blood vessel, in the reactionary type, the hæmorrhage recurs within 24 hours of hæmostasis while in secondary hæmorrhage, generally caused by

infective processes in a wound, the bleeding starts after the first 24 hours, usually 8 to 10 days after the infliction of the wound. General constitutional symptoms after hæmorrhage are due to loss of a large amount of blood from the body. Signs such as pallor, loss of consciousness, subnormal temperature with blanched skin, shallow rapid respirations, restlessness, etc. supervene as a result of cerebral anæmia with subsequent failure of function of the vital centres of the brain. Intense thirst is complained of due to dehydration of the tissues of the body. Children and old people stand loss of blood badly and regeneration is much more prolonged than that in young adults. As an immediate after-effect of hæmorrhage, the following changes take place. There is generally no change in cell counts or the percentage of hæmoglobin within two hours after hæmorrhage. The vascular system adapts itself to the loss of blood by contracting, thus a diminution of the vascular area occurs. The diminution of hæmoglobin, red cells and blood protein does not reach its maximum for two weeks. The prognosis is grave if the percentage of hæmoglobin is below 25 per cent. Four hours after a hæmorrhage, there is an increase in the leucocytes of the blood and this may persist for a week. Within 48 hours the platelet count reaches the maximum. The cell increase is more rapid than the hæmoglobin increase which accounts for the colour index being below 1 in hæmorrhagic anæmia. The blood volume usually comes back to normal in six weeks, but in severe hæmorrhages the recovery time is much more prolonged. The specific gravity of the blood is lowered in all hæmorrhages.

CLASSIFICATION OF HÆMORRHAGES. *Group I.* Hæmorrhages due to injuries or localised diseases such as epistaxis, apoplexy, œsophageal varix, peptic ulcer, gynæcological conditions (placenta previa, postpartum hæmorrhage, ectopic pregnancy, etc.), hæmorrhoids and bleeding ulcerating tumours. *Group II.* Spontaneous hæmorrhage as a complication of a general disease. This includes acute infectious diseases such as septicæmia, measles, small pox, etc., jaundice, various forms of anæmia. *Group III.* The true hæmorrhagic diseases of the new born, purpura hæmorrhagica of Werlhof or thrombocytopenic purpura, hæmophilia, pseudohæmophilia.

GENERAL LINE OF TREATMENT. *Natural arrest of hæmorrhage.* In hæmorrhage from the medium-sized arteries, the contraction and retraction of the middle and inner coats may be sufficient to stop the bleeding. Sometimes a temporary arrest of hæmorrhage is brought about by the formation of clots at the mouth of the bleeding vessel. Changes in the blood such as an alteration of the specific gravity, an increase in the number of white cells and a fall in blood pressure associated with the shock of the injury, all help in the formation of clots. Ultimately a natural permanent arrest of hæmorrhage takes place by the formation of granulation tissue at the cut ends of the vessel.

In all emergency cases of accessible surgical hæmorrhage a temporary arrest of bleeding may be secured by the application of a tourniquet sufficiently tight to block the main artery supplying the part. Certain positions are advantageous in the procedure as in cases of bleeding from a limb, the latter should be elevated to empty it partially of blood and then bandaged with an elastic bandage. Other temporary measures include digital compression, ligature of the vessel, where convenient, compression with forceps, etc. The general treatment aims at promoting the rapid formation of internal clot in the bleeding vessel, procuring for the brain a sufficient amount of blood during the period of shock and supplying the necessary amount of fluid to the vascular system to maintain the blood pressure and lastly stimulating the hæmopoietic organs to replace the blood lost during hæmorrhage. The patient should be at complete rest with the foot end of the bed raised, directing the blood of the body towards the brain and if the hæmorrhage is severe the limbs should be bandaged to prevent stasis of blood in the dependent parts of the body. Restlessness should be controlled with an injection of morphia $\frac{1}{2}$ gr. In most cases the cause of death is the profound fall of blood pressure due to the loss of an excessive amount of blood from the body. As soon as the bleeding vessel is controlled, or sometimes even while doing this, intravenous administration of normal saline with glucose or a transfusion of blood becomes a necessity. Fluids may also be given by the oral, rectal and subcutaneous routes. Several pints of normal saline (1 dr. NaCl to a pint) at a temperature of about 100°F. must be administered per rectum till the blood pressure rises or about a pint or a half at a time may be injected subcutaneously into the loose, cellular tissues under the breasts or in the flanks. In the intravenous method of administration of fluids, the vein usually selected for operation is the median basilic vein of the arm. The fluid used is normal saline at the body temperature, the quantity being 2 to 3 pints at a time for an adult patient. The administration should be undertaken under strict aseptic measures. For detailed technique and precautions of blood transfusion see page 49. Drugs are of little use in the general treatment of hæmorrhage. Various preparations of ergot, given by mouth or injected hypodermically, have given good results especially in obstetrical and gynæcological cases. Intravenous injection of calcium chloride, 2 to 5 c.cm. of a 10 per cent. solution, is helpful in increasing the coagulability of the blood. Injection of whole blood 10 to 20 c.cm., hæmostatic serum 2 c.cm. or normal horse serum 20 c.cm. are also effective measures.

Diet has an effect on bleeding tendencies. Lipins and globulins which are contained in the liver, kidney, brain, egg yolk, bacon, nuts, beans and peas produce a definite increase of blood-clotting powers within twenty-four hours. A diet consisting of vegetables and low in food value such as cabbage, tomatoes, cauliflower and stewed fruit

will decrease the clotting power of the blood. Articles rich in iron are suitable for cases of secondary anæmia after hæmorrhage.

CAPILLARY HÆMORRHAGE. Considerable blood is sometimes lost by capillary oozing. *Treatment.* *Heat.* This may be applied in the form of hot water (115°F), cantery at a dull red heat, etc. The drawback in case of a cautery is that there is a chance of recurrence of hæmorrhage when the slough separates.

Cold. This is applied in the form of cold water or ice and is very effective in the treatment of hæmorrhage from the nose, mouth and throat. *Pressure.* Well graduated pressure as by plugging a wound from the bottom is very often effective in arresting a capillary oozing. Care should be taken not to devitalise a part during such a procedure. *Hæmostatics.* Local application of hæmostatics such as adrenalin, turpentine, compound tincture of benzoin, perchloride of iron, horse serum, coagulin, etc., are very often effective in checking local oozing from many parts of the body. Wright's styptic is an extract of the thymus or testis made with saline to which 5 per cent. of calcium chloride and a trace of sodium carbonate are added with 1 per cent. phenol as a preservative. The styptic is applied locally. The wounds should be well dried before the application of hæmostatics.

HÆMATEMESIS. Vomiting of blood may be due to various causes. The common sources include gastro-duodenal ulcer and œsophageal varices resulting from the chronic passive congestion of the portal circulation and cirrhosis of the liver. Gastrostaxis or gastric oozing from a local lesion in the stomach is also an occasional cause of profuse hæmorrhage. Coffee-ground vomiting is characteristic of gastric carcinoma. Aneurysm of the aorta by leaking into the œsophagus may cause hæmatemesis. Serious hæmatemesis may also occur in enlargement of the spleen especially in Banti's disease and thrombosis of the splenic vein. Mechanical injury and corrosion of the gastric mucosa by corrosive poisons are also important causes. The general toxic causes include poisons such as arsenic and phosphorus and toxins of various diseases such as acute yellow atrophy, infective and toxæmic jaundice, small-pox, malaria, yellow fever, hæmorrhagic disease, etc. A slight degree of hæmatemesis is not infrequently associated with vomiting of sea sickness, cyclical vomiting, post-anæsthetic vomiting, pernicious vomiting of pregnancy and acute intestinal obstruction. The vomited blood in hæmatemesis might not originate in the stomach itself but may have been swallowed as in cases of epistaxis, a bitten tongue in epilepsy or from bleeding gums.

In hæmatemesis, giddiness and faintness precede the actual bringing up of blood, the blood is dark in colour, clotted and often mixed with food materials. It is usually acid in reaction.

Treatment. The treatment of hæmatemesis is essentially that of its primary cause. If the source of bleeding is easily detected, it may be controlled under aseptic surgical measures. Usually a gastro-duodenal

ulcer is a common cause of hæmatemesis. The bleeding may be profuse and prove rapidly fatal. Such a hæmorrhage may be capillary, venous, or arterial. Medical treatment should always be tried first in case of hæmatemesis from acute gastric ulcer. Absolute rest should be imperative. The patient should be laid horizontally and an ice bag may be applied to the epigastrium. No food or stimulant should be given by the mouth but small fragments of ice or sips of iced water may be allowed at times. Morphia $\frac{1}{4}$ gr. may be administered hypodermically to calm the patient and as much as 1 gr. of the drug may be administered in 24 hours. A rectal injection of normal saline (about 4 to 6 oz.) containing 4 dr of glucose may serve as nutrition to the patient and may be repeated every 6 hours. Hæmostatics like horse serum 10 c.cm., coagulin 5 c.cm., etc., may be injected intramuscularly. Intravenous injection of a 10 per cent. solution of calcium chloride in 5 c.cm. doses is very often effective. Styptics such as adrenalin chloride (1 in 1000) 10 to 15 min., or turpentine oil 5 to 10 min. by mouth, are also advocated in these cases. When there is considerable loss of blood, transfusion is of particular value.

HÆMOPTYSIS. The term hæmoptysis or the spitting of blood is employed to indicate bleeding from the lungs or the respiratory passages. It may be true or spurious. When true, the blood is derived from the larynx, trachea, bronchi or lungs whereas in spurious hæmoptysis, the source of bleeding is above the larynx. The commonest cause of hæmoptysis is pulmonary tuberculosis. It may also occur in pneumonia but the sputum is usually rusty in colour. Pulmonary infarction is another cause of hæmoptysis. Passive congestion from heart disease, especially mitral valvular disease, is a cause of repeated bleeding from the lungs. Rarer causes of pulmonary hæmorrhage are abscess, gangrene, hydatid disease and neoplasm. Ulcerations of the larynx trachea, or bronchi also cause hæmoptysis. An aneurysm may leak into the trachea or a bronchus and the blood may be spat out. In bronchiectasis, a brisk hæmorrhage may occur. Among the rarer general causes of hæmoptysis are hæmorrhagic fevers, scurvy, leukæmias, etc. Trauma as from a fractured rib or gun-shot wounds, is another cause. Blood is sometimes expectorated in cases of high blood pressure, arteriosclerosis and emphysema.

In hæmoptysis, the blood is coughed up; it is frothy, bright red in colour, and is alkaline in reaction. After the actual attack, the sputum is streaked with blood for days together.

Treatment. Absolute rest in bed in the recumbent position is imperative. Food and stimulants should not be allowed. Morphia $\frac{1}{4}$ gr. may be injected hypodermically to calm the patient. If the focus of bleeding is detected in one of the lungs, an ice bag may be applied over it. In such cases, the patient should be inclined to that side as this will prevent the blood from being aspirated into the healthy lung. If the hæmoptysis is severe, the affected lung should be collapsed by an artificial

pneumothorax (for details of the technique of artificial pneumothorax see page 960). Other measures such as the inhalation of amyl nitrite 5 min., the injections of hæmostatic sera (Hæmoplastin) 2 c.cm., or the daily injection of emetine hydrochloride 1 gr. intramuscularly for 5 or 6 days may also be tried to control the hæmorrhage. Blood pressure should always be lowered by saline purges. Cardiac depressants such as aconite, are useful. Intravenous injection of a 10 per cent. solution of calcium chloride in 2 to 5 c.cm. doses, is often effective in these cases. Alcohol, tobacco and other stimulants should be forbidden. A mixture containing turpentine oil 10 min., tincture of squill 10 min., syrup $\frac{1}{2}$ dr. and cinnamon water to 1 oz., one dose thrice daily, is sometimes helpful. A solution of congo-red has been used in the treatment of hæmoptysis and is found to be a reliable hæmostatic. It is given as an intravenous injection, the usual adult dose is 10 min. of a 1 per cent. solution. This is often followed by a rigor of short duration. If there is recurrence of the hæmorrhage after the first dose, a further 10 min. dose may be given after four to six hours.

HÆMORRHOIDS OR PILES. These constitute a varicose condition of the veins of the anal canal and the lower inch or two of the rectum. Their characteristic course, situation in the loose areolar tissue and dependent position at the lowest part of the portal area with absence of valves, predispose to the condition and any pressure or obstruction in the portal or systemic circulation is reflected to the most dependent part where anastomosis of vessels occurs. They form a series of oval purplish swellings from which blood is readily expressed on pressure and hence piles are rarely detected on digital examination per rectum.

Piles are met with at all ages and in all conditions of life. They are common in young people with sedentary habits and are also common in elderly individuals especially with an enlarged prostate. Malignant diseases of the rectum often lead to piles. Pregnant women or women with pelvic and uterine tumours or displacements are also predisposed to this condition. Other ætiological factors are chronic constipation associated with a sedentary life, overuse of purgatives, a loaded rectum and obstruction to the portal circulation as from cirrhosis of the liver. Clinically piles are divided into external or internal. The external piles are situated at the anal margin and are covered with skin. Internal piles are situated above the anal canal and form a series of purplish ovoid bulges in the lower rectum. In the absence of complications, piles very seldom present symptoms beyond a little pruritus, some irritation and a sense of fullness at the anus immediately before and after defæcation. Hæmorrhage, inflammation, suppuration, thrombosis, prolapse and strangulation are the common complications of piles.

TREATMENT. (1) *External piles.* In all cases, the cause, if discovered, should be removed when possible. The regular use of a suitable laxative may prevent the condition. The anal region should always

be kept clean and all sources of external irritation removed. Where the piles are inflamed and thrombosed, absolute rest in bed, fomentations and warm enemata are indicated. If necessary the thrombosed mass may be incised and the clot removed, thus relieving the tension.

(2) *Internal piles.* As in external piles, the primary cause and all possible sources of venous congestion should be removed, the bowels should be regulated with mild aperients like confections of senna and sulphur, liquid paraffin, etc. The anus should be washed with cold water after defæcation and it is desirable for the patient to rest for some time after the act. If bleeding is severe, astringent suppositories or ointments of adrenalin, hamamelis, tannic or gallic acid should be used, for moisture and pruritus, soothing ointments or powders are indicated.

Infection treatment In cases where there is no permanent prolapse of the piles, several injections of a solution of 10 per cent. carbolic acid in liquor hamamelidis or of quinine and urethane into the mucous membrane of the anal canal are of much benefit. The treatment aims at the clotting and ultimate fibrosis of the hæmorrhoidal mass. Radical treatment by surgical operations are indicated where the loss of blood from the piles is rendering the patient anæmic and interfering with his general health and if the prolapse and inflammation be frequent. On the other hand, operations are contraindicated when piles are secondary to some conditions that can never be cured or relieved.

HEADACHE. This is one of the commonest symptoms met with in medical practice, and the various conditions with which it is associated are numerous. Headache may be the first symptom calling attention to the existence of grave organic disease, and the correct diagnosis of the cause of this symptom is very important. Too often unfortunately, treatment of headache precedes a careful investigation as to its cause, and an increased risk may thereby be incurred by the patient through the delay in recognising the actual cause.

The explanation of the mode of production of the pain known as headache is not easy, as the brain substance itself is insensible to mechanical stimulation. The membranes or at least the dura mater is on the other hand, sensitive, the arachnoid contains no nerves and the pia mater receives only sympathetic twigs for its blood vessels, but the dura is supplied with a large number of sensory fibre which leave the three divisions of the trigeminal nerve distant to the Gasserian ganglion and pass to the membrane as recurrent meningeal branches. The most important of these are the anterior and posterior ethmoidal and the tentorial nerves from the ophthalmic division and the recurrent branch from the mandibular division that re-enters the skull through the foramen spinosum. A recurrent branch from each vagus also contributes to the supply of the dura of the posterior fossa.

There can be no doubt that these dural branches are concerned in the production of headaches after the extirpation or injury after

herpes of the Gasserian ganglion the headaches rarely or never occur on the same side of the head. It might be assumed that all headaches are not due to irritation of the dural nerves, but it is obvious that pain can be felt only through the mediation of the nerves and these are the only sensory filaments that are distributed to the intracranial cavity. The dural nerves may be stimulated in many different ways:—

(1) By a rise of pressure within the skull, *e.g.*, by cerebral tumours and abscesses, meningitis and congestion of the cerebral vessels. (2) By poisons and toxins circulating in the blood, *e.g.*, alcohol, nicotine, toxins of the infectious fevers, nephritis, etc. (3) It may be a referred pain, *e.g.*, in disease of any visceral organ pain may be referred to a corresponding area on the surface of the body causing a state of abnormal excitability of that portion of the grey matter of the cord in which the visceral afferent fibres terminate (Ross, Mackenzie and Head). Disease in the distribution of the trigeminal nerve may excite pain that is referred to the head. Similar are the headaches of eye strain, and that associated with diseases of the nose and accessory sinuses. Head has also shown that local headaches may be the result of pain referred from one of the thoracic or abdominal viscera, due to the close central connection of the afferent fibres of the vagus with the central root of the trigeminal.

The following points are to be noted whilst investigating a case of headache: (1) Its position, whether general or circumscribed, the position of greatest intensity and whether it is superficial or deep in the head. (2) The time of the day in which it occurs or becomes more severe, whether it is constant or variable, and if it is liable to occur at more or less regular intervals. (3) The nature of the pain, whether it is a feeling of a pressure or a deep boring pain, a constant dull aching or a throbbing pain, an intermittent shooting pain or a feeling of the bursting of the head. (4) Exciting or aggravating causes, what it is that starts the headache and whether it becomes worse on lying down or walking about, when quiet or under excitement, and if food, exposure to cold, worry, or work, has any influence on it. (5) Conditions associated with the headache should be carefully investigated as they frequently throw light on its origin, *e.g.*, presence of vomiting or gastric disturbances, vasomotor or cardiac symptoms, the mental state during the attack, if the scalp becomes tender during or after the headache or whether it is accompanied by vertigo or ocular symptoms.

Though it might not be possible to include all the headaches in the categories suggested, the following classifications will be of practical value.

MIGRAINE. Most of the familial and constitutional headaches are migranous (see page 1410).

HEADACHES FROM RAISED INTRACRANIAL PRESSURE. The most important causes are tumours and abscesses of the brain, meningitis and cerebral

syphilis. Headache is not infrequently due to high blood pressure, especially when associated with arteriosclerosis.

The headache associated with cerebral tumour is generally described as a dull, deep-seated pain; sometimes the patient gets an intense throbbing pain or a feeling that the skull would burst open, from its severity. As a rule it is general but is often most severe in the frontal region or behind the eyes; occasionally it is worse in the occipital region, especially when the tumour lies in the posterior fossa, and then the pain, frequently radiates down the back of the neck. The pain is more or less constant though severe exacerbations may occur, but many patients are free for considerable periods. An important feature is that it is usually most severe at night. If the intracranial pressure be very high, vomiting is generally associated with severer bouts of pain. The presence of papilloedema and symptoms of progressive cerebral disease are important signs in diagnosis.

In acute meningitis the headache is usually general but more intense in the occipital region. It is accompanied by stiffness of the neck and is aggravated by every movement of the head on the vertebral column and by pressure on the suboccipital region as these increase intracranial tension by compressing the distended posterior arachnoid cistern.

Headache due to syphilitic involvement of the brain may either occur soon after infection or be associated with the later manifestation of the disease. In early syphilis the pain is more or less constant and spreads from the occiput to the vertex or forehead and is particularly severe when the patient lies down or lowers his head. It may be a result of toxins reaching the brain as the infection becomes generalised, but is more probably caused by the early vascular and meningeal changes that often occur at this stage. Headache in the later stages of syphilis may be due to meningitis, infiltrations or cerebral vascular disease. Cerebral vascular diseases and arterial hypertension often give rise to headache. The arterio-sclerotic variety occurs in the fifth and sixth decades of life, in men more frequently than in women and usually on those who have led active and vigorous lives. It is associated with premature senility, mental deterioration and vertigo, and frequently insomnia or disturbed sleep at night with drowsiness during the day. The headache that is increased by mental and physical exertion, by worry and by bad ventilation is generally constant but never severe. The state of the retinal vessels by ophthalmoscopy gives valuable confirmatory evidence regarding the state of the vessels of the brain.

Treatment. The treatment should be directed towards the removal or alleviation of the cause. In cerebral arteriosclerosis the patient's mode of life must be carefully regulated, diet should be light, constipation avoided and alcohol limited or prohibited. The patient is always invariably better in the open air, and country life is consequently

advisable. A moderate amount of regulated exercise is usually advantageous. Iodide with bromides are usually the most effective drugs, nitrites in alkaline mixture are also frequently of value.

VASOMOTOR HEADACHES. Vaso-motor disturbances are frequently assumed to be causes of headache. There is some evidence that migraine is due to a periodic vasomotor upset, and headaches associated with disorders of the ductless glands and with certain physiological processes, such as menstruation, may be of this nature. Headache following prolonged physical and mental work, and epileptic seizures, are probably due to disturbances of the cerebral circulation. Another common cause of headache of this nature is paroxysmal cough, which raises the venous pressure producing venous congestion of the brain. The distressing headaches that sometimes occur in phthisis, bronchitis and asthma, are directly due to this cause. A rare variety, of sudden onset occurring in persons subject to angioneurotic oedema is probably due to patches of oedematous infiltration of the brain and meninges.

Treatment. The treatment of headaches due to circulatory disturbances is usually easy and effective. Cough must be checked by appropriate means, and overexertion must be avoided where this is the cause. When true vasomotor disturbances are responsible preparations of the ductless glands should be tried. Belladonna combined with bromides are also of value.

TOXIC HEADACHES. These may be due to exogenous poisons such as alcohol, nicotine, carbon monoxide, and lead, or to toxins manufactured within the body, those developed in the specific fevers, pneumonia, influenza, and those produced by gastro-intestinal disorders and in nephritis. The headaches that are so common in chlorosis are also of toxic origin. In fact, most poisons circulating in the blood cause headache, probably by their irritant action on the meningeal nerves.

The character and the situation of the pain depend upon the severity and nature of the intoxication. It is usually vertical or diffuse and of an intense bursting or boring character in acute infections and a more or less constant dull aching in chronic poisoning.

Treatment. In acute intoxications treatment can be rarely more than symptomatic. Rest preferably in a dark room, with cold application to the head and forehead and the administration of such drugs as antipyrin, phenacetin, caffeine and aspirin generally give some relief. In the more chronic cases one should always try to remove the cause. The importance of gastro-intestinal intoxication must never be forgotten, occasionally a purgative alone is sufficient but more radical and systematic treatment is usually required. The regulation of the diet and the use of liquid paraffin are usually effective remedies.

REFERRED HEADACHES. Defective eyes are certainly the most important source of this form of headache. The pain is usually bilateral and either frontal or temporal. It is seldom present or severe in the

morning. Diseases of the ear, especially when the middle ear is involved often give rise to pain which almost always spreads to the parietal and vertical regions and is often accompanied by tenderness on the scalp. Referred headaches of nasal origin are most commonly due to hypertrophy of the turbinates or deviation of the septum so that they press against one another. But headaches may also result from the absorption of toxic products when drainage is imperfect, and from inflammatory diseases of the nasal sinuses.

Treatment. The treatment consists in treating the primary causes only.

HEAT-STROKE (See page 218). This appears to be due to an auto-intoxication caused by lack of escape of heat from the body owing to insufficient evaporation from the skin and to the effects of muscular fatigue. As a result, toxic substances accumulate which have a selective action on the nerve cells. There is also deficient oxygenation of the blood. Some believe the condition to be a tissue acidosis, there being a retention of carbonic and lactic acids and a consequent depleting of the blood of its alkali content. In any case there can be no doubt that high relative humidity of the air is a very potent factor in producing attacks of heat-stroke and prostration as it notably checks cutaneous evaporation. Alcoholism is one of the chief predisposing causes. The milder forms are known as heat-exhaustion and heat-prostration; the severe form is sometimes associated with, and so far as pathology is concerned, may indeed be identical with, sun-stroke, in which there is a direct action of the solar rays.

Heat-stroke proper is a much more serious matter, and two clinical types may be differentiated: (1) thermic fever, (2) heat-cramp. An early warning sign in heat-stroke is a desire for frequent micturition and other prodromata are dryness of the skin, drowsiness, vertigo, headache and intolerance of light. The pulse is quick, rapidly becoming irregular, the skin is hot and dry and the temperature elevated. Delirium, coma or convulsions may ensue. The attack may come on very suddenly. Three main types have been observed:—(a) Asphyxial, where the soldier, fighting against an overpowering feeling of prostration, continues to march with tottering gait, fixed stare, contracted pupils and cyanosed face until he collapses senseless and apparently dead. His breathing is in abeyance, his pulse imperceptible at the wrist and his face deeply cyanosed. (b) Paralytic, in which there is deep coma, recurring convulsions, vomiting, diarrhoea and hyperpyrexia. The skin and ejecta may emit a mousey odour. (c) Psychopathic, which is not so deadly and in which the patient's mental balance is upset. His mind may be merely confused or he may pass into a muttering delirium or become violent and excited, or harbour delusions which may drive him to suicide.

Heat-cramp is chiefly seen amongst ships' firemen in the tropics and need not be further considered here. True heat-stroke must not be mistaken for an attack of cerebral malaria, though it is often very difficult to distinguish between them. The blood should be examined for parasites, the splenic region palpated and percussed, and the history if possible, obtained. Cerebral hæmorrhage in which the rise of temperature follows the insensibility, and cerebro-spinal fever have been mistaken for heat-stroke.

PROPHYLAXIS. Alcohol must not be taken at least during the day, the skin should be kept clean, the clothes should be loose and easy and the head, especially the occiput and the nape of the neck, well protected. Dark or tinted glasses protect the eyes from glare and the action of actinic or light rays.

TREATMENT. The milder degrees of sun headache are benefited by doses of caffeine and antipyrin or caffeine and phenacetin. For heat prostration get the patient into the shade, in a cool place if possible, lay him on his back, loosen his clothing especially about the neck, and massage his limbs. If there is collapse give ammonia or camphor and restore his bodily heat by hot applications. A warm bath may do good.

The special treatment for the asphyxial type of heat-stroke is artificial respiration, prolonged if necessary for a couple of hours. The paralytic type also requires prompt and vigorous treatment. The indications are to reduce the temperature, to get rid of toxic substances and to prevent cardiac failure. A simple means of reducing pyrexia is the cold abdominal pack. Where ice can be got it must be used to bring down the temperature, an iced bath or ice pack or rubbing the body with lumps of ice. A handy way is to lay the patient naked on a slightly inclined stretcher, pack him with ice and play a stream of iced water on his head from a distance of 15 to 20 inches. This ice-cold stream must not be continued for more than one or two minutes and collapse must be guarded against. Hence the rectal temperature must be taken and the cold applications stopped when the thermometer registers 102°F. Thereafter wrap the patient in blankets and apply hot bottles to the trunk and limbs. An ice-bag may be applied to the head. If perspiration sets in the prognosis is good. If the temperature rises again the cold applications must be resumed. Where ice cannot be got, a sheet soaked in water or dilute alcohol over which a draught of air plays, may be tried or cold water enemata given. There seems to be an advantage in making these alkaline, *i.e.*, give 1½ pints of a solution containing 2 per cent. sodium chloride and 2 per cent. sodium bicarbonate. All patients with a temperature of 103°F. or over should be placed at once in a bath of water, the level of which is high enough to cover the body except the head, which may be supported in a hammock or sling containing ice. Vigorous friction should be applied to the entire body by several persons, ice added freely to the water and the rectal temperature taken every minute. When the temperature falls to 102°F.

remove the patient from the bath and wrap in sheets or blankets, proceeding as above. Cardiac stimulants, especially caffeine and strophanthus should be freely given. A rectal enema containing 1 drachm of chloral hydrate has been found useful in quieting wildly delirious patients. Scopolamine, morphine and the bromides are useful in controlling restlessness and convulsions.

As there may be tissue acidosis slow intravenous transfusion of about 1½ pints of a 1 or 2 per cent. solution of sodium bicarbonate is indicated when the patient does not quickly respond to the treatment by cold. Such cases tend to develop oedema of the lungs and brain, hence before the transfusion, venesection should be practised as this will also help to eliminate toxic products. Normal saline may also be given intravenously after the bleeding. Recent work shows that certain cases of severe heat-stroke are markedly benefited by lumbar puncture, and the withdrawal of 20 c. cm. or more of cerebro-spinal fluid. It is probable that this operation will be more generally practised than heretofore, especially in cases classed as true sun-stroke.

Stimulants are often required, but strychnine is contra-indicated owing to its tendency to cause convulsions. When the latter occur give cautious inhalations of chloroform, watching the heart. Calomel and salines are indicated at a later period. Treat the psychopathic form as for heat prostration and on general principles.

COMPARISON OF THE ESSENTIAL FEATURES OF THE DIFFERENT DISORDERS
DUE TO HEAT

<i>Condition</i>	<i>Pathological changes</i>	<i>Clinical features</i>	<i>Treatment</i>
Heat cramps	Loss of sodium chloride.	Cramps	Salt and water by mouth. Hypotonic saline intravenously.
Heat exhaustion and heat prostration.	Circulatory failure from deficient blood supply.	Fainting, prostration, collapse, skin cool and moist, blood pressure low, temperature subnormal or elevated, pulse soft and small.	Fluids especially normal saline intravenously. General treatment for collapse.
Heat hyperpyrexia.	Failure of sweating.	Delirium, convulsion and coma. Skin dry and hot. Temperature 100° F. or more. Pulse rapid and full.	Cold water spray and fan.

HELMINTHIASIS. See page 254.

FILARIASIS. *Wuchereria bancrofti* infection (see page 335). Owing to the low-grade toxin of this parasite there may be no signs or symptoms in an infected individual for a long period. In susceptible individuals, however, there may be periodical anaphylactic symptoms like urticaria, headache, low fever, etc. At this stage the parasite is active and embryos are invariably present in the blood stream. There is moderate eosinophilia and complement-fixation test with *Dirofilaria immitis* antigen is positive.

According to the intensity of infection in an endemic area, various filarial diseases develop in the infected individual, viz., elephantiasis of limbs, breasts or genitals; chylocele, lymph-varix or chyluria. Hydrocele due to filarial infection is common in endemic areas. Lymphangitis of the extremities or of the abdominal region, orchitis, epididymitis or funiculitis recurring periodically is a common manifestation of filarial infection. When the worm dies in a lymphatic vessel or gland it is eliminated by abscess formation or it may become calcified or be absorbed.

Diagnosis. (1) Examine the blood for microfilariae. The method of examination of blood is to take 20 drops of peripheral blood at midnight in 10 c.cm. of 2 per cent. acetic acid solution. The blood is centrifuged and the deposit examined for embryos. In chyluria, examine the centrifuged deposit of urine for embryos; and in lymph-varix or lymph-scrotum examine the exudate or aspirated lymph for their presence. It is a general rule that the embryos are present in the blood in the early stages of the infection before the obstruction of lymphatics is complete. But in cases of chyluria they are invariably present in the blood as the block is near the juxta-aortic region where, owing to free anastomosis of lymphatics, they are able to reach the blood circulation. (2) Examine the blood for eosinophilia. Moderate eosinophilia of about 5 to 15 per cent. (total 500 to 1500 per c.cm. eosinophiles) is seen in early cases. In cases of lymphatic obstruction there may be no eosinophilia, but on the other hand, there may be leucocytosis of polymorphonuclear type during an acute attack. (3) Complement-fixation test with the *Dirofilaria immitis* antigen. A positive reaction indicates the presence of toxin of the parasite. In cases of lymphatic obstruction and where the lymphangitis is due to secondary organisms the test is negative. (4) Dermal test with the *Dirofilaria immitis* antigen. A positive reaction is indicative of filarial infection.

TREATMENT. The treatment of filarial infection, therefore, depends upon whether the infection is active or dead. It will be possible to classify the patients as toxic or septic types by the above procedure. In the case of the former, preparations of arsenic or antimony give beneficial results. In the case of the latter type, a thorough examination of the patient with a view to detecting any focus of secondary infection has to be made. The sites of secondary infections are septic gums, carious teeth,

tonsils, septic sinuses, bowel lesions or skin infections. Bradiate the focus or foci; immunise the patient with auto-vaccine wherever possible. Stock filarial mixed vaccines consist of streptococci 100 millions and staphylococcus albus and aureus each 500 millions per c.cm. the dose commencing from 0.1 c.cm. generally increased to 1 c.cm. and a course of 10 or more injections has always been found to be very beneficial. Mixed types need combined treatment.

The routine course of treatment followed: 1. *Filarial lymphangitis, lymph-adenitis, orchitis and funiculitis.* Rest in bed, calamine lotion applied locally and diaphoretics and hydrotherapy for fever. For prevention of recurrence of acute attacks treat the case according to whether it is the toxic or septic type. 2. *Filarial abscess.* Hot boric compresses and surgical treatment by evacuation and aseptic dressings. A course of antovaccine, wherever possible, is recommended. 3. *Lymph-scrotum, lymph-varix and hydrocele.* Treatment is chiefly surgical. Palliative treatment consists in the application of suspensory or pressure bandages. 4. *Elephantiasis.* (a) Elimination of septic focus. (b) Vaccine and non-specific protein therapy. (c) Elastic pressure bandage. (d) Surgical treatment (Kondoleon's operation, etc.). 5. *Chyluria.* Compounds of arsenic or antimony (e.g., tryparsamide, founadin and neostibosan) have given good results in relieving this affection. Since there is generally a secondary infection in cases of chyluria 'midstream' urine or a catheter specimen culture and a course of autovaccine is to be recommended. Rest in bed and restriction of fats and fluids during treatment are helpful. Liquid extract of Hamamelidis (B. P.) and Liquid extract of Lodh are sometimes effective in dram doses orally.

GUINEA-WORM INFECTION. *Dracunculus medinensis.* (See page 333). This is very local in its incidence, the infection is endemic in several areas in North-West Frontier Province, the Punjab, Rajputana, Central Provinces, Bombay and Madras Presidencies. It is essentially an infection of the areas in which there is water scarcity and where the supply of water is obtained from step-wells or tanks, etc. The adult female usually appears on the lower extremity where it causes a blister; when the blister opens the uterus protrudes and discharges embryos every time it comes in contact with water. The embryos develop inside the hæmocele cavity of cyclops and undergo development. They become infective in 2 to 4 weeks. When the infected cyclops are swallowed by man with drinking water the hydrochloric acid in the stomach kills the cyclops but the larvæ become active and piercing the dead cyclops escape and enter the tissue. They reach maturity in about one year.

Anaphylactic symptoms like urticaria, giddiness, and vomiting, etc., are complained of just before the production of the blister. The adult worm during its migration may die and get calcified if it is not able to reach the skin surface. Such calcified worms produce rheumatic pains, synovitis or periostitis when it is desirable to remove them. They can be easily detected by X-rays. Secondary infection with streptococci or

staphylococci is very common in this infection. If the worm breaks in the process of extraction acute cellulitis may result due to streptococcal infection.

Diagnosis. Generally the diagnosis of guinea-worm infection is easy. In difficult cases the following points are of help. (1) Knowledge of distribution of guinea-worm infection. (2) History of previous appearance of worms. (3) Moderate eosinophilia 10 to 15 per cent. (1000 to 1500 per c.cm.). (4) Positive complement-fixation test. (5) Positive dermal test with *Dirofilaria immitis* antigen.

Treatment. Anaphylactic symptoms are relieved by the injection of liq. adrenalin hydrochloride $\frac{1}{4}$ c.cm. intramuscularly. Repeated pouring of cold water over the worm will hasten the discharge of the embryos, but it takes 2 to 3 weeks to empty the worm of its embryos by this method. Ethyl chloride spray hastens and empties the worm in less time. Gentle traction and winding the worm on a match-stick day by day is an ancient method of treatment. Injections of 1 or 2 c. cm. of chinosol solution 1 in 400 or acriflavine 1 in 100 into the body of the worm or into the subcutaneous tissue will kill the worm and it may be easily extracted in a day or two. Injection of tartar emetic intravenously, reported by Macfie to kill the adult worm, has not been confirmed.

Prophylaxis. Prevention of this infection is simple. Filter drinking water through coarse muslin. Step wells and tanks are the source of infection. Surrounding the wells with a parapet and the introduction of pumps for drawing water will prevent the spread of the infection. Various measures for destroying the cyclops such as heating well-water by steam or the addition of caustic potash, permanganate of potash or bleaching powder have been recommended but they are expensive as they would have to be done periodically.

INTESTINAL WORMS (see page 266). *Diagnosis of helminth infections in stools.* A supply of saturated salt solution must be prepared. To be certain it is of sufficiently high specific gravity, excess of salt is placed in a vessel containing water and put over the fire where it is allowed to boil gently until a scum forms on the surface of the water. When this occurs it can be allowed to cool and it is placed in a bottle where it will last indefinitely.

Take a small receptacle (a tin pill box or *dibia* is one of the best) with a capacity of about 20 c. cm. Place about 1 c. cm. of stool in the tin and add a few drops of salt solution. Stir thoroughly with a glass rod or piece of stick until the stool is completely emulsified into a smooth paste. This thorough breaking up of the stool is the essential step in the method if it is to be successful. Add more salt solution slowly, stirring meanwhile, until the tin is nearly full, and then add more salt solution drop by drop until the fluid is just level with the top of the tin. Place a microscope slide over the top of the tin, and if it has been correctly filled almost the whole of the slide within the borders of the tin is in contact with the fluid but none has run down the sides. Allow this

to stand for twenty minutes and lift the slide steadily, taking care to keep it horizontal and then turn it over. Examine with the ordinary low power and the eggs will be found floating on the surface of the fluid on the slide. It is not necessary but it is preferable to use slides 2" x 3" rather than the ordinary 1" x 3" slides as the former completely covers the opening of the tin with a wide dry border all round, and hence holds the fluid better than the narrow slide, when it is being turned over. The eggs found by this method are hook-worm, ascaris, trichuris, *trichostrongylus*, *enterobius*, *strongyloides* (occasionally), *hymenolepis nana*, and *hymenolepis diminuta*.

EGGS THAT FLOAT IN SATURATED SALT SOLUTION

(By salt flotation method)

	Appearance, colour, etc.	Size.	Measurement in microns.
<i>Ancylostoma duodenale</i> .			
<i>Necator americanus</i> .			
<i>Ancylostoma braziliense</i> . (hookworms).	Colourless.	Medium	70-60 x 35-40
<i>Ascaris lumbricoides</i> (roundworm).	Brown, knobby.	Large	70-50 x 50-40
<i>Trichuris trichiura</i> (whipworm).	Dark brown, knobbed at each end.	Small	55-50 x 25-20
<i>Trichostrongylus</i> (similar to hook- worm, rare, and does not cause symptoms).	Colourless.	Medium	95-75 x 45-35
<i>Enterobius vermicularis</i> (threadworm).	Colourless, with tadpole larva.	Small	60-50 x 30-20
<i>Heterodera radicola</i> (not true parasites, accidental).	Colourless.	Large	100 x 45
<i>Strongyloides stercoralis</i> (rare, larvae in stool).	Colourless.	Medium	50 x 30
<i>Hymenolepis nana</i> .	Colourless. Onchosphere with fila- ments.	Small	45-30. (Oncho- sphere 19-16).
<i>Hymenolepis diminuta</i> .	Brownish, no filament.	Large	85-60. (Oncho- sphere 36-18).

The eggs that do not float in saturated salt solution are unfertilised ascaris, *tænia saginata*, *tænia solium*, and all fluke eggs.

EGGS THAT DO NOT FLOAT IN SATURATED SALT SOLUTION

	<i>Appearance, colour, etc.</i>	<i>Size.</i>	<i>Measurement in microns.</i>
<i>Ascaris lumbricoides</i> (unfertilized).	Brown, knobbed. Yolk granules.	Large	80 × 40
<i>Tænia saginata</i> (beef tapeworm).	Dark brown, 3 pairs of hooks.	Small	40-30 × 30-20
<i>Tænia solium</i> (pork tapeworm).	(Indistinguish- able from the last)		
All trematodes, e.g., <i>Fasciolopsis buski</i> .	Light brown with oper- culum.	Large	140-130 × 85-80

TREATMENT. HOOKWORM. (1) *Oil of chenopodium*. This form of treatment is employed when carbon tetrachloride is contraindicated. One gelatine capsule containing 10 min. of oil of chenopodium is given each hour for three doses and this is followed by a purgative two hours after the last dose (see page 298). (2) *Carbon tetrachloride*. Only chemically pure samples must be used. It is administered in a dose of 48 min., well shaken up in 2 oz. of haustus magnesium sulphate (see page 284). (3) *Oil of chenopodium and carbon tetrachloride*. The combined treatment is of use, because it gets rid of more hookworms than either drug alone and the oil also acts on any ascaris that may be present. The dose is 15 min. of oil of chenopodium and 45 min. of carbon tetrachloride, thoroughly shaken up in 2 oz. of haustus magnesium sulphate immediately before administration. (4) *Oil of chenopodium and tetrachlorethylene*. The latter drug is not so toxic as carbon tetrachloride and it can be given in doses of 1 dr. shaken up in magnesium sulphate solution with 15 min. of oil of chenopodium in the same way as carbon tetrachloride.

For children. In the case of oil of chenopodium 1 min. for each year of age is given up to the age of sixteen and in the case of the other drugs the usual formula (age divided by, age + 12) may be employed.

ASCARIS. *Santonin and oil of chenopodium*. In uncomplicated ascaris infection, 3 gr. of santonin and 15 min. of oil of chenopodium are used. The oil of chenopodium is placed in a hard gelatin capsule and swallowed at the same time as the santonin, with a draught of water, followed in two hours by a dose of haustus magnesium sulphate (see page 310).

*TAPEWORM (see page 271). The best treatment for this is carbon tetrachloride alone.

THREADWORM OR OXYURIS. *Enterobius vermicularis*. Carbon tetrachloride in the dose employed for hookworm infection has been found

to be the most effective drug. The worms are difficult to eradicate, and combined with drug treatment precautions should be taken to prevent re-infection by carrying eggs from the anus to the mouth on the fingers. The region of the anus should be smeared every night with dilute ammoniated mercury ointment (5 gr. to 1 oz.). This serves the double purpose of relieving the pruritus and killing the female worms which wander out of the anus at night. Gloves which are washed every day may also be worn all night. If this routine is persisted in a cure is usually effected.

WHIPWORM (*Trichuris*). No cure is effective; but the worms rarely cause symptoms.

STRONGYLOIDES. Gentian violet in doses of 1 gr. three times daily for three days is sometimes efficacious.

FASCIOLOPSIS BUSKI (see page 331). This is the only fluke infection in human beings in India and it is not common. Carbon tetrachloride in the dose employed for hookworm is a sure cure.

Other anthelmintic treatments have proved relatively ineffective in spite of the reports of their success in other parts of the world. Among these may be mentioned gentian violet for strongyloides and trichuris, hexylresorcinol, a drug recently strongly recommended has been tried but has not been found nearly as good as existing treatments.

General instructions. The only purgative employed in anthelmintic treatment of any kind is the magnesium sulphate mixture.

All patients are given a light meal the evening before treatment, the treatment is given the first thing in the morning, and no food is allowed until the bowels have acted freely at least on one occasion.

None of the above anthelmintic treatments should be repeated in less than ten days, on account of the possibility of cumulative effects of the drugs.

HEPATIC ABSCESS. See page 374.

HEPATOMEGALY. The liver is the largest gland in the body. Its normal weight varies between 45 to 60 oz. It is composed of numerous lobules which may be diagrammatically considered as made up of a series of radiating tubular glands with the closed ends towards the central hepatic vein. The polygonal glandular cells lie along the walls of the tubular glands. Their lumens constitute the bile capillaries which open into the bile duct. Between the tubular glands run the wide portal vascular capillaries passing from the portal tract to join the branch of the hepatic vein in the centre of the lobule. Along the walls of these capillaries lie a number of endothelial cells known as Kupffer's cells. Each portal tract contains a branch of the hepatic artery, vein and biliary duct.

The main functions of the liver may be broadly defined as arresting, storing, modifying or transforming all substances brought to the

liver by the portal vein. The various functions are briefly reviewed as follows: (1) Secretion of bile, which helps digestion especially of fat. (2) Glycogenic function; glucose is absorbed, some of it is utilised at once while the excess is arrested by the liver, dehydrated and converted into a colloid substance known as glycogen. It can be again hydrated and changed back into glucose according to the necessity. This is done by the ferment amylase, which is present in normal hepatic cells. (3) Protein metabolic function, *i.e.*, production of urea, uric acid and creatinin. (4) Hæmopoietic function (a) it acts as a storage of iron, (b) it acts as a blood-forming organ especially in foetal life, and (c) it manufactures fibrinogen. (5) Protective function, *i.e.*, the power of detoxicating the poisonous substances absorbed from the alimentary canal.

Both the liver and the spleen become considerably enlarged in bacterial and protozoal infections and intoxications. Various causes of hepatomegaly are: malaria, kala-azar, leukæmia, cirrhosis (portal and biliary), venous congestion as in heart failure, tropical liver (this vague term has been applied to the hyperæmic condition of the liver occurring in warm climates; it is really due to over-indulgence in food and alcohol, accompanied by lack of exercise), amoebic hepatitis, abscess, syphilis, malignant tumour, hydatid cysts, splenic anæmia, Hodgkin's disease, rickets, cholangitis, bronzed diabetes, perihepatitis, degenerative changes *e.g.*, fatty and amyloid, relapsing fever, Weil's disease and trypanosomiasis.

For diagnosis and treatment of the tropical conditions of hepatomegaly the reader is referred to respective sections in the book.

HERPES. See page 1212.

HICCOUGH. This is a sudden clonic spasm of the diaphragm accompanied by a spasmodic closure of the glottis which produces the characteristic sound. In most cases it is transient and of little importance but it is of grave prognostic importance when it sets in as a complication during the course of a disease. The condition starts very early and may be seen in breast-fed babies and is probably due to overdistension of the stomach after feeds and swallowed air. Inflammation of or pressure on the phrenic nerve or a reflex through the vagus nerve often initiates the process in adults. It is a common symptom and an evil omen in many diseases, particularly, in general and local peritonitis, in acute intestinal obstruction, when tympanitis sets in as a complication in enteric fever and in the last stages of many chronic exhausting diseases such as tuberculosis diabetes, etc. It sometimes occurs after the ingestion of hot, irritant and spicy food. It may be excited reflexly by organic diseases of the nervous system such as meningitis, tumours of the brain and encephalitis. It is a common symptom in neurosis, hysteria, epilepsy and chorea. It is commonly seen in toxic states of pregnancy

such as hyperemesis gravidarum, eclampsia, etc., and it may complicate Grave's disease or Addison's disease. The condition also starts as a reflex cause in diseases of the pleura and pericardium. Besides all those that have been mentioned, there are the idopathic and epidemic cases.

Epidemic hiccough is a nervous form of hiccough and has been regarded as a form of encephalitis lethargica. The condition may persist without intermission for several days.

TREATMENT. In all cases attempts should be made to investigate and detect, if possible, the primary causes and when found, it should be properly dealt with. When hiccough persists, it is most distressing and troublesome to the patient and various measures have been tried to control it. In children a spoonful of hot water, weak solution of sodium bicarbonate or dilute lemon juice may help to control it. The most frequently employed household remedies in cases of mild attacks are pressure on the back of the neck, holding the breath, swallowing a bolus of food, tickling the nose to induce sneezing, gentle compression of the upper part of the thyroid cartilage, traction of the tongue, sipping cold drinks and swallowing small lumps of ice. A tumblerful of warm water containing bicarbonate of sodium 20 gr., flavoured with peppermint, may be tried in some cases. Applications of stimulating nature to the epigastrium such as warmth and small mustard plasters are occasionally useful. Sometimes faradism may be tried and a tight bandage or plaster around the upper part of the abdomen may give relief.

In intractable troublesome cases sedatives are indicated to afford rest to the patient and opiates, bromides, chloral, hyoscine and even apomorphine may be tried in such cases. Benzyl benzoate is highly spoken of in the treatment of persistent hiccough, 20 to 30 drops of a 20 per cent. alcoholic solution may be given with milk or water; 25 to 30 min. of ether injected intramuscularly has been found to give relief in a few cases.

Of other internal remedies, nitroglycerine in doses of 1/100 gr., has been found effective in some cases. Oil of turpentine in doses of 10 min., has been highly recommended by some. Liquid extract of ergot in 1 dr. doses frequently repeated, has been very successful in some cases. One minim doses of tincture of hyoscyamus, repeated every half hour, are said to yield good results in most cases. Musk 5 to 10 gr. in a pill with liquorice may also be tried.

Sopars advocates gastric lavage in persistent cases. Lichtenstein (1928) has obtained good results with a dilute cocaine-epinephrine solution containing a small amount of phenol applied to both nostrils on pledgets of cotton. The inhalation of carbon dioxide gas mixed with varying proportions of oxygen has given encouraging results. An ordinary paper bag of medium size is placed over the mouth and nose

and the patient is asked to breathe into it. By rebreathing the expired air, the concentration of carbon dioxide in the blood is raised.

In severe intractable cases of hiccough operation on the phrenic nerve has also been suggested.

HILL DIARRHOEA. See page 884.

HOARSENESS. Hoarseness or alteration in the voice of an individual may be physiological or pathological. The former is generally seen in subjects at puberty where a marked alteration or a sudden break in voice is noticed in the individual. The pathological causes are manifold and may be met with at any period of life from the cradle to the grave. It may be acute, of transient duration as in simple laryngitis or it might turn to a chronic form resulting in a permanent change in the quality of the voice. The causes may be briefly discussed as:—(1) *Congenital syphilis*. The hoarse cry of the new born is highly suspicious of inherited syphilis and other symptoms of the disease should be looked for. If the diagnosis is positive, anti-syphilitic treatment should be started at once. Inunction with mercury is a favourite old treatment of the syphilitic child. The child is debilitated, of low resisting powers and should be given nourishing food. The child is liable to pulmonary complications and hence should always be kept warm. A drastic antisymphilitic treatment is always indicated for the parents in such cases. (2) *Papillomata of the larynx*. The combined symptom of hoarseness and stridor in otherwise healthy children should arouse a strong suspicion of growths in the larynx. It might encroach on the glottic area and precipitate an emergent necessity of low tracheotomy. The condition is often confused with diphtheria. The growths require frequent surgical removal though recurrences are common. They are locally infective and hence do not permanently disappear till a sufficient degree of immunisation is established. (3) *Functional aphonia*. Like the breaking of voice at puberty in young males, this condition is most frequently met with in the female sex from puberty to the menopause. This is caused by paresis of the adductor muscles of the cords. It is seen in young healthy women though sometimes it follows a slight attack of tonsillitis, laryngitis, sudden physical or mental shock. The diagnosis is easy as when such a patient is asked to cough, the sound of the voice is produced in normal manner, that is the adductors for the moment come into close apposition. It can be cured by suggestion only. The relatives of the patient are sent away and the patient is assured that she would be cured with the medicine prescribed which would strengthen the weak muscles of the sound-box. As a rule, definite improvement has followed such treatment. Sometimes the application of a strong faradic current between the intra-laryngeal electrode and the external terminal over the larynx produces the desired effect.

(4) *Vascular fibroma of the vocal cord*. These are small peasized benign growths, sessile or pedunculated, found near the edge of the vocal cord. They are generally seen in adult males and interfere with the production of normal voice. The treatment is to remove the growth surgically and the patient is to be asked to whisper for at least a fortnight after such operation. (5) *Singers' nodules*. They are small white discrete projections found at the edges of the cord. The condition is generally met with in teachers or singers who use their voices at the maximum pitch. The treatment is to give a prolonged rest to the voice but the use of the galvanocautery may be necessary where the growths exceed the normal size. (6) *Chronic laryngitis*. Here the infection is spread from the neighbouring regions such as the nasopharynx and the accessory air-sinuses. It affects both the vocal cords and is seen in adults. The condition flares up in the presence of constitutional diseases such as syphilis, gout, rheumatism, diabetes, albuminuria, etc. The treatment should be directed to improving the neighbouring pathological condition and to curing the constitutional diseases, if any. (7) *Syphilitic laryngitis*. This condition is generally seen in the tertiary stage of the disease. Gummatus infiltration, ulceration, perichondritis, necrosis of bone or of the cartilage are the pathological changes met with in the course of the disease. Hoarseness results when the vocal cords are infiltrated or ulcerated by the breaking down of gummata. The treatment includes the administration of anti-syphilitic drugs to the patient. (8) *Tuberculous laryngitis*. It is always secondary to a primary lesion in the lungs. The patient is generally young and debilitated, and in addition to hoarseness of voice, complains of a slight cough. Clinically, the lesion consists of a nodule or an ulcer affecting the vocal cord. The ulcer might spread to the glottic region. General anti-tuberculous measures combined with prolonged vocal rest go a long way to improving the condition. If the pulmonary condition improves, a galvano puncture of the ulcer might facilitate a rapid healing fibrosis of the same. (9) *Cancer of the larynx*. Squamous-celled epithelioma is common in the larynx and is generally seen in males over forty years of age. It is the intrinsic variety of the malignant growth affecting the vocal cord that causes hoarseness at a very early stage of the disease. Diagnosis is made by laryngoscopy and time should never be lost till the movement of the cord is impaired during phonation. Treatment of an early epitheliomatous condition of the vocal cord is more hopeful. The most favoured operation is laryngofissure and its radical removal after it. On the other hand, the insertion of radium needles after a window resection operation promises a better chance of recovery of voice afterwards. (10) *Paralysis of cords*. Besides those that have already been dealt with, another causal factor of hoarseness is paralysis of one or both vocal cords due to a lesion of the recurrent laryngeal nerve. Such a lesion may be both central or peripheral. Paralysis

of the cord of a central origin is met with in progressive bulbar paralysis, basal pachymeningitis near the region of the jugular foramen, syringomyelia, disseminated cerebro-spinal sclerosis and in tabes. Radiograms often disclose factors responsible for peripheral lesions of the nerve resulting in unilateral paralysis of the cord. Treatment of such a condition aims at removing the factors or treating the diseases responsible for bringing about the change in the voice. Local treatment in form of sprays, paints and gargles of the neighbouring regions should also be adopted while carrying out the specific ones where needed.

INFECTIOUS DISEASES. *Isolation.* In undertaking the care of an infectious case the physician is responsible for the treatment of the patient and the protection of the community. Isolation is therefore the most obvious duty. This can be most satisfactorily attained in the local hospital particularly in cases of small-pox, cholera, cerebrospinal meningitis, diphtheria, etc. Diseases such as measles, mumps and chicken-pox may be treated at home. A good airy room should be chosen for the sick-room. An overall apron is used by the attendants and arrangements are made for scrupulous washing of hands in some suitable antiseptic solution (mercury perchloride lotion 1 in 2,000) on leaving the room. Domestic utensils should be set aside for the exclusive use of the patient and thoroughly disinfected before they are taken out of the room. All bed-linen and clothes should be soaked in 1 in 40 solution of carbolic acid before being sent to the laundry. In diseases like cholera and enteric fever, the excreta should be mixed with an equal amount of 1/20 carbolic acid and allowed to stand for an hour before being thrown into the drains.

Nursing. The patient should be sponged at least once a day, the whole body being washed with soap and warm water, limb by limb, and dried rapidly with light friction. If the temperature rises above 102.5°F., an ice-bag is applied to the head; if it rises above 103.5°F. a tepid or cold sponging may be given. The back and dependent parts should be rubbed every morning and evening with a little spirit and powder. Attention should be directed to the cleanliness of the mouth. All decaying matter and sordes should be carefully removed from the teeth and gums and the whole mouth cavity including the tongue should be cleaned at least twice a day, and in bad cases more often with a cotton wool swab. This should be followed by application of boroglycerine. It must be remembered also that a free supply of fluids helps to keep the mouth moist and comfortable and the patient should be encouraged to drink plenty of cold water.

Diet. A fluid diet, consisting chiefly of milk, is the most suitable to adopt (see page 1399).

Medicinal treatment. It depends on the nature of the disease, etc., and should consist of specific (if any) and symptomatic treatment.

INFECTIOUS DISEASES
INCUBATION, ISOLATION AND QUARANTINE PERIODS AND DAY OF
APPEARANCE OF THE RASH

Disease	Incubation period	Date of eruption	Isolation period
Cerebro-spinal fever	1 to 5 days	2nd day	Till the naso-pharyngeal swab is negative
Chicken-pox	10 to 21 days (generally 14 days)	1st day	Till all scabs have separated
Cholera	A few hours to 6 days		Till stools are free from bacilli
Dengue	4 to 7 days	Initial erythematous on 1st day. Morbilliform eruption on 4th or 5th day	
Diphtheria	2 days (1 to 5)		Until 3 consecutive culture reports are negative
Dysentery—bacillary	A few hours to 7 days		Till the stools are free from bacilli
Enteric fever	14 days (5 to 23)	7th day	Till excreta are free from bacilli
Influenza	A few hours to 3 days		For a few days after the acute symptoms have passed off
Measles	10 to 17 days	4th day	14 days
Mumps	2 to 3 weeks		3 weeks from onset of parotitis (1 week after the swelling subsides)
Plague	3 days (2 to 7)		4 weeks after the temperature is normal
Relapsing fever	5 to 10 days		Till the patient is well and deloused
Rubella (German measles)	15 to 18 days (10 to 21)	1st day	7 days from appearance of rash
Small-pox	12 days (8 to 16)	3rd day	Till all scabs have separated
Typhus fever	12 days (5 to 23)	5th day	4 to 5 weeks from commencement of illness
Whooping cough	7 days (5 to 21)		6 weeks (till no whoop for 2 weeks)

Quarantine period is usually 2 to 3 days longer than the maximum incubation period.

INFLUENZA. See page 983.

INSOMNIA. See page 223.

INTRAVENOUS THERAPY. See page 34.

INSECT STINGS. Mechanical removal of the venom by suction is impossible in the case of insect stings. Surgical procedures are rarely necessary, except in case of œdema of the glottis. In the case of the bee stings the removal of the sting is important. Another therapeutic measure is the neutralization of the toxins. This measure is based on the erroneous belief that formic acid is involved in the action of insect venom, but in spite of this, the frequently employed ammonia is not entirely ineffective. Other substances that formerly were thought to be neutralizing agents, such as sodium bicarbonate, lime water, magnesium oxide, are sometimes beneficial because they counteract the tension. Some measures are employed to make the venom insoluble. In this connection mention is made of one of the oldest remedies, namely, sodium chloride, which is dampened and applied or rubbed in. Other substances belonging to this group are magnesium sulphate, ammonium sulphate, some alcoholic preparations tannic acid, plant juices that contain tannin and certain heavy metals. The use of heat likewise produces coagulation of the venom. Frequently attempts are made to burn out insect stings. Tincture of iodine, compound solution of iodine chlorine water, surgical solution of chlorinated soda and similar preparations aim at a chemical destruction of the venom. Potassium permanganate likewise is much used. To counteract the pain, local anæsthetics may be employed and the itching may be counteracted by anti-inflammatory agents, such as the phenols and the volatile oils. As a prophylactic measure it is advisable to disinfect the wound with iodine, formaldehyde or a phenol preparation. Most fatalities which occur in connection with insect stings are the result of bacterial infections rather than of the insect venom. The general treatment varies in the different cases. Stings into the blood vessels may produce severe symptoms that resemble anaphylactic shock. To counteract allergic conditions, epinephrine and intravenous calcium therapy have been recommended.

JAUNDICE. The word *jaundice* is derived from the old French *jaunisse*—yellow. It represents a morbid condition due to increased amount of bile pigments in the plasma and tissues. It is characterised by varying grades of yellowness of the skin, mucous membranes, conjunctiva, fluids and tissues. The central nervous system, nerves and cartilages are the only tissues which do not absorb the pigment. The substance primarily involved in the production of jaundice is bilirubin, which is normally found in the blood serum and bile. The yellow colour of the tissue is due to the presence of this pigment.

Two methods of production of jaundice are recognised :—

(a) One is primarily due to an increased amount of serum bilirubin, *i.e.*, hyperbilirubinemia and is associated with a diminution in the bilirubin excretory ability of the liver. This type of jaundice is seen in diseases such as pernicious anæmia, myocardial insufficiency, hæmolytic jaundice, etc., where there is increased red blood cell destruction and probably a diminished excretory ability of the liver.

(b) The other is primarily due to discontinuity of the cells lining the bile canaliculi, thereby permitting the reabsorption into the lymph vessels and capillaries, of bile which has been excreted through the liver cells. In this manner, bilirubin, bile salts and cholesterol are increased in the blood serum. Associated with this there may be an increase of serum bilirubin which has not been excreted through the liver cells due to the damage done to these cells. Discontinuity of the cells of the bile canaliculi is caused by biliary obstruction. The back pressure and increased intrabiliary tension separate the cells and permit the absorption of bile into the lymph and blood. This can also be produced by toxins or infections destroying the liver cells. Such cases are associated with an increase of serum bilirubin which has not been excreted by the liver cells on account of the damage to these cells. Jaundice of this character need not be associated with the absence of bile in the stool.

Jaundice has been recently classified clinically by Arnold Rich into two main types : 1. *Retention jaundice*. In these cases there is an excessive production of bile pigments by the reticulo-endothelial cells and diminished excretion of bile by the liver cells. The latter is due to sub-normal function caused by various factors such as anoxæmia, febrile disease or immaturity of liver cells. The excess of bile pigments enters the general circulation. The causes of this group are (a) pernicious anæmia, sickle cell anæmia, paroxysmal hæmoglobinuria, mismatched transfusion, phenyl-hydrazine poisoning; (b) chronic passive congestion as a result of cardiac decompensation; (c) febrile diseases associated with anoxæmia resulting from hæmolytic septicæmias, malaria, blackwater fever; and (d) immaturity of liver cells in the new born. 2. *Regurgitation obstruction jaundice*. The bilirubin in the blood is not excreted normally either owing to necrosis of the liver cells or to obstruction of bile canaliculi or ducts. The ducts rupture and bile passes back into the blood channels. The main causes of this group are (a) toxic agents, chemical, vegetable, bacterial or undetermined as in cases of idiopathic acute yellow atrophy; (b) plugging, stricture or pressure of the biliary passage by calculi, inflammatory exudates, parasitic masses, neoplasms, or enlarged hepatic lymph nodes. A combined form of jaundice may also occur, in which there is an excessive production of bile pigments.

Rich holds that excessive production of bile pigments alone will not cause jaundice. An additional factor, namely, derangement of the liver

cells, which interferes with excretion, is required. Totally dissimilar clinical types of jaundice, such as toxic processes caused by chloroform and an obstructive process due to a calculus, are classed together by Rich as regurgitation jaundice.

Van den Bergh's test. It is often utilised to distinguish the different types of jaundice. He showed that when Ehrlich's diazo reagent was added directly to normal serum no unusual colour developed. When, however, the serum proteins were precipitated by alcohol the addition of the reagent to the supernatant fluid produced a lilac colour (indirect reaction) in a great number of cases. He further showed that when bilirubin was increased in the serum, this colour became intensified. He later on showed that in conditions of jaundice, produced by a flow of bile back into the blood stream, an immediate colour reaction (direct reaction) could be obtained by the addition of the reagent directly to the serum without the need of previously precipitating the proteins. The colour was produced by the formation of diazo-bilirubinate.

The explanation of the direct and indirect Van den Bergh reaction was finally given by Barron in the following manner. When bilirubin in small amounts is taken up in a watery solution, the addition of Ehrlich's diazo reagent will immediately cause the formation of violet, blue or pink colour depending upon the acidity or alkalinity of the solution. When a small amount of bilirubin is added to normal serum the addition of Ehrlich's reagent does not produce a prompt reaction. If, however, before the addition of the reagent a small amount of any surface-tension-reducing substance, such as bile salts, cholesterol, sodium oleate, etc., is added to the treated serum, the addition of Ehrlich's reagent will produce an immediate reaction. The addition of the surface-tension-reducing substance apparently splits off the bilirubin from its protein combination and the freed pigment, when brought into contact with the reagent, causes a prompt positive colour reaction.

Generally three types of Van den Bergh reaction are described.

1. *Indirect reaction.* No colour appears for at least 1 to 2 minutes after the addition of the reagent. Some colour may appear after this time, but not in maximum intensity. The major reaction occurs only after the precipitation of serum proteins.

2. *Direct reaction.* The colour appears at the time of addition of the reagent and reaches its maximum intensity in about 30 seconds.

3. *Biphasic reaction.* The colour appears at once at any time up to 30 seconds after mixture of the serum and reagent. The maximum intensity may occur at almost any reasonable time after this.

The interpretation of these reactions is as follows.

- (a). Jaundice produced by an accumulation of bilirubin in the blood serum in those cases in which there is no destruction of the bile canaliculi, is represented by the indirect Van den Bergh. Values as high as 20 mg. per 100 c.c. of serum have been reported in these

cases, although the usual finding is about 2 to 5 mg. It is interesting that although the tissues can remove the pigment from the blood, the kidneys are unable to do so and bilirubin is not found in the urine of these cases.

(b) Jaundice produced by an accumulation of bilirubin in the blood serum in those cases in which there is destruction of bile canaliculi as shown by the direct Van den Bergh and is found (according to Barron) in association with a substance which reduces the surface tension of the serum. In these cases there is a direct passage of bile from the liver into the circulation and bilirubin, bile salts and cholesterol increase in the blood serum.

(c) It is questionable if the biphasic reaction has any real significance as an entity. It may be better to place it in the group of direct reactions. The basis for this reasoning is as follows: any colour that appears within the first 30 seconds is reagent and non-absorbed bilirubin, *i.e.*, bilirubin not taken up by protein, and therefore, diagnostic of the presence of bile products which have passed through the liver and have been reabsorbed into the serum (discontinuity of bile canaliculi). The colour which appears after this time may represent bilirubin which has not passed through the liver or reabsorbed bilirubin which has been absorbed by serum proteins because of a lack of surface-tension-reducing substances.

When there is necrosis of the liver cells, the organ may become unable to excrete the normal amount of bilirubin. Furthermore, in such diseased conditions, there is often an overproduction of bilirubin from an increased destruction of red blood cells, and a stage is reached in which there is a marked increase in the indirect Van den Bergh reaction. The liver necrosis permits passage of bile into the blood stream and direct reaction is produced. When these factors are considered the biphasic reaction has real significance.

There are other conditions, particularly obstruction, which demonstrate all these reactions. During the first few days or hours after a sudden plugging of the common bile duct by a stone, the serum gives an indirect reaction. At this period the bile canaliculi are intact and the increased hepatic pressure causes a reflex which stops or reduces the excretory ability of the liver. This is similar to an anuria due to ureteral stone. As the pressure of the dammed-back bile becomes greater, small amounts of bile leak between the hepatic cells and into the circulation. At this time, a biphasic reaction is found. Later on, if the obstruction remains complete, so much bile is thrown back upon the circulation that the reaction becomes direct. This is due to much greater concentration of the unattached bilirubin. As the duct dilates round the stone and bile reaches the intestine, the Van den Bergh again becomes biphasic. Gradually the bile canaliculi regain their continuity and only the indirect reaction persists. This

continues only until the excretory function of the liver returns to normal.

Bilirubin is found in the urine in relation to this type of jaundice. When there is no discontinuity of the bile canaliculi, the pigment is not found in the urine. When there is sufficient liver cell destruction or intrahepatic pressure to separate the cells lining the bile canaliculi, bilirubin is generally found in the urine. In terms of Van den Bergh reaction, there is rarely, if ever, a bilirubinuria in association with an indirect reaction. There is, however, a bilirubinuria to be found in association with a direct reaction. The significance of this is that the kidneys are unable to separate bilirubin from its protein conjugation, but when it is lying free in the serum it is easily excreted by them.

Galactose tolerance. In order to assist in the differentiation of the jaundice of hepatitis and that of obstruction, a number of tests have been brought forward. The one now in vogue is the galactose tolerance test. The normal liver has the power to utilize galactose and store it as glucose, therefore, it was believed that the liver in which there was only biliary obstruction would be much more likely to retain its galactose-consuming function, than the one in which there was parenchymatous disease. In the early stage of obstruction, this supposition was found to be quite true but, as the obstruction continued there was a greater and greater necrosis of the liver cells; consequently the galactose test has in these cases, no basis to differentiate it from the cases of hepatitis.

Latent Jaundice. Latent jaundice is a term applied to conditions where the bilirubin content of the serum does not reach 4 units, so that the usual symptoms are missing. The hæmolytic type of this is seen in pernicious anæmia, anæmias due to worms and in the new-born. Its occurrence is of prognostic value when salvarsan is being given, as it is an evidence of the approach of poisoning by the drug. An obstructive type of latent jaundice occurs in cirrhosis. In this connection it is interesting to note that in the ordinary jaundice so common in the new-born (icterus neonatorum), the blood serum gives an indirect Van den Bergh's reaction, so that it is hæmolytic in origin. Before birth the foetus has a polycythæmia reaching about $6\frac{1}{2}$ millions per c.mm. On the second day after birth this excess has disappeared, and probably there will not be more than $4\frac{1}{2}$ millions. In a sense this polycythæmia may be regarded as a protection against the risk of loss of blood at birth. Once this has passed, hæmolysis occurs, and obvious hæmolytic jaundice may follow. The fact that latent jaundice is constant after birth supports this view. Severe jaundice in the new-born is generally due to suppurative pyelephlebitis from septic infection through the umbilical cord or to congenital syphilis. Rarely it results from congenital atresia of the bile ducts.

Dissociated jaundice has been described by French observers as the bile pigments going one way, the bile salts another. But as they did not take the condition of the blood into account judgment must be reserved on this. There may, indeed, be renal dissociation in obstructive jaundice, both pigments and salts being found in the blood, while only bile salts are filtered out by the kidney.

Urine. The best test for bile pigments is Gmelin's. The play of colours obtained by successive stages of oxidation with fuming nitric acid, green being the most important thing to look for. Rosenbach's modification of dipping filter paper into the urine and then placing a drop of nitric acid on the paper is the easiest way of performing the test. The green colour given on pouring tincture of iodine on to the surface of the urine is not so sensitive a test, and usually only succeeds when the jaundice is obvious. Huppert's test enables us to extract bile pigment from a urine containing other pigments. Ammonia and calcium chloride are added to urine, and the precipitate is then boiled with alcohol, acidified with sulphuric acid, when an emerald green solution results.

The only test of any value for bile salts in urine is Mathew Hay's test. Flowers of sulphur poured on to the urine sink if bile salts are present, owing to reduction of surface tension. No other test is sensitive enough to demonstrate the small quantity found in the urine, but a control with normal urine makes the test more reliable.

Blood. It has now been conclusively demonstrated that in jaundice the bile enters the blood-stream rather than the lymphatics, appearing there within two hours after experimental ligature of the bile-duct. Bile salts *in vitro* have a marked hæmolytic action due to their solvent action on the lecithin and cholesterin of the red corpuscles, and the serum of a jaundiced patient will hæmolyse foreign corpuscles readily, so that it may be impossible to carry out Wassermann's test, because hæmolysis occurs in all the tubes. But in the body the patient's own red corpuscles acquire a heightened resistance against bile salts which increases with the intensity of the jaundice. This sharply differentiates ordinary jaundice from acholuric family jaundice in which the red corpuscles are unduly fragile. Occasionally small subcutaneous hæmorrhages may occur, but more usually the hæmorrhagic marks on the skin are produced by scratching excited by the pruritus, or are really small telangiectases.

Heart and vessels. One of the most definite results of jaundice is bradycardia. High tension usually accompanies a slow pulse, but in the bradycardia of jaundice the pressure is low and the pulse dicrotic. High tension stimulates the cardioinhibitory centre in the medulla, and thus slows the heart through the vagus, but bile salts have a slightly depressing effect on the heart. Hence the slow pulse with low blood-pressure. The action can be demonstrated easily on the isolated heart of a frog. As the effect can be abolished by atropine,

bile salts probably act through the intracardiac endings of the vagus. The blood-pressure is also kept low by the toxic action of bile salts on the smaller blood vessels producing some degree of vaso-motor paralysis.

Central nervous system. Any severe toxæmic jaundice will be accompanied by marked nervous symptoms such as headache, delirium, and hepatic inadequacy caused by the action of the toxins on the liver and not to the jaundice. Indeed, bile salts are probably not produced in this condition, the liver being too damaged to elaborate them. A mild degree of poisoning of the nervous system by bile salts is, however, common in ordinary jaundice, causing headache and depression. Bile pigments and bile salts are generally found in the cerebrospinal fluid removed by lumbar puncture.

Skin. Bile pigment usually appears in the skin soon after it does in the conjunctiva, but in the hæmolytic jaundice of pernicious anemia the latter usually escapes. In obstructive jaundice the colour of the skin gives no indication whatsoever of the amount of bilirubin present in the serum. In the deep green jaundice of prolonged obstruction there may be less pigment in the serum than in early stages when the skin is just beginning to show a yellow tinge. This suggests that the skin is used as an alternative organ of excretion, though, as will be pointed out later, it does not usually escape by sweat. It is merely stored up in the skin as if to free the more vital structures. Pruritus is a more troublesome symptom, but it is inconstant. Here the bile salts are responsible, as they cause alteration in surface tension which set up currents of lymph between the prickle cells. The patient indulges in much scratching, but without relief, for, as he often says and truly, the itching is beneath the skin.

Secretions. Saliva, tears, and milk are not bile-stained in jaundice. It is frequently stated that the sweat is bile-stained, but this is exceptional. Nasal and bronchial mucus is not tinged with bile. Inflammatory and passive exudates are, however, invariably bile-stained. Thus if mastitis occurs in jaundice the milk will be coloured with bile. The expectoration in bronchitis is not coloured, but if pneumonia occurs as a complication bile at once appears in the sputum. In a case of jaundice without pneumonia the occurrence of bile-stained sputum is of serious import, being evidence of heart failure. Fluid in the pleural or of abdominal cavity, being either the result of inflammation or of passive exudation, will accordingly be coloured by bile in jaundiced patients.

• In conclusion, it will be observed that apart from an unpleasant but harmless discoloration produced by bile pigments all the important symptoms in jaundice are due to bile salts. Their absence from the intestine causes steatorrhœa and wasting from deficient absorption of fats, increased intestinal putrefaction and constipation. Their presence

in the blood causes bradycardia, headache, depression, pruritus and sometimes subcutaneous hæmorrhages.

TREATMENT. The treatment of jaundice must depend upon the cause, but the following general principles are applicable. During the initial stages the patient should be confined to bed. Although calomel is only indirectly a cholagogue it may be given in doses of $\frac{1}{2}$ gr. every hour for six doses, this often relieves the vomiting, and has the additional advantage of being aperient without causing drastic purgation, which should be avoided. Ten hours after beginning the calomel treatment, a seidlitz powder should be given, for repeated doses of calomel, if not effective in opening the bowels, may set up mercurial stomatitis. Alkalies are indicated as solvents of mucus in catarrhal cases, and, if the vomiting persists, may be combined with 10 gr. of bismuth salicylate. As soon as the state of the stomach permits, the more active sodium salicylate should be substituted as a diluent and disinfectant of the bile. Hexamine is frequently used in an alkaline medium along with salicylates as a biliary antiseptic. Preparations of bile salts, *e.g.*, decholin and felamine have proved efficacious in certain cases. In toxæmic cases the patient should be encouraged to drink large quantities of barley water and the like. With the onset of severe symptoms it is advisable to purge freely and to give an intravenous infusion of a pint of normal saline at body temperature. Venesection has the advantage of removing toxins while infusion dilutes them. Theocinacetate in 2 gr. doses is a useful diuretic. As dextrose is the most easily metabolised food-stuff in this state, it should be given by mouth or rectum.

In even mild cases the diet will naturally be light. Milk is usually regarded as the mainstay, but owing to its comparative richness in fat it is not really suitable, and is often much disliked by the patient. It is preferable to give barley water flavoured with lemon, with the white of an egg, and a teaspoonful of plasmon to each half pint. Tea is usually forbidden, though it is difficult to see on what grounds, jaundiced patients often crave for it, and if made in the Russian fashion without milk, but with a slice of lemon in it, it seems free from objection. If the practitioner feels reluctant to abandon milk, it should be separated or thoroughly skimmed to get rid of as much fat as possible. A grain of sodium citrate should be added to each ounce of milk, to diminish curdling. Lienger's food made with water, cow's foot jelly and lemon sponge can usually be taken without difficulty. Alkaline mineral waters may be given freely.

When the bile pigments have returned in the fæces in obstructive cases, the patient feels much better though still jaundiced; he can now get up, and the diet should be cautiously increased. There is sometimes considerable depression during convalescence, for which strychnine and calumba may be given. Dilute, nitro-hydrochloric acid in 10 min. doses is often recommended, but should not be given until

all signs of obstruction have passed off. For pruritus, hot alkaline baths may be tried, or some of the following preparations : a lotion of 1 dr. creolin and 1 oz. glycerine made up with 10 oz. of water ; an ointment of 20 gr. camphor, 30 gr. menthol and 1 oz. vaselin ; a dusting powder of $1\frac{1}{2}$ dr. camphor, $\frac{1}{2}$ dr. zinc oxide and 1 oz. starch powder ; a paint or inunction of $2\frac{1}{2}$ dr. ichthyol, 3 dr. absolute alcohol and 2 oz. ether. Other preparations which may help are Nicholls' superfatted ichthyol salicylic acid soap, prepared by inucin of Cologne, or 10 per cent. of anæsthesine in olive oil. Thyroid extract in $\frac{1}{2}$ gr. doses may help by diminishing the formation of bile salts.

KALA-AZAR. See page 436.

LABORATORY EXAMINATIONS IN GENERAL PRACTICE.

Routine examinations. 1. A general qualitative and microscopical examination should be done for all specimens of urine. A quantitative examination of some of its important constituents such as sugar, chlorides, phosphates, sulphates and urea should be undertaken. The estimation of hæmoglobin percentage, a red cell count and a total and differential count of white cells of the blood should be made. The coagulation time and blood grouping are essential in some surgical cases only. In all chronic complaints, a Wassermann test should also be done. The sputum should be examined for tubercle bacilli and cultured if necessary. The stool should be examined for the ova of parasitic helminths and a test for occult blood should be undertaken. The cultures of swabs taken from the nasal and pharyngeal regions are required in case of children suffering from chronic cold.

2. To investigate into the causes of prolonged fever, urine should be examined for pus, centrifugalised and examined for tubercle bacilli. A cultural examination may also be made for *Bact. coli*. In females, smears from the urethra and cervix should be cultured and examined for Gram-negative diplococci. A total and differential leucocyte count is also indicated in such cases. Cultural and agglutination tests of blood should also be undertaken. Blood films should be examined particularly for malarial parasites and microfilæria. The sputum should be repeatedly examined for tubercle bacilli and it should be cultured and an animal inoculation test performed to confirm a diagnosis. A tuberculin test is most essential. If cerebral symptoms are present a lumbar puncture should be performed and the cerebro-spinal fluid stained and examined for cells and bacteria. If ascites is present, the ascitic fluid after paracentesis should be examined for cells and bacteria. A cultural examination of the fluid for bacteria should also be done and an animal inoculation test performed for tubercle bacilli.

3. In cases of exophthalmic goitre the basal metabolic rate should always be estimated. In Hodgkin's disease, tuberculous adenitis and malignant diseases biopsy of the part is essential. In cirrhosis of liver, icterus index and bromsulphthalein tests should be done. In cases

of gastro-duodenal ulcers the gastric contents should be examined for total acidity and a fractional test meal examination should be undertaken and the stool should be tested for occult blood. Stomach washings in children may sometimes show tubercle bacilli.

4. In cases of emaciation the following causes such as neurosis, febrile diseases, tuberculosis, Grave's disease, diabetes, malignant disease, inanition should be borne in mind. The urine should be examined for sugar, albumin, casts, etc.; the sputum, specially the morning specimen for tubercle bacilli, stool for gross appearance, occult blood, mucus and parasites. A culture may be done if necessary. The gastric contents should be examined for appearance, retention, odour, acidity and blood. Blood should always be examined for Wassermann reaction in these cases. The basal metabolic rate should also be estimated to detect hyperthyroidism.

5. In all cases of anemia, the estimation of the percentage of hemoglobin, a total and differential white cell count and an icterus index examination should be undertaken. A red cell count, a cell volume estimation, testing for red cell fragility and a platelet count are also essential in these cases.

6. The percentage of sugar in blood in cases of diabetes, obesity, arteriosclerosis, gall bladder disease, and suspected hypoglycæmia should be estimated. The fasting blood sugar should also be estimated. The carbon dioxide combining power of plasma in ketosis condition in diabetes, uræmia with nitrogen retention, protracted vomiting, and intestinal toxæmia should be known. The carbon dioxide combining power of the plasma can be determined by the Vanslyke's manometric apparatus or by Fradkin's where available. A strong acid is added to the plasma and some vacuum is created to collect the carbon dioxide gas liberated. This is recorded in cubic centimeters per 100 c.cm. of blood plasma (volume per cent.). Estimation of the blood urea should be undertaken in these cases. There is no necessity for estimating creatinine in blood unless the urea nitrogen is over 30. The uric acid in the blood in cases of gout and also calcium in the blood in osteomalacia, tetany, rickets and other metabolic disorder diseases and the cholesterol in blood in nephrosis and gall bladder diseases should be estimated.

7. In cases of acute diarrhœa, the stool should be cultured for bacilli of dysentery, typhoid, cholera, and *entamoeba histolytica*. The gastric contents should be examined for total acidity. A blood culture should be undertaken for enteric fever with a total and differential white cell count. A high icterus index is indicative of acute arsenic poisoning. In all cases of chronic diarrhœas a proctoscopic examination is of utmost importance to exclude local causes. The stool should also be examined for occult blood, parasites or their ova. A positive urobilinogen test in urine indicates cirrhosis of the liver or arsenical poisoning.

8. Jaundice and liver functions. In these cases the urine should be examined for bile, urobilinogen, diastase and sugar. Bile is present in obstructive and catarrhal jaundice and is absent in hæmolytic jaundice. Urobilinogen is present in early disorders of the liver but is absent in complete obstruction of the common bile duct. Diastase and sugar should be looked for in malignant diseases or necrosis of the pancreas. A positive icterus index of blood signifies a severe jaundice. A Wasserman reaction of blood should be done to detect syphilitic affection of the liver. In case of familial hæmolytic jaundice the fragility test of red blood cells should be performed. A radiogram of the gall bladder after administration of some opaque dye is helpful in diagnosing gall bladder disease.

LABORATORY TESTS IN VENEREAL DISEASES. In acute cases treatment should be withheld for twelve hours and then the urethral discharge should be microscopically examined for cells and bacteria. In chronic cases no treatment should be given for 24 hours and then the following tests for urine should be undertaken :—

(a) *Two bottle tests.*

Types of urethritis.	First specimen	Second specimen
(1) Anterior urethritis (early).	Cloudy with shreds.	Clear.
(2) Anterior urethritis (late).	Turbid with shreds.	Clear with shreds.
(3) Posterior urethritis with prostatitis.	Turbid with shreds.	Clear with shreds.

(b) *The urethral discharge and prostatic secretions after prostatic massage should be microscopically examined.*

In case of a genital sore it should be washed with normal saline and then scrapings should be taken from it and examined for spirochaetes by the dark ground illumination method on three successive days. The blood should be examined for Wasserman reaction every month for three months following a genital sore.

In females, smears from cervical discharge should be taken and examined microscopically for the exclusion of infection with *trichomonas vaginalis*.

LATHYRISM. See page 1036.

LEISHMANIASIS. VISCERAL LEISHMANIASIS OR KALA-AZAR. *Diagnosis.* The diagnosis of kala-azar by clinical signs and symptoms is not to be relied on. The demonstration of leishmania is usually necessary.

Demonstration of leishmania. The following methods may be adopted :—(a) *Spleen puncture.* The patient is prepared by withholding food for at least 3 hours before the operation and a dose of calcium lactate 20 to 30 gr. is given about half an hour before the puncture; this dose is repeated immediately after the puncture. A dry sterilised 5 c.cm. syringe with a medium-sized needle is recommended. The

operation is performed in two steps, the skin over the site of puncture having been sterilised, is punctured. The puncture should be made about an inch below the costal margin and midway between the anterior and posterior borders of the spleen. Secondly, with the syringe at an angle of 45° with the patient's body, the needle is plunged through the abdominal parietes into the spleen in an upward and outward direction. The plunger is withdrawn once or twice rapidly and the needle withdrawn. It is advantageous to have an assistant to steady the spleen during the puncture, if the special spleen-puncture syringe is not used. (b) *Liver puncture.* The patient is prepared as for a spleen puncture. The liver is usually punctured through the 8th intercostal space in the mid-or posterior axillary line. The material from the syringe is smeared on a slide and examined after being stained with either Giemsa's or Leishman's stain. (c) *Examination of peripheral blood.* Success in this examination is largely dependent on the preparation of the slide. The best slide is one that has a blood film with straight edge to it, where the greater number of white blood cells will be found. To prepare such a slide the smear is begun in the usual way, but when it is seen that the blood between the two slides is getting exhausted the slide used as the smearer is flicked abruptly upwards. With a little practice this movement will produce a straight end to the smear. The slide is stained and the white blood cells examined for the contained Leishman-Donovan bodies. (d) *Blood culture.* One or two cubic centimetres of blood are withdrawn under strictly aseptic conditions and about a cubic centimetre is dropped into a tube containing 10 c.cm. of sterile citrated saline. The cells are allowed to settle. After sedimentation two or three tubes of N.N.N. medium are inoculated with the corpuscles with a sterile pipette, and incubated at 22° to 24°C . The first tube should be examined on the 10th day, but the cultures cannot be declared negative until at least a month has elapsed. The material from the spleen or liver puncture can be similarly cultivated.

Serum reactions. (a) *Napier's aldehyde reaction* (see page 446). (b) *Chopra's antimony test* (see page 446). (c) *Chopra's finger-prick blood test* (see page 447).

TREATMENT (see page 436). Neostibosan and urea-stibamine are two of the best drugs. Freshly prepared neostibosan is given in doses of 0.2 to 0.3 gm. for an adult of 100 lb. weight in a five per cent. solution. Injections may be given every day commencing with a dose of 0.2 gm. increased to 0.3 gm. until a total dosage of 2.3 to 2.9 gm. is reached. In resistant cases a course of 12 injections commencing with 0.3 gm. reaching a maximum of 0.5 gm. should be given and repeated after 14 days' interval. Urea stibamine is used in smaller doses commencing with 0.05 gm., 0.2 to 0.25 gm. being the maximum used at an injection. It is usually given every other day.

Test of cure (see page 446).

DIAGNOSIS OF DERMAL LEISHMANIASIS. Leishman-Donovan bodies are easily demonstrated from a nodule in this condition. The nodule should be snipped off and a smear made from the cut surface; this should be stained by Leishman's method and parasites will usually be seen in fair numbers. In the depigmented patches they can be demonstrated by cultural methods; a small quantity of sterile citrated saline is injected under the dermis and as much of it as possible is sucked back into the syringe. This is then inoculated into one or two tubes of N.N.N. medium and incubated at the usual temperature. A provocative injection of antimony may be given with advantage. Sandfly feeding is also helpful.

Treatment. More intensive treatment with pentavalent and trivalent compounds of antimony is necessary in this condition. Iodides are also given by mouth.

ORIENTAL SORE. *Laboratory diagnosis.* (1) Examination of the stained smear of the material obtained by scraping the edge of the ulcer. (2) Culture of the causal organism on N.N.N. medium. In obtaining material for this purpose it is necessary to sterilise the unbroken skin at the edge of the sore.

Treatment. Unless the lesions are numerous, a condition which is uncommon, the sore should be treated by local infiltration with 1 to 2 per cent. solution of acid berberine sulphate.

Antimonial injections are advocated only when the lesions are too numerous to be dealt with by the local infiltration method.

ESPUNDIA. It is a form of American Leishmaniasis resembling oriental sore. It produces ulcerating granulomatous lesions of the mucous membrane of nose and mouth.

Treatment. (1) Antimony injection as in kala-azar. (2) Locally, (a) aseptic dressings, (b) carbon dioxide snow, (c) X-ray treatment, (d) berberine sulphate injection $\frac{1}{2}$ gr. in 1 c.cm. once a week by local infiltration, (e) zinc oxide ionisation.

LUMBAGO. This denotes a pain in the lumbar muscles due to inflammation of the connective tissue between the muscle fibres. It might also extend and affect the fasciae, ligaments, tendons and nerve sheaths in the lumbar region of the body. It is met with in persons of both the sexes and in all stations of life. In most cases, the cause can be attributed to exposure, wet or cold or to a chill, but the exciting cause is frequently a strain or even a trauma to the lumbar muscles. This combination of trauma and exposure in the causation of fibrositis is mostly seen in the male sex and during the active periods of middle life. Besides, some form of chronic or subacute infection is said to be responsible for the condition. Gout, endocrine dysfunctions and the influences of changes in climatic conditions are also suggested aetiological factors. Lumbago from physical injury of the tissues as a result of a blow or sudden wrench is a form of fibrositis where the

devitalised tissues are invaded by bacterial toxins, the sites of infection being in foci like teeth, tonsils, nasal sinus, intestines and the biliary apparatus. This type of fibrositis may start with minor pains in the back but frequently its onset is acute. The spasm of the muscles relaxes at times and the patient is then much relieved. The pain is referred to the lumbar muscles and aggravated by movements of the lumbar spine. The cramp-like pain is at first limited to the muscles which may afterwards diffuse and spread over the ilium or into the loin. The lumbar regions on examination are found to be very tender at this stage and the patients are usually most comfortable lying on the back on a firm bed. Occasionally the inflammatory process may extend to involve the sheath of the sciatic nerve, resulting in sciatica. Generally an acute attack takes 3 to 4 weeks to subside, but is liable to recurrences. In chronic cases of fibrositis organisation of fibrous tissue and thickening of the walls of the blood vessels and nerve sheaths in the area involved takes place.

TREATMENT. The general treatment of this type of fibrositis includes absolute rest in bed during the acute stage of the disease, avoidance of over fatigue and occupations involving strains to the part, thorough investigation for septic foci in the body and their eradication when detected, regulation of the bowels and elimination of dietetic principles leading to dyspepsia, colitis, obesity and lastly avoidance of sudden changes in temperature. Drugs that are mostly used are analgesics including the coal tar series, aspirin, phenacetin, etc., and in acute lumbago the relief of pain may be obtained with codeine or barbiturates, allonal or veramon. Sometimes the intramuscular injection of $\frac{1}{2}$ gr. of morphine or 5 c.cm. of a 1 per cent. solution of hydrochloride of quinine and urea may be required to inject deeply into the tender nodule for the relief of acute pain. If there is a tendency to gout, atophan 10 gr. three times a day for three days in the week is of benefit. The drug, however, should not be used where the hepatic functions are deranged. For non-specific protein therapy see page 1418. Endocrine therapy is of particular value in cases where glandular deficiencies are suspected. Physical therapy is more effective than drugs in these cases. During the acute stage absolute rest in bed should always be aimed at and relief of pain may be obtained by immobilisation with strapping, by analgesic liniments and poultices and especially by local radiant heat. Ionisation with potassium iodide and salicylates, diathermy and local ultra-violet light, are also of benefit at this stage. Elimination of toxins may be encouraged with spa treatment and measures should be adopted to promote the healthy action of the skin, such as by radiant heat, vapour baths, etc. Absorption of exudates is generally aided by heat, elastic pressure, counter-irritation and ionisation and breaking down of the fibrous tissues by dry or douche massage. When the pain diminishes in severity, deep massage of the lumbar muscles should be employed

combined with gentle active and passive movements of the back. In chronic long-standing cases the body resistance should be raised by means of general ultra-violet light and wasting of muscles prevented by massage and faradic stimulation.

MALARIA. DIAGNOSIS. (1) *Thin film.* Stain by one of the following modifications of the original Romanowsky stain. (a) Leishman's stain which is both a fixative and a stain. (b) Giemsa's stain. In using this stain previous fixation with methyl or absolute alcohol is necessary. (c) Combined Leishman and Giemsa's stains. (2) *Thick film.* Dehaemoglobinise with a mixture of a solution of glacial acetic acid and tartaric acid. Fix with methyl alcohol. Wash very thoroughly with slightly alkaline distilled water. Stain by combined Leishman's and Giemsa's stains or by Giemsa's stain only. (3) *Cultivation of parasites.* Take 5 c.cm. of blood and defibrinate in a flask containing glass beads. Into the bottom of a small test tube ($12\frac{1}{2} \times 1\frac{1}{2}$ cm.) introduce one drop of 50 per cent. dextrose solution with a capillary pipette; aspirate off the defibrinated blood from the flask and introduce it into the tube. Warm the upper part of the tube and put a rubber cap on. Incubate the culture tube in a vertical position at 37°C . Cultures should be examined at different intervals up to 48 hours or more. (4) *Enumeration of parasites.* A suspension of fowl's cells is prepared and standardised according to Sinton's technique. Equal volumes of the blood and the fowl cell suspension are taken with a capillary pipette and blown out on a clean slide. The two fluids are thoroughly mixed by drawing the mixture in and out of the pipette a number of times and then a thin film is drawn on a clean slide. In making a count the ratio of the number of fowl corpuscles to the number of parasites is determined and from the known strength of the standard suspension of fowl corpuscles one can calculate the number of parasites per c. mm.

TREATMENT. (1) *Cinchona alkaloids* (see page 516). Quinine sulphate 10 gr. twice daily; totaquina or cinchona febrifuge 10 gr. twice daily. Whether given in mixture or tablet form, a dose of an alkaline mixture is always given half an hour before. The course of treatment is 7 to 10 days and for every fresh attack or relapse this course should be repeated. Cinchona alkaloids have no effect on the sexual forms of malignant tertian parasites. (2) *Plasmoquin.* It is the only drug that destroys crescents; 0.01 gm. twice daily for two or three days is sufficient to cause disappearance of the crescents from the peripheral blood. In safe doses it has little effect on *P. vivax*, *P. malariae* and on the asexual forms of *P. falciparum*. It should not be used for routine treatment of malaria. (3) *Atabrin.* 0.1 gm. thrice daily for 5 to 7 days eradicates all forms of *P. vivax* and *P. malariae*; also the asexual forms of *P. falciparum*. Like cinchona alkaloids it has no effect on the crescents.

MALIGNANT DISEASE. It commences as a local affection in one spot or an area and possibly in one individual cell. As the disease

spreads, a local tumour or a new formation of tissue develops, which sooner or later makes itself manifest as a visible or a palpable swelling. Symptoms of pain or disturbance in the normal function of the parts of the organism supervene. Malignant disease, in its early stages is often painless and if a cure is to be obtained by treatment, the earlier the patient is submitted to proper measures the greater are the chances of success. The onset of an abnormal secretion or excretion from the part affected, especially when marked by the presence of blood or blood-stained material, should always be seriously considered and the patient submitted to appropriate examination and investigation. This is especially the case when blood or sanguinous materials appear in the stool, urine, vaginal discharge, discharge from the nipple in women, or in discharges from or in connection with one or other orifices of the body. While taking the history from the patient, the chronological onset of the various symptoms and signs which bring the patient for observation and examination should be carefully ascertained as it is of considerable importance for the clinician to know the duration of the growth.

METHODS OF EXAMINATION. Clinically the examination comprises visual observation and palpation by which the position, extent and relations of the tumour are ascertained and also its connection with adjacent tissues or organs. Its consistency, whether solid or fluid, should be determined. The extent of the swelling and its relation with the surrounding tissues should be defined and the presence or absence of pain on manipulation noted. The tumour should be transilluminated to determine the presence or absence of opacity. Most malignant tumours are opaque. The presence of a solid swelling of recent development with indefinite margins, almost painless on manipulation and opaque on transillumination generally suggests early malignancy. After the local examination of a tumour is completed, the lymphatic glands draining the affected area should always be palpated. Solid enlargement of lymphatic glands helps to confirm a diagnosis of malignant disease. When a swelling has been detected or suspected near or adjacent to one of the normal orifices of the body, examination should be made with the finger or failing this, visually, through one of the special instruments available for the purpose. These instruments should however only be used by experts. The use of the œsophagoscope, bronchoscope and sigmoidoscope by untrained observers has often led to the injury of the part examined and moreover too much reliance cannot be placed upon their interpretations.

Microscopical examination. Materials such as blood-stained matter or solid particles obtained from a supposed malignant tumour or ulcer, should be submitted to microscopical examination. Very often, characteristic tissues suggesting malignant growths may be revealed.

Biopsy. In a readily accessible swelling such as a tumour involving the tongue, the floor of the mouth, the lower portion of the rectum

or the region of the cervix uteri, the clinician should remove a portion of it and submit it to a histological examination. Such a procedure is likely to spread the tumour by the lymph or the blood channels if it is malignant. This can be probably avoided by the use of a diathermic knife. Whenever possible, the portion selected for removal should be at the junction of the normal tissue and the suspected tumour and it should be cut at right angles to the surface.

Biochemical examination. It includes an ability to diagnose cancer from an examination of the blood or the blood serum. One of the latest of these is that claimed by Bendien by a flocculation test of the blood serum.

X-ray. Under certain circumstances, radiograms of the parts give most important aid in the early diagnosis of malignant disease especially in suspected disease of the stomach and alimentary tract or the lungs with no associated tumour or swelling. Radiograms are of particular value in the investigation of suspected tumours of bone.

Exploratory operation. An exploratory operation is often desirable to confirm a diagnosis and ensure subsequent successful treatment. The clinician, the radiologist, the clinical pathologist and possibly the anatomist, should all co-operate to make the diagnosis a correct one, at the early stage of the disease. As soon as the diagnosis is confirmed by an exploratory operation, it is often desirable to completely remove the diseased tissues where possible and if not to perform some other operation for a temporary relief of the patient's condition.

For the treatment of malignant growths by deep X-ray therapy and radium see page 135 and 141.

MALTA FEVER (Undulant fever). See page 907.

MEASLES. The disease seems to be due to a filterable virus which is present in the patient's blood and can be transmitted to other susceptible human beings and monkeys. One attack confers immunity against subsequent attacks. The highest attack rate occurs in children between the ages of 3 and 4. Fatality is at its maximum in the first year of life and it remains high till the third year. *Ætiological factors* are exposure to infection, under-nourishment (victims of avitaminosis), debility and unfavourable hygienic conditions of living. Incubation period is 14 days.

DIAGNOSIS. It is made from symptoms of coryza, fever, and characteristic rash.

TREATMENT. No specific remedy is known. (1) *Sick-room.* The patient should be entirely isolated, the room should be large, well ventilated and sunlight should have free access. (2) *Diet.* Fluids tolerated are sweetened lemonade, barley water, lime whey, milk and plain water. (3) *Attention to the mouth and nasal passages* is most essential to prevent subsequent complications such as otitis media, suppurative adenitis and broncho-pneumonia. Laryngitis disappears with

the appearance of the exanthem. Mild antiseptic alkaline lotions like sodium bicarbonate and glycothymoline are useful for cleansing the mouth. A prescription with potassium chlorate taken internally is almost specific in alleviating stomatitis and preventing ulceration and cancrum oris. (4) If diarrhoea is present grey powder and lime water are useful. (5) Treat on general lines if complications such as pneumonia and emphysema set in. (6) Latest so called specifics are pyramidon, ultra-violet ray therapy, but results are not encouraging. (7) *Serum therapy.* Convalescent serum has been used both in prophylaxis and treatment in the acute stage. Donors must be healthy and not exposed recently to any infectious disease. The blood is withdrawn 10 to 14 days after deferescence and amounts up to 20 c. cm. from a child of 5 years, 100 c. cm. from a child of 10 years and 250-500 c. cm. from an adult may be taken. The clear serum is withdrawn and tested for W. R. and sterility. It is customary to filter the serum and add phenol or other preservative; the ampoules are stored at 4°C. To afford complete protection a minimum dose of 5 c. cm. of the serum is given intramuscularly within the first five days after exposure to infection. To produce an attenuated attack the same dose is injected between the 6th and 9th day after exposure or preferably half the above dose is given before the 6th day. Sometimes whole blood injection from parents to children contacts is given. The approximate dose in such cases is double that of convalescent whole blood and 4 times that of convalescent serum. After such sero-attenuation, the attack is always mild and uncomplicated. (8) Mixed vaccines may be used when resolution is delayed or recovery incomplete. (9) Maline method of disinfection. The contacts are dosed with eucalyptus oil and the patient's tonsils and pharynx are swabbed with 10 per cent carbolic oil and he is put in a gauze tent sprayed with eucalyptus. (10) Aspirin 5 gr., Dover's powder 2½ gr. and phenacetin 2½ gr. are useful. Alkaline mixtures should be prescribed during the febrile period and sedative expectorants are given for coryza.

MIGRAINE. This is usually described as a paroxysmal affection with severe unilateral headache, preceded by visual phenomena and followed by nausea and vomiting. Sometimes one symptom is sufficient to represent an attack of migraine. The characteristic periodic headache with other symptoms such as irritability, confusion, loss of appetite, giddiness, photophobia, etc., is diagnostic of migraine. Though termed hemicrania, the headache is not always unilateral. Repeated attacks of migraine result in severe mental and physical prostration and this is again followed for some time by severe neuralgic pain over a limited area of the head or face. Inequality of pupils, persistent hemianopia, ocular paresis and persistent hemiplegia with or without aphasia or agraphia have been seen as sequelae to chronic migraine. Several clinical types of the disease are recognised and theories have been advanced to explain its nature; the treatment is resolved according

to ætiological factors: (1) *Alimentary type*. Dysfunction of the gastro-intestinal tract, including the biliary apparatus, has been thought to be a potent ætiological factor and bilious, abdominal and duodenal types of migraine are recognised. These facts cannot be ignored as the treatment of hepatic dysfunctions with glucose, decholin tablets, etc., has relieved many migraine attacks. (2) *Allergic and dietetic type*. Migraine has been regarded as an anaphylactic shock. Non-specific protein therapy has also been tried on the basis of such an assumption though sometimes the taking in of a particular article of diet has precipitated an attack and the treatment has been to exclude this article from the dietary without effect. (3) *Endocrine type*. Endocrine dysfunction has been regarded as a common ætiological factor. This is particularly marked in ovarian dysfunction where migraine occurs at the menstrual periods. Excellent results have followed the administration of *emmenin complex* (Collip's placental hormone) $\frac{1}{2}$ to 1 dr. twice daily, except during the menstrual period, in such cases. Thomson recommends three injections of theelin, each 1 c.cm., to be given in the week before the period is due. It is suggested that such treatment causes a diminution in size of the pituitary which would otherwise cause headache by pressure against the sella turcica or a large diaphragma sellæ. (4) *Metabolic type*. Errors in diet, faulty metabolism and defective elimination of waste products are considered to be causal factors in precipitating an attack of migraine. The onset of migraine in the early hours of the morning, starvation, prolonged physical strain and its subsequent relief by administering glucose, all go to confirm the metabolic factor. (5) *Ocular type*. Subjects with defective vision due to errors of refraction and slight ocular muscle imbalance are known to suffer from intense unilateral headache. Correction of such defects with correct glasses has very often relieved the distressing symptom. (6) *Para-epileptic and cerebral type*. The close similarity between migraine and epilepsy has led to the treatment of the para-epileptic type by bromides, luminal and ketogenic diet. Symptoms of cerebral tumours and other intracranial lesions closely simulate those of migraine and this led to the recognition of the cerebral type of migraine. (7) *Psychological type*. Psychological factors, such as mental overwork, anxiety, 'suppressed rage and humiliation', play an important role in the ætiology of migraine. Psychotherapy has improved many such cases. (8) *Vasomotor and sympathetic type*. Migraine is thought to be the result of a localised intracranial oedema. The advocates of the sympathetic origin of migraine hold that the disease is due to an excessive stimulation of the sympathetic system resulting in spastic contraction of the cerebral arterioles with their subsequent relaxation. Calcium therapy and the administration of irradiated ergosterol have been beneficial in these cases. Lennox tried ergotamine tartrate in the treatment of migraine. It is probable that the benefit derived from ergotamine in migraine is due to its effect upon the smooth muscle of the cerebral blood vessels. It is

likely that ergotamine abolishes the pain by increasing the tone of the cerebral vessels and hence diminishing their stretch. The doses of the drug recommended are 0.5 mg. subcutaneously or 1.0 mg. by the mouth. If the headache is not relieved the dose can be repeated after an interval of 2 to 3 hours. The drug should not be used in pregnancy and cardiovascular diseases. A few untoward symptoms such as vomiting, increase in systolic blood pressure, decrease in pulse pressure, and bradycardia may be met with after its administration.

TREATMENT. Bearing all the aetiological factors in mind a thorough investigation of the case, including radiographic and biochemical examinations where possible, is necessary before adopting treatment. Treat the patient during and in between the attacks. During the actual seizure, the patient should be removed to a dark quiet room and sedative drugs such as veramon (6 gr.), phenacetin (10 gr.), caffeine citrate (5 gr.), compral (3 tablets) etc., may be tried to relieve the pain; luminal ($\frac{1}{2}$ to 1 gr.) has given good results. Between the attacks, drugs discussed under the aetiological factors may be tried. A useful prescription in migraine is : sodium bromide 10 gr., nitroglycerine 1 min., strychnine hydrochloride solution 5 min., dilute hydrochloric acid 10 min., tincture of gelsemium 5 min., and chloroform water up to $\frac{1}{2}$ oz. This is given three times a day.

MOLLUSCUM CONTAGIOSUM. This is an infectious type of epithelial overgrowth consisting of rounded or flat papules from pinhead to bean size, pearly gray, with a central depression from which a caseous plug, called the molluscum body, may be squeezed. The molluscum body contains only degenerated epithelial cells and keratin. The principal sites of involvement are the face, hands and genitals, but they may be widely distributed.

TREATMENT. Manual expression and cauterisation with trichloroacetic acid diluted or undiluted.

MUMPS. It is an acute infectious disease characterised by parotitis and constitutional disturbances. Mumps is due to a filtrable virus present in saliva (Kermorgant). The incubation period is longer than general infectious diseases and is usually between 18 to 22 days. One attack usually confers immunity for the rest of life. A second attack is very rare. *The complications.* Orchitis is common, but atrophy of the testis is rare; pancreatitis is rare; encephalitis or meningo-encephalitis, meningitis, polyneuritis, arthritis, occur.

DIAGNOSIS. (1) Make a careful examination of the fauces to exclude hypertoxic diphtheria. (2) Presence of orchitis in males in absence of gonorrhoea and with a history of facial swelling. (3) Lumbar puncture. In genuine mumps cerebrospinal lymphocytosis is constant and marked in early stages and lasts for several months.

TREATMENT. (1) Rest in bed during the acute stage. (2) Erotic excitement of any kind should be avoided as well as any sort of violent

exercise as riding or cycling, for some weeks after the attack. (3) Mouth to be kept clean by gargles and mouth washes, potassium chlorate 10 gr., tincture of lavender 10 min., glycerine acid boric 1 dr., water up to 1 oz., to be diluted with an equal quantity of warm water before use. (4) Locally, hot fomentation, ichthyol and belladonna paint are useful. (5) Injections of salvarsan and other arsenicals are advocated. (6) Orchitis ; suspensory bandages, lead and opium compresses.

MYIASIS. It is due to the invasion of the skin and subcutaneous tissue by the larvæ of *Cordylobia anthropaga* or an allied species of fly. This condition may be cutaneous, nasal or intestinal. It is not known how infection takes place, but it is possible that the fly lays its eggs, apparently about 150 at a time, on the ground, and that the larvæ creep from the earth on to their human hosts, perhaps when the latter are sleeping on the ground. It is also possible that the fly lays its eggs on clothing, as when the latter is put out to dry it exhales the odour of sweat and so attracts the fleas. There is no evidence to show that oviposition takes place directly on the skin. Its usual host appears to be the domestic dog, the skin of the scrotum being specially affected. The lesion produced is like a small boil or urticarial wheal, in the centre of which there is an opening which may be obscured by the discharge or it may be patent.

TREATMENT. Instillation or local application of pure chloroform is the usual remedy. Insufflation with calomel has also been tried with success.

NAUSEA. See page 1413.

NEURALGIA. It denotes pain which follows the distribution of certain nerves in the body. It is generally due to fibrositis confined to the connective tissue forming the sheath and surrounding the fibres of the nerve. Besides, an undue toxic state of the blood is a most common factor in the causation of pain. The toxins in the blood directly irritate the nerve and as in gout, by causing a vaso-constriction, deprive the nerve of its nutrition. It is also suggested that the pain is due to congestion or a local vaso-dilatation in the neighbourhood of the nerve. An irritant causing fatigue of the nerve is held to be another ætiological factor. The condition may affect any nerve in the body but the nerves commonly involved are the sciatic, brachial, peroneal, intercostal, occipital, facial and trigeminal. The involved nerve is found to be pink in colour and swollen and on puncture of its sheath, drops of fluid exude from between the fibres of the nerve. The pathological changes are usually confined to the interstitial tissue but sometimes a true neuritis or nerve atrophy results from pressure of scar tissue on the nerve elements. Sensory disturbances, such as paræsthesia, tenderness and pain aggravated by stretching

of the nerve often appear and in severe cases motor paralysis or trophic changes are also met with.

SCIATICA. Pain along the sciatic nerve may be due to causes other than fibrositis. Sciatica may be caused by a loaded rectum, by uterine and ovarian displacements, by tumours and disease of the spinal cord itself and such possible factors should always be carefully and exhaustively investigated before the pain is pronounced to be due to neuralgia, and treated as such. It is important to determine whether the pain is due to pressure, or to some factor in the nerve itself or in its sheath. If caused by pressure the pain will not be sensibly aggravated when the nerve is put on the stretch, it may be to some extent relieved by the process, whereas, when the mischief is in the nerve or its sheath, the stretching will obviously increase the pain. In order to set this point at rest, the patient is placed upon his back and the pelvis firmly fixed against the bed by an attendant. The limb on the affected side, which must be kept fully extended at the knee, is then gently and gradually raised by the examiner until it is at right angles to the couch. This will put the nerve on stretch and if no aggravation of pain results, then the cause is to be sought outside the sheath of the nerve. The condition starts with pain in the back of the leg aggravated on straightening the knee, especially if the thigh is flexed. Afterwards the pain becomes acute and constant and the course of the nerve becomes very tender on palpation. The distribution of pain and tenderness however depend on the part of the nerve affected. In addition to the characteristic pain in sciatica, the presence of wasting of the gluteus maximus muscle considerably aids the diagnosis. Points of maximum tenderness are located at definite sites of the distribution of the nerves. The duration of an attack is variable and the ultimate prognosis is generally hopeful.

Treatment. The treatment of sciatica in the early stage demands rest, counter-irritation and analgesic drugs for the relief of pain. In cases of strain, correction of the fault is of the first importance. The exact manipulation required depends, of course, on the lesion. If manipulation is very painful a preliminary course of treatment in form of heat, local massage, etc. to reduce congestion is indicated. Radiant heat is most useful, and the infra-red rays have been used with good effect, and ultra-violet light is of some value in the most superficial forms of fibrositis. Diathermy is useful in bringing the affected area under the direct influence of heat, but in the majority of cases, heat applied to the surface appears to be more effective. Ionization applied to the buttock sometimes proves useful, especially in neuritis. The effect is due rather to the action of the current on the tissues than to the drug used. Massage is a valuable method of treatment relieving the deep-seated congestion, restoring muscular tone, removing the products of disordered metabolism, and correcting spasmodic muscular contractions. Massage combined with radiant heat is the most useful

treatment in lumbar and sacro-iliac strain, sciatic neuritis, and fibrositis.

Counter-irritation may be applied with radiant heat, hot bottles, poultices, belladonna plaster, liniment of aconite or tincture of iodine may be applied daily to the line of the sciatic nerve on the skin until the skin is on the verge of blister formation. Aspirin, phenacetin, caffeine and allonal are the most useful analgesic drugs for the relief of pain. In the more resistant cases injection of oxygen usually affords much relief. The technique is easy, harmless and painless. A pneumatic cushion is formed by distension of a wide area around the nerve, due to introduction of oxygen through a hypodermic needle connected by thick Indiarubber tubing to an oxygen cylinder. Injection of a salicylic acid solution in doses of 15 to 30 min. (1 in 20 of sterile water) very often gives relief. A preliminary injection of cocaine should be given before the injection is given as this might cause pain afterwards. Acupuncture of the nerve is not performed nowadays, and open operation to stretch and free the nerve from adhesions is a better procedure, which often gives relief in a severe acute attack of sciatica. When the acute stage is over, physical therapy in form of immersion baths with underwater douche massage over the nerve and subsequent manipulation is of value, and the patient should be asked not to make any sudden movement that will stretch the nerve.

Harris advocates an injection of normal saline at the sciatic notch, or the gluteal fold, the dose is 20 to 100 c.cm. and this is preceded by the injection of a few drops of novocaine solution. It is very effective in perineuritis, and particularly when the site of the trouble is in the region of the sacro-iliac joint. Injections of oxygen and even air have given relief in some cases, probably by breaking down adhesions and reducing congestion.

Before treatment is commenced a search should be made for septic foci and when found, these should be eradicated. Metabolic disorders should be corrected on similar lines.

In interstitial neuritis of the brachial plexus either the whole plexus or certain roots only are involved. The site of pain depends on the distribution of the nerves and there are usually no motor, trophic or sensory changes. The pressure due to vertebral diseases, a cervical rib or involvement of glands in the axilla may be responsible for the pain. In brachial neuritis the onset is usually sudden and the pain is made worse by abduction and circumduction of the arm. Tenderness is particularly marked over the upper half of the deltoid muscle as the axillary nerve is usually involved in the inflammation. The arm should always be supported in the abducted position. *Intercostal neuralgia* may be caused by fibrositis of the intercostal nerves or muscles and is generally accompanied by intense acute pain simulating that of pleurisy or by pressure on the nerves by mediastinal growths. In neuralgia of the twelfth thoracic nerve, the pain and tenderness are superficial and

the condition is very often wrongly diagnosed as appendicitis. Similar involvement of the occipital nerve causes severe headaches, especially in the morning with tenderness over the course of the nerve. A true Bell's palsy is due to involvement of the nerve after its emergence from the stylo-mastoid foramen, by pressure of a parotid tumour, or as a result of common cold, etc. Irritation within the buccal cavity is also a frequent cause of facial neuralgia. Radiograms of the teeth will reveal any anomalies and malformations which act as sources of peripheral irritation. The treatment of the above conditions is the same as that of lumbago.

In neuralgia of unsatisfactory blood states, chiefly due to anæmia, the treatment resolves itself into the treatment of the anæmia by suitable hygienic, dietetic and medicinal means. An outdoor life in a bracing climate is the best hygienic treatment in these cases. The diet should include abundance of vitamin-containing foods in which butter and cream should receive a prominent place. Fats seem to be concerned in some very special manner with the nourishment of the nervous system and in the form of butter and cream, they may be freely given to these patients. Alcoholic drinks may be allowed only in moderation. Iron is the best drug in these cases, but the stronger salts, the sulphate and perchloride, are much less efficacious than the citrates and tartrates. The two latter are readily assimilated whereas the former are very apt to upset the stomach. A useful formula is : citrate of ammonium and iron 10 gr., alkaline liquid extract of arsenic 2 min. and watery infusion of quassia to $\frac{1}{2}$ oz., to be taken thrice daily after meals. When the patient improves, the following may be prescribed : citrate of quinine and iron 20 gr., alkaline liquid extract of arsenic 5 min., tincture of nux vomica 4 min. and orange water to $\frac{1}{2}$ oz., to be taken thrice daily after meals. The presence of quinine even in such doses may help to subdue the neuralgia. In prescribing preparations of iron, the bowels should always be kept open ; this is best done by aloes at first because this drug enhances the effect of iron, and later cascara should be given. A daily morning dose of a natural mineral water is also very useful. When the neuralgic pain is severe, drugs having a direct influence upon the pain should be prescribed. A useful prescription, for the purpose, is hydrochloride of quinine 5 gr., dilute hydrobromic acid 20 min., tincture of gelsemium 10 min. and chloroform water to $\frac{1}{2}$ oz., to be taken every 20 minutes till the pain ceases and not more than 4 doses to be taken.

The state of the blood in goutiness is highly provocative of neuralgic pains and so iodide of potassium is very useful in these cases. Sometimes the following may help : salicylate of sodium and phenazone each 5 gr., syrup of ginger 1 dr. and chloroform water to 1 oz., to be taken every 15 minutes until pain ceases, and not more than four doses should be taken. This is a most admirable combination in migraineoid neuralgic attacks to which the gouty are peculiarly

prone. A fruitful and easily overlooked cause of neuralgia, especially in women, is toxæmic condition induced by chronic constipation. Along with the usual treatment of constipation, neuralgia should be treated with phenazone and the salicylate mixture, quinine and gelsemium are to be preferred where the patient is anæmic and emaciated. In them peripheral irritation from septic teeth, tonsils, errors of refraction, etc., should always be borne in mind.

In neurotic women complaining of neuralgia, the best drug to use is belladonna and should often be combined with phenazone. For the relief of facial neuralgia, butyl-chloral is probably the best of all internal remedies. It should be given in a pill of 5 gr. every half hour until the pain ceases and not more than six pills given. It is usefully combined with gelsemium which has a selective influence over cranial neuralgias. Locally, liniment of aconite painted over the painful area, is sufficient to cut short an attack. For vague, ill-defined neuralgic pain, chloride of ammonia 20 gr. combined with tincture of cimicifuge 20 minims is effectual. Acetanilid (antifebrin) is a valuable drug for the relief of neuralgic and neuritic pains. It is better to prescribe the drug cautiously in small doses (2 gr.) for fear of its untoward effects. Apart from morphia, this drug is the most powerful anti-neuralgic inasmuch as it relieves the pains of locomotor ataxy and of other organic diseases of the nervous system. The drug is practically insoluble in water and so is best given in cachets combined either with salicylate of sodium (10 gr.) or camphor monobromate (6 gr.). Morphia is unequalled regarding its effects in relieving intense neuralgias accompanying fevers like influenza and other toxæmias but its prolonged use in recurrent neuralgias is undesirable. In full-blooded individuals, leeching often affords relief in neuralgic pains and this is of particular value where the pain seems to be in or to radiate from the ear.

TRIGEMINAL NEURALGIA. Sigwald in discussing the various methods of treating trigeminal neuralgia, favours section of the trigeminal nerve above the Gasserian ganglion. This however is a serious operation which belongs to the scope of the neuro-surgeon and not the general practitioner and so other methods of treatment have frequently to be relied upon rather than such a severe procedure. Injection of alcohol into the nerve certainly relieves many cases, though it may not cure the condition. Radiotherapy has also had successful results, therapeutic X-rays being directed to the ganglion. Ionization with aconite or with calcium chloride has also proved successful, carried out thrice weekly for a month. A prescription containing aspirin 6 gr., pyramidon 4 gr., opium powder $\frac{1}{3}$ gr. may alleviate the severe pain for a time. Injections of parathyroid extract, insulin and horse serum have also brought about temporary alleviation.

NON-SPECIFIC PROTEIN THERAPY. Non specific protein therapy or protein shock therapy consists essentially of the injection of a protein either in the form of a sterile solution of albumose or a bacterial vaccine by the intravenous or intramuscular route.

Within the last few years this form of therapy has gained considerable popularity. The value of non-specific therapy was empirically established many years ago. Bokenham (1896) reported that diphtheria antitoxin was effective in typhoid and streptococcal infection. Rumpf (1893) treated typhoid patients successfully with pyocyaneus vaccine. Koch and Matthes observed that tuberculous patients reacted not only to tuberculin but also to injections of dextro-albumose. Renaud (1911) found that a typhoid vaccine killed by quartz light radiation had a definite therapeutic effect on a number of inflammatory conditions of non-typhoid origin. Kraus and Mazza (1914) reported similar results using *Bact. coli* as well as typhoid vaccine in puerperal infections. Similar instances of success in treatment with purely non-specific proteins, such as Coly's fluid, autoserum, whole blood, milk, intramuscularly and intravenously, have been reported. But the place of non-specific protein in treatment was definitely established as a sequel to Wright's vaccine therapy in 1916. Since then the agents used in the past few years, with the idea of immunizing the patients, are legion. The therapeutic effect produced by these substances, though considered different previously, are now considered to be of the same type. These substances act as non-specific stimuli to the normal immunity mechanism and help to produce the various reactions on which depend the beneficial effects.

The non-specific proteins that have been commonly employed are :—

1. **BLOOD AND BLOOD SERA.** (a) *Whole blood* either citrated or not may be given subcutaneously or intramuscularly in doses of 10 c.cm. (b) *Normal sera*, human, horse, sheep, ox, goat, etc. (c) *Immune sera*, e.g., human convalescent sera, pneumococcus, streptococcus and dysentery sera, diphtheria and tetanus anti-toxin.

2. **PROTEIN SOLUTIONS.** (a) *Proteins of animal origin.* Nowadays milk is the chief agent employed, 2 to 10 c.cm. being given intramuscularly twice a week; aolan which is a preparation of milk is often used. Other proteins of this nature are egg-albumin, serum albumin, casein, snake venom, etc.

(b) *Proteins of plant origin.* Nucleic acid and sodium nucleinate are used; the dose is 0.5 gm. hypodermically or intramuscularly in 5 per cent. solution. Other examples are agar-agar, pollen extracts, etc.

(c) *Protein split products.* Proteoses prepared from milk are given daily in doses of $\frac{1}{2}$ to 2 c.cm. of 2 to 10 per cent. solution. Peptone, for the production of shock, is used in 10 per cent. solution in doses of 5 to 10 c.cm. intravenously. Peptones are also used in hæmorrhagic diathesis, paroxysmal hæmoglobinuria, septicæmia and in allergic conditions, for which 5 per cent. solution is given intravenously and 7.5 per

cent. solution intramuscularly in doses of 5 to 40 min. Peptones, e.g., Witte's peptone, are also given by mouth.

3. ENZYMES. Trypsin, amyllopsin and leucocytic extracts.

4. BACTERIAL PRODUCTS. *Typhoid vaccine* in doses of 25 or more million organisms intravenously. *Bact. coli* vaccine 20 or more millions. Coly's fluid for malignant tumours. Malaria inoculation in parasymphilitic condition. Tuberculin has also been used in non-tuberculous subjects.

5. TISSUE EXTRACTS. Spleen extract has been used in hæmopoietic diseases and allergic skin conditions; 5 c.cm. of 40 per cent. solution is given on alternate days for 12 injections. Tumour extracts, autolysates, vascular and muscle extracts are also used.

6. CHEMICALS AND OTHER COLLOIDAL METALS. Gold, silver, manganese, sulphur, iron, platinum, mercury and antimony are used. These substances when employed non-specifically are said to act by breaking down inflammatory tissues with resulting protein absorption. Similarly X-rays, radium, cauterization, diathermy, freezing with CO₂ snow, and ultra-violet light treatment may be considered to be indirect methods of protein therapy.

7. MISCELLANEOUS. Hyper- and hypotonic salt solution, distilled water, glucose, etc.

Character of reaction. Certain focal and general reactions develop during treatment which depend upon a variety of factors, such as age of the patient, nature, duration and type of illness, the choice of protein and the dosage employed. The general and focal reaction is the goal aimed at in non-specific protein therapy, though no satisfactory explanation has been offered as to the manner in which it influences the process of the disease. It seems likely that the mechanism of the reaction is the general stimulation of the whole defensive forces of the body against an irritant introduced in the circulation, and that this reaction in some cases may lead to inhibition or even destruction of the causative organisms of disease. A focal reaction is always desirable, but the best results are obtained when it is slight. It consists of an intensification of any local inflammatory process followed by a diminution until the original condition is reached. Generally within fifteen minutes of the injection chill or rigor may occur, which passes off within half to three-quarters of an hour. A rise in temperature occurs which varies with the patient and the agent employed. When a vaccine is given intravenously, a maximum temperature of about 104°F may be reached in 3 to 4 hours, while with milk intramuscularly the maximum is attained in 6 to 8 hours. Increase in pulse rate and rise in blood pressure are to be expected. On the leucocytes, the effect is a primary leucopenia, probably due to the accumulation of the leucocytes in the viscera; later this is followed by leucocytosis which reaches its maximum in 4 to 8 hours. Very strong stimuli produce long-continued leucopenia followed by hyperleucocytosis. The degree of these reactions has

different significance for different diseases. In cases of chronic diseases, such as arthritis, marked focal and general reactions are indicative of a beneficial effect, while in diseases like asthma or typhoid fever, such reactions will be harmful. *

Following vaccine therapy, headache is quite common. Nausea, vomiting and herpes occasionally occur. The coagulation time of the blood is said to be diminished, metabolism and glandular activity are augmented. The injected foreign protein is said to be removed from the blood stream by the cells of the reticulo-endothelial system.

MODE OF ACTION. The exact manner of action of non-specific proteins is unknown. It has been shown that certain reactions such as rise in temperature, pulse rate, etc., are followed by increased glandular activity and augmentation of metabolism. All these reactions gradually subside leaving the patient in a clinically improved state.

The essential changes observed in the blood after injection of a non-specific protein are. (1) change in the leucocyte count, and (2) antibody changes. Spektorovskaya (1925) found an initial leucopenia in 80 per cent. of cases after injection of non-specific proteins, but from the third to the seventh day a moderate leucocytosis occurred. Other observers have, however, shown that the initial leucopenia is of very short duration and is followed within a few hours, by leucocytosis lasting for several days. Both granular and non-granular leucocytes have been shown to be increased; others found that after injections of proteins, e.g., milk, peptone and typhoid vaccine, an increase in neutrophils occurs, while distilled water produces an increase in mononuclear cell response.

With regard to antibody changes, it has been shown that after injections of non-specific proteins there is an increase in the titre of antibody already present in the serum. But many workers showed that they had no power to increase the antibody titre when this had become steady, but when these proteins are given at the same time as the bacterial antigen, they appeared to increase the anti-body production. The results of these experiments have been summarised by Topley (1929), who states that non-specific stimuli cannot cause the appearance *de novo* of any of the known antibodies in the serum but they can cause an increase in any of the normal antibodies present. They may also cause an increased production of antibodies if given during the early stages of immunization or when the effect of preliminary specific immunization is declining.

Though serological, cellular and other changes occur after injections of foreign proteins the mechanism of cure is still undetermined. Different theories have been postulated to explain the phenomenon. Gay and Claypole (1914) ascribed the beneficial effect to the leucocytosis produced, but it has been observed that the clinical result is not always commensurate with the blood changes. Paltanoff (1915) considered the beneficial effects to be due to thermogenic substances in the proteins

used. Rohonyi (1916) thought that non-specific therapy produced some neutralizing substances against the invading organism. Weichart (1919) attributed the action to a general stimulation of blood and tissue cells, thereby increasing the general resistance and speeding up the mechanism of detoxication, but Dollken showed that it was due to selective stimulation of certain organs, such as the liver, spleen and bone-marrow. Larson (1919) thought that injections of foreign proteins liberate the so-called sessile antibodies into the circulation. Pemberton (1920) considered the effect to be due to increased catabolism of glycogen. Mackenzie and Frahlaner (1927) showed that it acted by the re-awakening of an old immunity that has died away due to lapse of time, to this they applied the term 'anamnesic reaction.' Peterson (1928) believed that the true mechanism of action lies in a combination of several factors, such as, (i) a decreased permeability of cell membrane and hence increased tolerance to intoxication, (ii) cellular stimulation and mobilization of proteolytic enzymes with power to destroy toxic material, (iii) the lymphagogue effect that floods the lymph spaces with plasma rich in antibodies, (iv) increase in the anti-enzymes which makes the proliferation of bacteria difficult. Others have suggested that besides the increased production of antibody, complement, etc., the part played by the sympathetic nervous system and the endocrine glands may not be insignificant.

Therefore it seems probable that this form of treatment is based on rational and scientific foundations. When introduced into the body it assists the reactions which are common to all infections and conditions in which sensitization has occurred, and so enables the individual to desensitize or immunize himself. It is significant in this connection to note that an attack of one disease often has a beneficial effect on another entirely different in origin, from which the patient may be suffering at the same time.

THERAPEUTIC USES. *Infectious diseases* Infectious diseases, e.g., typhoid, tuberculosis have been treated with non-specific proteins. But it should not be used indiscriminately, as in this way, there is chance of converting an otherwise latent infection into an acute one. It is particularly suitable in localised rather than generalised infection and where the disease is of an undetermined nature or where the foci of infection cannot be reached for preparation of a vaccine. When the specific therapy has proved of little value, non-specific therapy may in such cases reactivate the healing mechanism. One or other of the bacterial vaccines or whole blood may be injected in these cases.

Arthritis. Non-specific protein therapy is most commonly employed in arthritis (see page 1251).

Asthma and other allergic conditions. In allergic conditions non-specific therapy has been used with advantage (see page 1232, 1262).

In other allergic conditions such as urticaria and angio-neurotic oedema, localised and generalised pruritus and pemphigus

autohæmotherapy and autoserotherapy have been tried. After withdrawal of blood from a vein, it is reinjected intramuscularly after defibrination, in doses of $\frac{1}{2}$ to 2 c.cm. every 24 hours or less or as freshly separated serum in doses of 2 to 4 c.cm. repeated at 2 to 7 days interval until a dose of 10 c.cm. is reached. In case of urticaria and angioneurotic oedema the best results have, however, been observed with injections of 33 $\frac{1}{3}$ per cent. peptone solution, given at first intradermically for the smaller doses and later subcutaneously. Urticaria papules in children is said to be cured after one or two injections of mother's serum.

Skin diseases. In dermatological conditions non-specific protein therapy has often proved useful. In eczema and dermatitis all methods have been used, but the most frequently employed is auto-sero and auto-hæmo therapy. Turpentine injections also give just as good results. Vaccines (typhoid, staphylococcus and streptococcus) have also been used but less frequently. Psoriasis has been treated with autoserotherapy, auto-hæmotherapy, intravenous vaccines, especially typhoid, milk and its derivatives. This form of therapy has been extensively used in lichen planus, lupus vulgaris, lupus erythematosus, leucoplakia, chronic X-ray dermatitis, etc. The consensus of opinion seems to be that in most of these dermatological conditions, the non-specific agents increase the susceptibility of the lesions to local treatment and so hasten the cure.

Syphilis. All stages of syphilis have been treated with non-specific injections either alone or in combination with specific drugs. Milk injections or a combination of milk and autohæmotherapy have been used in primary syphilis. Tuberculin injections have been used in secondary syphilis, as also typhoid and cholera vaccine, but the results have not been very satisfactory unless drugs are given at the same time. An attack of malaria is also known to influence beneficially cases of syphilis, but it has been found that induced malaria is probably without effect in the early stage while it does good in the later stages. This is especially true in cases of neurosyphilis. Within recent years malarial therapy has been very extensively used in the treatment of neurosyphilis and especially in tabes and G. P. I. The malarial treatment has however some disadvantages; it is always difficult to control the severity of an attack and there has been a certain amount of mortality from this treatment. Injections of typhoid vaccine and tuberculin have also been advocated and the results are said to be just as good both with regard to clinical conditions and their effect on the Wassermann reaction.

Gonorrhœa and its complications. Milk injections have been used with satisfactory results in both gonorrhœal urethritis and its complications. Autoserum has been recommended for gonorrhœal prostatitis and equally good results have been obtained with auto-hæmotherapy. Milk, bacterial vaccines, such as typhoid and *Bact. coli*, have all been used. Apparently it seems that non-specific methods give just as good results

in the treatment of gonorrhoea and its complications as the specific gonococcal vaccines and antiserum.

Other miscellaneous affections have been treated with non-specific therapy. In iritis and gonorrhoeal ophthalmia, milk injections are said to act like a specific remedy. Beneficial results often follow the use of milk in cases of keratitis, choroiditis, retinitis, conjunctivitis, corneal ulcers, etc.

In cases of purpura and hæmophilia where patients give manifestations of a hæmorrhagic diathesis, milk has been employed largely on account of its additional styptic effect. Vaccines of staphylococci and *B. prodigiosus* have been tried in neuritis. The beneficial effects of injections of tumour or bacterial autolysates in decreasing the growth of tumours have been described. Recently non-specific therapy has been employed to cause local vasodilatation in such diseases as Raynaud's disease, thromboangitis obliterans and arteriosclerosis.

MODE OF ADMINISTRATION. The patient should have a liberal carbohydrate meal 2-4 hours before injection, and preferably a feed of glucose one hour before it. He should be in bed during the period of reaction, and allowed to drink plenty of fluids; a small dose of codeine or adrenalin should be given to shorten the reaction and lessen the discomfort.

Injections may be given intravenously, intramuscularly, cutaneously and subcutaneously. Injections are given usually at a distance from the lesion but may also be injected locally around it. These are administered at short intervals of 2 to 4 days, as too long an interval may produce anaphylactic shock. The dose should be sufficient to cause a general moderate reaction.

Contra-indications. Although there is less risk of anaphylactic shock with this treatment than with specific desensitization, there are certain dangers associated with it. Milk is liable to give rise to these symptoms, autoserum and autohæmotherapy are less liable to cause them. The patient who is undergoing this treatment should be in a fairly good state of health. Alcoholism is an absolute contra-indication. In generalised or chronic multiple infections of long duration, or states of exhaustion following prolonged illness where it is impossible to stimulate the fatigued cells, non-specific therapy should not be used. Pregnancy has also been given as a contra-indication, but it may be mentioned that pregnancy dermatoses have been successfully treated. Patients with chronic myocardial changes and advanced arteriosclerosis should not be treated by these methods. Pulmonary diseases, especially tuberculosis, may show focal reactions after non-specific protein injections, and care must therefore be exercised in these cases.

It thus appears that provided certain precautions are taken, non-specific therapy is a safe and useful method of treatment for many diseases. The best results are obtained if it is combined with suitable general or local drug treatment. It is not very important which form

of protein is used, whether autohæmotherapy, milk, or bacterial vaccines, provided the dosage is regulated not to cause too severe reaction.

OBESITY. See page 1051.

CEDEMA. Œdema is a condition in which there is an abnormal accumulation of fluid in the intercellular spaces. Various theories have been propounded from time to time to explain the ætiology of œdema. Fischer holds that œdema is produced by the presence of an excessive amount of water in the tissues when the affinity of the colloids of the tissue for water is increased above normal. Under normal conditions, the tissue fluid is present only as an ultra-microscopic layer of fluid around the cells and according to Fishburg, œdema is produced only when such delicately adjusted dynamic equilibrium between the tissue fluid, the cells and lymph is thrown out of gear. About one-tenth of the water in the body is in the blood and œdema is produced as a result of changes in the blood. Wells holds that œdema is mainly the result of a process of filtration, while the vitalistic school maintains it is mainly the result of secretion. One is a plethoric condition with increased pressure and the other a diminution of protein-contents of the blood in such vessels. Starling held that œdema is due to increased permeability of the capillaries. Peptone and allied lymphagogues act as tissue-poisons and injure the capillary endothelium; the injured endothelium permits more fluid to pass through. Further there was a second class of lymphagogues advocated by Starling which produced a condition of hydræmic plethora and thus caused increased filtration.

According to a recent theory the capillary wall plays only a passive role in the fluid escape. The passage of water and crystalloids in and out of the capillaries is determined by forces on either side of the capillary wall and not by any active function of the latter. Fishburg maintains that increased permeability of capillaries plays a part only in cases where the œdema fluid contains considerable quantities of protein. With all these various theories, œdema may be defined as a condition in which fluid accumulates excessively in the intercellular spaces, in the tissues and in the serous cavities of the body.

Œdema occurs in many diseases and a correct knowledge of the factors responsible for its causation is essential for rational therapy. The common conditions which bring about œdema are increased capillary blood pressure, increased capillary permeability, impaired lymph drainage, decreased colloid osmotic pressure of serum proteins and the specific toxic excretory function of the kidney. The kidneys are said to normally eliminate certain electrolytes and under pathological conditions this eliminative process is interfered with, specially by sodium chloride but not potassium, ammonium and calcium ions. Loeb maintains, however, that the difference between the normal and nephrotic

kidneys is not so much qualitative as quantitative. This quantitative difference is attributed largely to the differences in the serum protein concentration of the blood.

CLINICAL TYPES. *Cardiac œdema.* It is met with in cases of congestive heart failure, where venous pressure is increased, capillary circulation retarded, the tissues suffer from lack of oxygen, nutrition of the tissue cells is impaired and tissue metabolism is interfered with, resulting in an accumulation of excessive fluid in tissue spaces, and lastly it is probably associated with some obstruction to the lymphatic outflow. In cardiac œdema the fluid is shared by all parts of the body. Bolton suggests the origin of the œdema fluid near the cardiac region and the visceral peritoneum. It then gravitates to the lower extremities whence it is partly reabsorbed by the local lymphatics. When the left chambers of the heart are primarily involved as in hypertension, aortic insufficiency or mitral stenosis, œdema appears and limits itself to the pulmonary regions. Facial œdema in cases of heart failure generally indicates a thrombosis of the jugular vein, or congestive renal changes as met with in the later stages of cardiac failure. Prognosis is usually grave in these conditions.

Treatment. The treatment of cardiac œdema should aim at reduction of the venous congestion by means of rest, venesection, pleural and abdominal paracentesis, careful massage, digitalis, diuretics such as diuretin, theocine, novasurol, salyrgan, ammonium chloride, etc., and hydragogue purgatives. Diet therapy includes a low protein diet in early cases and a high protein diet in later stages, when œdema is due to loss of an excessive amount of body protein malnutrition sets in. In early stages, it is always better to stick to a low protein and a high carbohydrate diet with a limitation in the amount of fluid intake. Efficient measures should be adopted early to avoid a later anoxæmia.

Nutritional œdema. In this condition the protein of the blood serum is decreased. The causes are to be sought in a deficient supply to the body of exogenous proteins in the food, excessive loss of protein through urine and from bleeding and lastly from non-absorption of nutritious materials from the gastro-intestinal tract. It is also met with in cases of vitamin deficiency and starvation, in chronic dysentery, in chronic tuberculous enteritis, in sprue, in hookworm infection, in piles, in pernicious anæmia, in pregnancy and lactation, in diabetes mellitus, in chronic alcoholism, in cirrhosis of liver and in cardiac insufficiency. These and other factors, help in precipitating the condition. The ideal treatment in nutritional œdema is to supply an adequate amount of protein in the diet with a restriction in the amount of salt.

Œdema in anæmia. In anæmia the amount of protein in the blood plasma is much diminished. Moreover, associated complications such as the involvement of heart and kidney as seen in pernicious anæmia, are also responsible for the condition. The treatment in these conditions

consists in treating the primary cause and supplying an adequate amount of protein in the diet.

Allergic œdema. In allergic œdemas, different parts of the body are attacked and symptoms too vary in such cases. The treatment in such cases aims at finding the cause of allergy and removing it as far as possible. Calcium and adrenalin therapy is useful in these cases. A small dose of thyroid alternating with ephedrine is able to control it more effectively.

Renal œdema. Here œdema may be generalised all over the body, or limited to certain places where loose areolar tissue predominates. Œdema is due to the renal damage as seen in cases of acute nephritis, nephrosis, and chronic nephritis. In acute glomerular nephritis, owing to the inflammatory changes in the glomeruli, the blood flow through the kidney is greatly reduced resulting in a retention of water, salts and nitrogenous waste products. In later stages the plasma proteins are diminished from loss of albumin in the urine and a condition of malnutrition sets in. In nephrosis, the œdema is associated with massive albuminuria. It is not always possible to attribute the œdema in these cases to a failure of the kidney to excrete salt or water. In such cases factors such as the total amount of serum protein, the hydrostatic pressure in capillaries and the ability of the kidney to excrete various ions should be considered to explain the causation of œdema. The serum protein is always low (being about 4 per cent.) in nephrosis, a disorder in which the kidney also is suffering just as any other part of the body would do. *Epstein's treatment of chronic nephrosis*—Epstein introduced the high protein diet in these diseases to cut short œdema. Epstein believes the effect to be partly due to the specific dynamic action of the protein, which counteracts the lowered basal metabolism in this disease, and partly to increase in the protein content of blood plasma. McLean believes that the reduction of œdema is due to diuresis set up by the large quantities of urea and other non-threshold bodies formed from the high protein diet. Renal functional tests should be performed before putting a patient on high protein diet. Epstein's diet contains: proteins 120 to 240 gm., fats 20 to 40 gm., carbohydrates 150 to 300 gm., giving a total calorific value of 1250 to 2500. Besides this, he allowed 1200 to 1500 c.c.m. of water and enough salt to give a certain amount of taste. The articles allowed are lean meat, fish, white of egg, oysters, gelatin, lima beans, lentils, split peas, green peas, mushrooms, rice, oatmeal, bananas, skimmed milk, coffee, tea, cocoa. He allowed 2 to 3 gm. of protein per kilo. of body weight. Medicinally, Eppinger advocates extract of thyroid, which induces diuresis in these cases, especially in nephrosis.

Neuropathic œdema. This type is often associated with disturbed function of the sympathetic system and is seen in different parts of the body. Ranvier has shown that the nervous system is responsible for the production of œdema in many cases. In paralytic limbs, the absence of

muscular activities retards the removal of lymph, resulting in œdema. Stimulation of vasodilators also causes œdema. The treatment mainly includes physical therapy in the form of massage, electro-therapy and splinting to prevent subsequent deformities, etc.

Lymph œdema. It is seen in cases of filariasis, leprosy, chronic leg ulcers especially those associated with cicatrization, cellulitis, and erysipelas. There is also a congenital and familial form of tropho-œdema known as Milroy's disease. Œdema is often met with after extensive surgical operations, cicatrization and infiltration may play a part in this.

Alkali œdema. It is sometimes seen in alkali therapy of diabetes, gastro-duodenal ulcers, lobar pneumonia, etc. and disappears on the discontinuance of the alkali. Fischer explains it by saying that sodium proteins have a greater affinity for water than calcium or magnesium proteins, and that the sodium salts administered replace the calcium and magnesium in the tissues.

Inflammatory œdema. Injury to the capillary wall plays an important part in the production of œdema. Increased blood pressure, impeded lymph flow, an excessive formation of metabolic products, the asphyxiated condition of inflamed tissues which favours acid formation and naturally increases the avidity for water in the tissues are the factors that influence the œdema in these cases. Oswald says that the permeability of the vessels for proteins is specifically altered in inflammation so that not only the less viscous albumin and pseudoglobulin pass through, but also the more viscous englobulin and fibrinogen.

GENERAL PRINCIPLES OF TREATMENT OF ŒDEMA. *Restriction of diet.* When œdema has set in, control of diet is most important and even in very early cases it may abort an attack. Salt and water are the two important œdema-producing factors in diet which need careful restriction. The daily supply of common salt to dietaries should be cautiously cut down, and to satisfy taste potassium chloride may be substituted instead. The symptoms of salt deficiency appear only when chloride excretion in urine becomes less than $\frac{1}{4}$ gm. per day. The symptoms of salt deficiency are vomiting, headache, pain in the muscles of the legs and irregularity of the rhythm of the heart. Most raw foods including vegetables contain very small quantities of sodium chloride, while milk, cheese, salted butter, salted fish and preserved meat contain larger quantities of this salt. Restriction of fluid intake depends on the integrity of renal functions. If the urine is of high specific gravity the intake of water should be encouraged to avoid uræmia in the long run. The dangers of too great fluid restriction should always be borne in mind.

Diuretics. Water is the best diuretic, but in œdema its intake cannot be encouraged. Volhard advocates the use of water not exceeding an amount of 1500 c.cm. in cases of anuric or severe oliguric patients with acute glomerulo-nephritis, but even this is not generally

accepted. Of the salts reputed as diuretics, sodium salts are contra indicated in cedema and potassium salts are preferable, those commonly used are citrate, bicarbonate and acetate. Strictly speaking, chloride of potassium, having no influence on the acid-base equilibrium, should replace all other salts. The idea of acidity causing diuresis has led to the use of ammonium chloride and calcium chloride, the former acts as a very good diuretic especially in cardiac cedema.

Urea is a very useful diuretic in cardiac cedema and sometimes also in nephrosis. It is given in large doses, three times a day in combination with a suitable corrective to hide its nauseating taste. Before the administration of urea, tests to prove efficient renal functions should be undertaken. Moeller holds that theophyllin by causing an increased transit of fluid and salt from the tissues into the blood stream, acts as a diuretic especially when the kidneys are functioning well. In cardiac cedema, the purines are said to act by their effect on the heart which they stimulate and on the coronary vessels which they dilate. Diuretin or the double salicylate of sodium and theobromine is a stronger diuretic than caffeine. It has a greater action on the heart and the kidney and a weaker action on the nervous system. It is given in doses of 10 gr. three times a day with plenty of water. Taylor advocates its use up to 90 gr. per day to obtain the maximum effect. Theophyllin or theocine is a stronger diuretic, a more powerful cardiac stimulant and it dilates the coronary vessels better. The dose is 3 gr. 3 times a day. Of the mercurial diuretics, the old and famous Guy's pills has not lost its place in the treatment of cardiac cedema. Very recently, other preparations containing mercury have come into use, of which novasurol deserves mention. Because of its irritating action on the intestine and kidneys it has now been replaced by salyrgan, which is equally powerful but less irritating to the bowels. The mode of action of these two drugs as diuretics is not known. Salyrgan is used in cardiac cedema, but it should never be given when renal functions are impaired. Ammonium chloride should be given about 48 hours before the administration of this drug. It can be given either intravenously or intramuscularly in doses of 1 to 2 c.cm. to be repeated every third day. Meyer has given injections of 2 c.cm. of salyrgan directly into the peritoneal cavity in cases of dropsy. He draws about 10 c.cm. of the ascitic fluid from the peritoneal cavity and leaving the needle behind in the cavity, draws 2 c.cm. of salyrgan into the ascitic fluid in the syringe, mixes them up, and then injects the whole slowly back into the peritoneal cavity again. The drug appears to cause no damage to the peritoneum. When given in this way the toxic effects produced by salyrgan are stomatitis, colitis, increase of albuminuria, hæmaturia, moderate fever and circulatory collapse. The double tartrate of bismuth and sodium has also been used as a diuretic in doses of 0.08 gm. injected intramuscularly. Endocrine products such as extracts of thyroid and parathyroid have

also been prescribed for their diuretic effects. In cases, where due to impaired kidney functions, the body cannot get rid of the oedema fluid and is water-logged, recourse can be had to other organs to serve the same function, *e.g.*, the skin and the bowels. Diaphoresis is best effected by means of hot packs, electric baths or a simple hot bath. It is suggested that the elevation of the temperature of the skin might cause a reflex vasodilatation of the kidneys and thereby bring about diuresis. Pilocarpine nitrate is a useful adjuvant in the treatment but it is dangerous in cases of weak heart or oedema of the lung. The administration of purgatives, *e.g.*, saline or vegetable, helps a great deal in draining the fluid from the body in cases of oedema. Recourse has to be taken to surgical operations sometimes, when other measures fail. Drainage of the pleural, pericardial and peritoneal cavities is essential, under strict surgical precautions. It relieves the patient in almost all cases and diuretics are found to act better after such procedures. In cases of dropsy of the lower extremities, the oedema fluid is generally drained by means of Southey's tubes inserted into the most dependent part of the extremities. The fluid led off by rubber tubing is collected in a clear bottle. The tubes are generally retained for 24 hours. Other accessory measures such as sun baths, elevation of the limbs, strapping, pressure bandages, etc., considerably help the treatment.

OPTIC NEURITIS. Inflammation of the optic nerve may develop at any spot in the course of the nerve. It is directly visible by ophthalmoscopic examination only when the optic papilla is involved it is called *neuritis intraocularis* or *papillitis*; when the extraorbital portion of the optic nerve is involved it is called *neuritis retrobulbaris* and this can hardly be detected by ordinary ophthalmoscopic examination. The disease is not always due to a local cause but it generally originates in some deep-seated affection and is often bilateral in development. Of the common aetiological factors responsible for the condition, brain diseases are by far the most common cause of optic neuritis. This they produce either by congestion of the brain or by a direct transmission of an inflammation from the brain to the optic nerve, as in cases of tuberculous meningitis or otitic processes. This increased intracranial pressure causes 'choked disc' due to the swelling of the optic papilla. The diseases of the brain complicated with optic neuritis are partly focal and partly diffuse in nature. The tumours of the brain, abscesses, thrombosis of the sinuses, aneurysms, apoplexies, disseminated sclerosis, acute and chronic meningitis and hydrocephalus afford examples of both the focal and diffuse affections of the brain responsible for optic neuritis. Neuritis also follows malformations and injuries of the skull particularly involving its basal part. Other common causes of optic neuritis are of a constitutional nature such as syphilis, acute infectious febrile diseases, chronic disturbances of

nutrition of various kinds, acute anæmia from sudden loss of blood, poisoning with lead, arsenic, alcohol and iodoform (toxic amblyopia of retrobulbar type). In the tropics, chronic cachexias resulting from long-standing illnesses such as malaria, chronic dysentery, albuminuria, diabetes, tuberculosis very often act as potent causal factors in optic neuritis. Septic foci in teeth, tonsils, accessory air sinuses, acute exanthemata such as measles, small-pox, scarlet fever, etc., acute infectious fevers such as diphtheria, pneumonia, influenza and whooping cough are also responsible for the condition. Disorders of the genital system, pregnancy and lactation in the female sex may also lead to neuritis of the optic nerve. Hereditary optic neuritis (Leber's disease), a retrobulbar type, is commonly met with in the male members of a family about the twentieth year. The disease is bilateral, the vision suffers at first though subsequent improvement is the rule. Ophthalmoscopic examination reveals a normal fundus or a slight blurring of the edges of the disc. Ordinarily, in optic neuritis ophthalmoscopic examination shows evidences of inflammation in the optic papilla, its normal colour is altered and is often mottled with white spots or extravasations of blood; the diameter of the papilla also appears to be greater than normal. The most important feature is the swelling of the papilla, projecting above the surrounding retina and the victim suffers from disturbed sight. The disease runs a chronic course and the prognosis is usually grave as the condition might result in optic atrophy.

TREATMENT. The treatment of optic neuritis is essentially a treatment of the underlying causes. Local treatment is hardly effective and consists in removal of congestion by abstracting blood at the mastoid process, diaphoretic measures, administration of absorbent remedies such as iodide of potassium, oleate of mercury (to be rubbed over the nape of the neck). To alleviate pain, aspirin and its derivatives may be prescribed. Surgical procedures such as trephining the skull, should be early resorted to before the vision is lost, in cases of increased intracranial tension. Vision often improves after the operation. Measures to promote general health should always be taken in hand early. In retrobulbar neuritis, treatment should be directed towards the eradication of septic foci of the mouth and nasal sinus. The eyes should be guarded from bright light and kept at rest by the use of mydriatic drugs. Herbert Fisher suggests that hereditary optic neuritis is due to transitory changes in the pituitary body often associated with physiological changes in sexual life and so endocrine therapy with thyroid and pituitary is of great benefit in these cases.

ORGANOTHERAPY. Formerly all organic correlations were assumed to be nervous, but now it is known that various body functions are not controlled by the nervous influences alone, but also by the chemical substances that pass from the tissues into the blood stream. To such

substances the name of 'hormone' or chemical messenger is given. The term hormone (Greek : *hormao*—I arouse) was coined by Starling, but Schafer pointed out that the type of action was not always one of stimulation, and he suggested the word 'autoroid' (Greek : *autos*—self, and *akos*—a drug). Such substances are divided into two classes, 'hormone' that stimulates and 'chalones' that depress activity. This classification, however, has no wide-spread acceptance. 'Incretion' is another term which is now accepted to denote the internal secretion.

Brown-Sequard impressed the medical world with the view that all glandular organs, whether they are with or without ducts, may give off to the blood, substances that are necessary for the welfare of the body as a whole. These include the ductless glands such as the thyroid, the parathyroid, the thymus, the hypophysis, the epiphysis and the adrenals, along with others which elaborate both an external secretion that escapes through a duct and an internal secretion that enters the blood. To the latter group belong the pancreas, the liver, the duodenal and gastric mucosa, and the sex glands.

The normal functions of the glands are only partially understood, and most of our knowledge has been gained by experimental physiology and clinical medicine. The functional abnormalities have been considered to result from insufficient (hypo-function) or excessive glandular activity (hyper-function). This is borne out by the fact that symptoms are relieved by administration of glandular products or by the successful transplantations of the gland in question or in the other cases by operative removal of a part of the gland. But there remains yet another type of clinical condition which does not fall clearly either into the group of hypofunction or hyperfunction. The cause of this aberrant type (dysfunction) is not clear. Possibly it is due to the complex structure of the gland and the different physiological properties of the different parts. Not only the quantity, but also the quality of the incretion may undergo variation and give rise to the clinical condition which represents a mixture of the effect produced by alteration in the component elements elaborated by the gland.

Our knowledge of the pure physiology of the endocrine glands does not help us to get over the difficulty that exists in the application of these principles to the applied science of organotherapy. The existence of the intimate relationship of the various glands and their relation to particular function has been revealed and the obstacle to the furtherance of rational organotherapy has been to a certain extent removed. It has now been demonstrated that the pathological lesions of the individual glands cause some disturbance in the functional relation of other glands, the so-called 'pluriglandular syndrome.' A perfect physiological balance is normally preserved by the proper distribution of harmony and antagonism between the functions of the various glands. The hormones are present in the body to be utilised when occasion arises. Thus a sudden call for increased energy is answered to by the adrenals

and to some extent by the thyroid. The growth of the body requires the action and interaction of many internal secretions, the thyroid, pituitary, thymus, suprarenals, gonads and digestive glands. With reference to the general effect upon metabolism, growth and development, the glands may be classified into two generally opposed groups.

1. *Acceleratory* (katabolic-dissimilatory):—Thyroid, hypophysis (posterior lobe), chromaffin tissue (suprarenal medulla) and sex glands.

2. *Retarding* (anabolic-assimilatory):—Parathyroids, hypophysis (anterior lobe), adrenal cortex, intestinal glands, thymus, pineal, and pancreas (insular part).

In general, the first group stimulates the action of the sympathetic system (sympathicotrope) and the second inhibits it (vagotrope). Of the particular relationship existing between glands and their combined action in functional activity, the following seems fairly well established as a result of experimental physiology and clinical investigations. Definite relationship has been shown to exist between thyroid-pituitary, thyroid-gonad, thyroid-adrenal, thyroid-thymus, thyroid-pancreas, pituitary-adrenals, pituitary-gonad, pituitary-pancreas, adrenal-gonad, adrenal-pancreas, adrenal-thymus and gonad-thymus.

Disturbed physiology in one endocrine gland produces functional and anatomic changes in one or more of the other glands. It has been shown experimentally that excision of one gland often gives rise to secondary changes in other glands. Thus, for example, an increase in the anterior lobe of the hypophysis is observed after thyroidectomy. Graves' disease is nearly always accompanied by menstrual disorders in females and often loss of libido in both sexes. Damage to the cortex of the adrenals produces an increased metabolism by stimulating the thyroid.

The manner by which the internal secretions bring about their characteristic effect, may be described as a direct action on the cell metabolism and through the medium of the autonomic nervous system. The first mode of action may be general and affect the metabolism of all the cells (e.g., thyroid) or specific and affect only one type of cells (e.g., pituitary). The second mode of action is through the autonomic nervous system and this probably accounts for the great majority of internal secretion effects. Through this channel it helps to maintain an efficient co-ordination of the most complex animal organism. The balanced action of the two parts of the autonomic nervous system—the sympathetic and the parasympathetic—is intimately bound up with the internal secretion and is of utmost importance in interpretation of the various clinical syndromes.

The branch of therapeutics in which certain diseases are treated by extracts from endocrine glands is known as organotherapy or opotherapy. It is a very ancient practice and was for very long on an empirical basis. A large proportion of modern organotherapy is, however, devoid of any scientific basis, but the modern development and

steady additions to our fundamental knowledge of the subject make it possible to offer some explanation as to their mode of action. The mechanism of modern organotherapy may be as follows:—

(a) *Substitution*. In cases of lessened or faulty secretion of a gland, a specific substance formed by the gland in normal physiology is introduced into the system. The results obtained cannot be wholly explained on a substitutional basis, probably some other factors are at play. Insulin therapy in diabetes and ovarian therapy belong to this group.

(b) *Homostimulation*. This valuable mode of action was originally postulated by Hallion and is usually referred to as 'Hallions Law.' "The extract of an organ administered in suitable amount has an elective stimulating action on the functional activity of the same organ in the patient to whom it is administered." Many clinical evidences may be put forward in support of it, but the extent of its applicability is still undefined. After administration of a glandular product, there is at first a stimulation to increased functional activity of the homologous organ and secondly, there is actual rebuilding of the affected organ. Thyroid therapy and pituitary therapy belong to this group.

(c) *Utilisation of a product for its physiological influence*. In this form of therapy, advantage is taken of the distinct physiological and pharmacological action of certain gland products. There is no idea, in this form, to obtain any profound endocrine (hormazone) effect. Epinephrine may be used to stimulate the heart's action or cause vasoconstriction in cases of shock.

(d) *Rectiprocal action*. This is based upon the intimate inter-relationship that exists between the different endocrine glands. The gland which plays the most important part in the clinical picture is not only dealt with in this therapy, but also other glands either compensatory or antagonistic, which act as an intermediate factor in bringing about the effect.

In this connection it may be mentioned that there is another aspect of the mode of action and that is known as 'antagonistic action.' Excessive secretion of one gland is neutralised by extract of another, assumed to be antagonistic. This adjustment to rectify a faulty hormone balance is very important in the field of organotherapy.

(e) *Empirical*. It is based upon the clinical observation that certain gland products or their combination have a favourable action upon some clinical syndrome. Our limited knowledge about the ætiology and pathology of these conditions and their relationship to the different endocrine glands, is responsible for the lack of any scientific explanations.

•The failure resulting from the use of a single gland product was in some cases due to the fact that the fundamental fact of endocrine inter-relationship was not taken into account in therapy. "Uniglandular organotherapy had its rise when clinical and experimental observation disclosed the phenomena which result from alteration or extirpation of

one or another glandular element, failing to take account for the most part of the anatomical and physiological connections between these elements. But when the complete functional unity and intimate biological connection came to be understood, their morbid manifestations ceased to be looked upon as due to separate factors and treatment became influenced by their physiological inter-relation, the only method of dealing fully with their functional insufficiency." Endocrine diseases are now recognised as pluri-glandular syndromes and successful results are obtained in cases by mixed organotherapy, where one gland fails to produce any improvement. Thyroid-ovarian medication in ovarian insufficiency is an illustration.

MODE OF ADMINISTRATION. The most popular method of administration is by the oral route. The hormones as chemical compounds pass through unaffected by the enzyme action although in some cases they have been known to undergo oxidation, *e.g.*, epinephrine. The hormones as a general rule are simpler bodies than the proteins; they crystallise and dialyse freely. They withstand boiling and, according to Abderhalden, are not destroyed by the action of the digestive enzymes. For those cases where it is apprehended that some destruction may take place in the stomach or intestine, the sublingual method of administration may be resorted to. Subcutaneous, intramuscular and intravenous routes are also resorted to in some cases, but they have limited scope, for the advantages claimed in their favour, *viz.*, the rapidity of action, do not apply in this case, for organotherapy has rarely been applied for treating emergent cases. Parathormone and cortical extract, however, have been used parenterally to obtain speedy effects.

The following are some of the endocrine glands which have been widely used in the field of organotherapy. It is not an inclusive list, but some of the better known preparations are mentioned.

THYROID GLAND. It is most widely used in the therapeutics. Sajous outlines the general field of thyroid therapy as follows:—

(1) In diseases due to slowed destruction of toxic waste products of body metabolism, as shown by its action in tetany, epilepsy, eclampsia, disorders of menopause, asthma, etc. (2) In diseases due to lowered general nutrition of all tissues including the bones, *e.g.*, cretinism, myxoedema, ricket, osteomalacia, etc. (3) In diseases due to lowered nutrition of the muscular elements, including the skeletal and vascular muscles, *e.g.*, adynamia, neurasthenia and myasthenia. (4) In all cases in which the processes of repair or absorption are deficient, *e.g.*, in delayed union of fractures, bone necrosis, etc. (5) In infectious diseases, owing to increase of auto-intoxication, thyroidase, and phagocytes, *e.g.*, in early stages of tuberculosis, typhoid fever, etc.

In certain skin diseases, characterised by a thickened, scaly and dry condition of the dermis, as well as in others, *e.g.*, dermatitis herpetiformis, prurigo, psoriasis and chronic eczema, thyroid therapy is very efficacious.

Preparations. *Thyroxin* is the crystalline autocoid of the thyroid gland. It is not the essential hormone of the gland and has not replaced the gland substance for therapeutic purposes except in the treatment of obesity. It is official in the U. S. P., the average dose is 0.5 mgm. (1/12 gr.). *Thyroid siccum* is a powder prepared from fresh and healthy glands of the sheep. No standard of strength is given. The dose is 0.03 to 0.25 gm. ($\frac{1}{4}$ to 4 gr.). For infants 1/20 gr. may be given thrice daily. In cretinism the dose may be larger. *Elitiran* is prepared by the Bayer laboratories and is a particularly potent form of dry thyroid containing as much as one per cent. of iodine. It is used in tablet forms, each one equivalent to 25 mgm. (2/5 gr.) of dry thyroid and may be given in corresponding doses.

The milk of thyroidectomised goats, the serum of thyroidectomised sheep and thyrolytic serum, have also been used with the object of neutralising the excessive and abnormal secretion, to which the unpleasant symptoms of the disease are believed to be due.

PARATHYROID GLAND. The main function of this gland is to regulate the calcium metabolism and to increase the ionisable calcium content of the blood. The glandular product is given in small doses and with good results in all cases of muscle irritability, *e.g.*, in chorea, epilepsy, spasmophilia, tetany, etc. Its use has been advocated in sprue with simultaneous administration of calcium. As it mobilises the calcium from other tissues, mainly the bones and muscles, its use in rickets is contraindicated. Extract of glands, freed from the calcium raising factor and injected into human beings suffering from carcinoma has been reported to have caused some improvement in the condition.

Preparations. *Desiccated parathyroid gland.* Tablets containing 1/20 gr. (0.003 gm.), 1/6 gr. (0.01 gm.), $\frac{1}{4}$ gr. (0.016 gm.) and $\frac{1}{2}$ gr. (0.03 gm.) are obtainable. The average dose is 1/60 gr. (0.001 gm.) to $\frac{1}{4}$ gr. (0.1 gm.) thrice daily. *Parathyroid extract liquid.* The potency of the extract is estimated by the rise in calcium in blood serum of dogs. It is used in cases where parathyroid glands have been removed by mistake. Injections prove curative. *Parathyroid hormone* or 'parathormone' is an aqueous solution of the active principle of the parathyroid glands of cattle. It is standardised physiologically on the basis of its calcium-raising property. It is specific in tetania parathyreopriva and in other conditions in which there is deficiency of serum calcium. The dose is 20 to 30 units given intramuscularly (one unit is one-hundredth the amount required to raise the serum-calcium of a dog weighing 20 kilo. to 5 mgm.).

Elixir parathyroid with calcium lactate contains 1/20 gr. of dried parathyroid gland and 8 gr. of calcium lactate in 1 dr. of the fluid. The dose is 1 dr. increased if necessary.

ADRENAL GLAND. It consists of two portions, the cortex and the medulla. Each contains a separate hormone; extract of the medulla is

known as adrenalin, while the exact nature of the hormone of the cortex is still under investigation. Medication by means of the medullary substance as well as with the whole gland has not been very successful; the hormone alone has got some therapeutic application. Adrenalin is mainly used as a vaso-constrictor as well as to maintain the normal tonus of the body. Another very important use of adrenalin is to relieve an attack of bronchial asthma, where it acts by causing the muscles of the bronchioles to dilate. Its use as a restorative during surgical shock and in the treatment of anaphylaxis is well-known.

The active extract of the cortical substance has been largely used in restoring the adrenal function in Addison's disease. Other conditions have also been treated with this, *e.g.*, post-diphtheritic asthenia, severe vomiting, etc. Adrenal cortex has also been tried in cancer but no encouraging results have been obtained.

Preparations. *Suprarenal gland*, dry, has got insignificant therapeutic value. The dose is from $\frac{1}{2}$ to 3 gr., three times a day. *Adrenalin* (synonyms—epinephrine, suprarenin, adrephrine) is an active principle of the suprarenal glands. It is best prescribed alone in solution as it is oxidised rapidly, especially in neutral or alkaline solution. The dose is 1/600 to 1/120 gr. or 0.0001 to 0.0005 gm. *Liquor adrenalin hydrochloride* contains one part of adrenalin, five of chloroform, nine of sodium chloride, three of dilute hydrochloric acid, and distilled water up to 1000. It is used either locally on the mucous membrane or by injection. After oral administration it is largely destroyed in the gastrointestinal tract. The dose is 2 to 8 min., subcutaneously. For resuscitation in cardiac arrest, intracardiac injection of adrenalin is very efficacious; still-born infants have been known to respond to adrenalin by intracardiac injection. *Suprarenal cortex*, desiccated, has been tried experimentally on the grounds that the cortex has a function distinct from the medulla. Dose, 2 to 5 gr. thrice daily. *Cortical hormone*, has been prepared free from adrenalin. It is issued under the name of 'eucortone' or 'cortin'. It is a watery solution of which 1 c.cm. contains the activity of 30 gm. of fresh cortical tissue. The dose is 10 to 20 c.cm. intravenously or subcutaneously in divided doses. Addison's disease responds well to this treatment.

PITUITARY BODY. The two lobes of the pituitary have distinct functions. Extract from the posterior lobe has been found to possess certain definite properties: (1) The pressor property which has the stimulant effect on the muscle of the blood vessels. (2) The oxytocic property, which has a stimulant effect on the muscle of the uterus. (3) The antidiuretic property, which has the power to delay the excretion of excess of water taken by the mouth. (4) The power to increase intestinal movement. Part of the antacid secreted by the anterior lobe is necessary for the normal growth and part for stimulating the ovaries into activity. Zondek considers the sex-stimulating antacid to be of a dual nature; one known as 'Frolan A' which influences the ripening of

the follicle and the other 'Prolan B' influencing the formation of corpus luteum. This factor is utilised in the Zondek-Aschheim test for pregnancy.

The general indications of pituitary therapy have been given by Bell:—(1) For pressor effects on the circulatory system, the uterus, the alimentary tract the urinary system and the spleen. (2) For supplementary effects. (3) For antagonistic and metabolic effects.

Pituitary preparations are particularly valuable in the field of gynaecology. In the treatment of amenorrhœa, dysmenorrhœa, menorrhagia, metrorrhagia, menopausal disorders, for the induction of labour and in cases of sub-involution and uterine hæmorrhage, pituitary extract is of potent value.

Preparations. *Pituitary body dried* (entire gland) has been employed to improve metabolism, to raise arterial tension, to increase diuretic action and improve metabolism. The dose is 1 to 3 gr. *Pituitary substance, dried* (ant. lobe) has been used to stimulate growth and in certain types of obesity. It is given in 1 to 4 gr. doses. *Pituitary substances, dried* (posterior lobe) is used in exophthalmic goitre, acromegaly and to relieve cardiac dilatation. It is also efficacious in intestinal paresis, diabetes insipidus and enuresis. Dose is 1 to 4 gr.

Liquid pituitary preparations of: (a) *Entire gland.* This has been tried in certain types of acromegaly. The dose advised is $\frac{1}{2}$ to 1 c.cm. intramuscularly; (b) *Anterior lobe.* In children with retarded growth this has been used with some evidence of benefit, but it is believed that no active principle from the anterior lobe can pass into the aqueous extract. The dose is 1 to 2 c.cm.; (c) *Posterior lobe (pituitary extract or liquor pituitary).* It is a sterile solution containing the active principle of the posterior lobe of the gland of ox. It has a special action on the uterine muscle and is used to hasten a sluggish labour. It should not be given at the first stage of labour when the os is not fully dilated or when there is some mechanical obstruction. Dose is $\frac{1}{2}$ to 1 c.cm. (1.0 c.cm. of the solution should contain 10 units, i.e., 3.5 per cent. extracts of the fresh gland). The main use of this property is to ensure that the uterus remains contracted after the delivery of the child.

The oxytocic and vaso-pressor principles of the posterior lobe have been separated as stable water soluble powders. *Pitocin* (formerly known as oxytocin) is the oxytocic principle, standardised to the oxytocic activity of the U.S.P. Pituitary solution (10 units per c.cm.). It is also available in such forms as Neo-infundin or Orasthin.

Pitressin is an aqueous solution of the pressor-diuretic-oliguric fraction standardised to correspond to double the pressor activity of the U.S.P. Pituitary solution (20 units per c.cm.).

PANCREAS. The pancreas consists of two types of tissue—the acinar, secreting the pancreatic juice containing the digestive enzymes and groups of cells known as 'Islands of Langerhans.' The latter are proved

to contain a substance which circulating in the blood stream, prevents an undue amount of glucose from accumulating in this fluid and also lowers the blood sugar and diminishes or abolishes excretion of sugar in urine in diabetic subjects. To this the name '*Insulin*' has been given. Besides the supply of these two secretions, the pancreas has other functions. The German workers have extracted a circulatory hormone, while another substance described as a hormone and called '*vagotonine*' has been isolated by Santenoz and his associates. The action of the latter is complementary to that of insulin.

In certain forms of severe glycosuria pancreatic preparations are particularly valuable. For invalids, aged persons and those suffering from weak digestions, preparations of pancreas may be employed, by which the food may be partially or wholly digested previous to administration.

Preparations. *Pancreatin* is a cream-coloured amorphous powder, consisting principally of amylase, trypsin and lipase. It is partially soluble in water. It digests albuminoids and converts not less than 25 times its weight of starch into soluble carbohydrates. The dose is 2 to 4 gr. *Liquor pancreaticus* is used in doses of 1 to 2 dr. in water with meals, to aid intestinal digestion. It contains amylolytic, proteolytic and milk-peptonising properties of the pancreas. *Trypsin* changes proteins into peptones in alkaline media. It is prepared commercially in the form of whitish powder and one part can peptonise about 100 parts of coagulated egg albumin in 1½ hours. The dose is 8 to 20 gr. *Padutin* is a solution of the circulatory hormone from the pancreas. It is used in such circulatory disorders as arterial spasm, Raynaud's disease and hyperpiesis. Dose, one or more injections daily. *Insulin* is of great value in glycosuria. On injection it converts glucose into the active form and if given at proper intervals blood sugar is maintained at normal level and urine remains free from sugar and there is a quick restoration to normal metabolism. The commercial insulin is composed of three substances, the true pancreatic hormone A, the anti-insulin B and co-insulin C. It is available in the form of aqueous extracts and crystalline insulin. Insulin in solution contains 20 units per c.cm. and tablets of insulin hydrochloride are each equivalent to 10 units. The Public Health Committee of the League of Nations lays down the unit of insulin as one-third of the amount of material required to lower the blood sugar of a 2 kg. rabbit which has fasted for twenty-four hours, from the normal level (0.118 per cent.) to 0.045 per cent. over a period of five hours. The usual dose is 5 to 100 units which can be varied according to the need. The details of the use of insulin in diabetes have been described on page 1447. Besides this above-named condition insulin has also been used in cases in which malnutrition is the outstanding feature, in exophthalmic goitre, hyperthyroidism, vomiting of pregnancy, skin diseases, etc., with encouraging results.

SEX GLANDS. The sex glands are of very great importance to normal health, but they differ from other endocrine glands in that they are not

essential to life. Their main functions are in reproduction, but in addition to these, the sex glands exert an influence upon the growth and development of the body, both physical and mental, and in the female in the process of menstruation.

TESTES. These contain two kinds of cells, the spermatogenetic and interstitial. The first one is responsible for the production of spermatozoa while the interstitial cells also known as 'Leydig cells' give rise to an internal secretion. This hormone is responsible for the general bodily development between the ages of twelve and twenty, but there is evidence also that diminished formation may lead to decay in old age. Preparations from this organ are widely used in the treatment of sexual neurosis, impotence and as a general tonic in old age. Orchic extracts have also been recommended in certain toxic dermatoses and in psoriasis. Transplantation of the testes (Voronoff's method) is supposed to cause rejuvenation and has been tried on the continent. Another method to combat senility is the ligation of the vas deferens (Steinach operation). The idea is that after ligation, there is atrophy of the glandular cells and a subsequent proliferation of the interstitial tissue, which can secrete more testicular hormone and produce the effect desired. The results of both these operations have not been satisfactory.

Preparations. *Orchic substance* is the desiccated product of the gland and is given in doses of 2 to 5 gr. three times a day.

Liquor testicularis (syn. orchidin, testiculín) is prepared from testes of animals by maceration with glycerine. The usual dose is 15 to 30 min., hypodermically or by mouth. Hypodermic injections in doses of 1 c.cm. twice weekly for 6 to 9 doses have good results in cases of loss of virility and general weakness. *Testogan* is a preparation of the hormones of the reproductive gland and of the glands of internal secretion. It is suggested for use in impotence in doses of one tablet three times daily after meals.

PROSTATE GLAND. There is no definite evidence that the prostate has an internal secretion. The association of neurasthenic manifestation with chronic prostatic disorders has led us to believe that probably this gland has some control over the nervous system and with this idea in view a preparation from this gland has been used in the treatment of neurosis. Dose is 1½ to 3 gr. two to three times a day.

OVARY. Like the testes, the ovaries have an internal secretion which in addition to the reproductive function, is responsible for the development of secondary sexual characteristics in the female. Marshall postulated that the ovary produces three factors:—(1) a factor governing development of the accessory organs of reproduction and of the secondary characters, (2) a factor concerned with oestrus (or menstruation in human beings), and (3) a factor controlling pregnancy. Three different hormones have been isolated from the ovary—oestrin (theelin or folliculin), corpus luteum hormone (or progestin) and interstitial hormone. *Oestrin* is mainly used as a means of curing sterility and amen-

orrhoea or as an agent to assist in inducing labour at the end of pregnancy. *Corpus luteum* may be employed in controlling the nausea of pregnancy or habitual abortion without demonstrable cause. Interstitial hormone causes a secretion of the posterior pituitary lobe.

Preparations. *Ovarian extract* is used in dysmenorrhoea, menorrhagia and for climacteric ailments. The dose is 1 to 3 gr. *Ova-mammoid compound* capsules contain 1 gr. each of ovarian extract and mammary gland extract. It is used in neurasthenia, hysteria, insomnia, amenorrhoea and dysmenorrhoea. *Theelin* is the ovarian follicular hormone issued in 1 c.cm. ampoules for intramuscular injection. It is standardised by the Doisy method and its potency is expressed in terms of rat units, being the amount of hormone necessary to induce oestrus as judged by vaginal smear. It is indicated for the relief of the subjective disturbances of the menopause, functional amenorrhoea, oligomenorrhoea, functional sterility, etc. Dose is 1 to 2 c.cm. daily or on alternate days. *Corpus luteum* is prepared from the inert substance of the ovaries and desiccated. Extracts of corpus luteum are found useful in neurasthenia in women in difficulties arising at the menopause, and in conjunction with thyroid or pituitary for incomplete development. The usual dose is 5 gr. thrice daily. *Agomension* is a preparation of early corpus luteum of the cow. It is used in doses of 1 to 3 tablets each 1/3 gr. thrice daily and is found to be of some efficacy in retarded sexual development, genital hypofunction, etc. *Sistomensine* is an extract of the hormone from older corpus luteum. It is said to regulate and stabilise menstruation and is used for menorrhagia, etc. The usual dose being 1 to 2 tablets thrice daily.

Progestin. It is the corpus luteum hormone carefully standardised by its proliferational activity in the immature rabbit uterus which has been previously treated with oestrin. It has been found to be of particular value in the treatment of habitual abortion, the rationale in such cases being to produce a type of endometrium suitable for the nidation of the fertilised ovum, and to inhibit the spontaneous activity of the uterine muscle and its response to the oxytocic principle of the pituitary gland, thus forming the quiescent uterine muscle necessary for the retention of the developing foetus. It is issued in ampoules containing two rabbit units for intramuscular injection.

PLACENTA. The chorionic epithelium of the placenta is supposed to have an action similar to that of the ovaries and during the period when the ovarian functions are in abeyance, the placenta may take up its work to some extent. The placenta is very rich in female sex hormone and its extract stimulates the development of mammary gland and uterus. The human placenta contains at least three hormones (1) the sex hormone, *oestrin* (now known as theelin); (2) an oestrogenic hormone known as *emmenin* and (3) the anterior pituitary-like substance. Of these three only oestrin is obtainable from the placenta of pig or cow.

Preparations. There are various preparations in the market made from the placental hormone which have been used in utero-ovarian hypoplasia, sterility, amenorrhœa, etc. *Œstrin* is a solution of the œstrus-producing hormone (B. D. H.). *Emmenin* has encouraging results in the treatment of dysmenorrhœa; the equivalent of 25 gm. of placenta is given daily for 17 days increased up to 75 gm. daily during the week preceeding menstruation and discontinued with the onset of the flow.

MAMMARY GLAND. The mammary glands have not been shown to possess any hormone but it has been suggested that the activity of the gland during lactation assists in the involution of the uterus. Some authorities hold that extracts from the mammary gland are capable of stopping excessive menstrual loss, while others think it inactive. Mammary gland tablets contain 2 gr. of desiccated glandular tissue from the udder of cows. These have been used in the treatment of uterine congestion, fibroid tumours and in menorrhagia in doses of 5 to 15 gr. thrice daily.

THYMUS GLAND. The thymus is a gland which is essential during the first decade of life. Basch concludes that the thymus gland is not indispensable to life, but that it exercises a transitory function during the earlier months of life when processes of growth and calcification of bone are most active. The therapeutic uses of the thymus gland are largely empirical and are based upon the idea of partial antagonism and partial synergism between the thyroid and the thymus. It has been used in various conditions, e.g., infantile marasmus and atrophy, exophthalmic goitre, rickets, but with little benefit. Its use in deficient development and defective bone formation in infants may have some value. Extracts of the thymus have been utilised by some observers in the treatment of psoriasis with successful results.

Preparations. *Thymus gland*, desiccated. One grain of this powder represents 5 gr. of fresh gland. It has been used in defective nutrition in childhood, hæmophilia, anæmia and various other conditions. The dose is 3 to 10 gr.

Liquid extract of thymus gland. Dose is $\frac{1}{4}$ to 2 dr. *Thymocrin* is a solution from the thymus of calves. Each cubic centimeter is equal to 42 gr. of the fresh tissue. It is used in psoriasis in doses of 1 c.cm. every day or on alternate days.

PINEAL GLAND. The function of this gland is not well understood. It is supposed to be concerned in the growth and development of the sex organs and of somatic growth in general. Extract of the pineal gland has been used mainly for backward children and apparent benefit sometimes follows in cases of mental deficiency with no physical stigmata of degeneracy. The desiccated gland substance is manufactured from the pineal glands of young bullocks. It is administered alone in tablets or in powder form or may be combined with other gland products. The dosage is from 1/20 to 1/10 of a gr.

DUODENAL AND GASTRIC MUCOSA. Bayliss and Starling in 1902 demonstrated the internal secretion of the duodenum and showed that an acid extract of the duodenal mucosa when injected intravenously provoked profuse pancreatic secretion. The active substance of this extract is known as secretin and is occasionally used in therapeutics as a stimulant to the pancreatic external secretion when this is deficient.

The successful use of desiccated stomach in the treatment of pernicious anæmia points to the presence of an anti-anæmic factor in the gastric mucosa. The British workers named this substance as hæmopoëtin and Americans call it addisin. Desiccated and defatted stomach substance has produced satisfactory hæmatopoietic remission. The effect on the reticulated erythrocytes and mature erythrocyte counts is generally very encouraging.

Preparations. *Liquid extract of duodenal membrane* (syn. *secretin*). Extract is prepared from duodenal membranes of pigs, the strength being 1 min. = 1 gr. of fresh mucous membrane. It is used in all forms of pancreatic insufficiency, where true organic changes have not taken place. The dose is 5 to 20 min. *Secretogen elixir* is a proprietary preparation containing pyloric prosecretion and duodenal secretin. It is generally used in faulty digestion of starch with fermentation and flatulence. The dose is 1 to 2 dr. *Desiccated stomach* or *ventriculin* is prepared from hog's stomach and is obtainable in vials containing 10 gm. The dose is 15 to 30 gm. per diem in water=approximately 300 gm. to 600 gm. fresh material. *Extomak* (Benger). The usual dose is 25 to 30 gm. daily in three portions (25 gm.=100 gm. of fresh whole stomach).

SPLEEN. No hormone has as yet been isolated from the spleen, and any treatment with splenic extract is empirical. It has been used in anæmia, tuberculosis, myxœdema, etc. Calcium metabolism is stated to be stimulated by spleen.

Preparation. *Spleen substance*, desiccated, is prepared from pig's spleen, 1 part representing 5 of fresh spleen. The dose is 5 to 10 gr. (0.3 to 0.6 gm.). *Splenex* is a liquid extract of spleen substance, 4 oz. is equivalent to 2½ lb. of raw spleen. The dose is ¼ to 1 tablespoonful daily for 3 weeks, with a week's interval between courses. *Hormonal* is said to be a solution of the peristaltic hormone prepared from cow's spleen. It is used in the treatment of constipation. It is given by intramuscular or intravenous routes in doses of 15 to 20 c. cm.

LIVER. The liver has not as yet been classed as an endocrine gland although with regard to its mode of action in the treatment of pernicious anæmia it has been suggested that the liver secretes a hormone necessary for the maturation of red cells in the bone marrow. The use of liver preparations and extracts in pernicious anæmia has been dealt with under anæmia.

EXTRACT OF MUSCLES. Within recent years this has been extensively used in the treatment of cardiac and circulatory disturbances, e.g., angina pectoris, intermittent claudication and other allied conditions.

The exact nature of the active principles is not known, but it is clinically evident and confirmed by physiological experiment that the extract acts as a powerful depressor. It is well established that in active muscle, some substances (metabolites) are present which are responsible for increased blood supply during exercise and these probably form the active principle of the muscle extract. They may contain adenosine, but physiological experiments indicate that they are not likely to be identical with it. •

The extract is given by intramuscular injection so as to make it potent by deamination in contact with the muscle tissue, the usual dose being 1 c. cm. daily. *Lacarnol*, an extract of heart muscle has been used in true angina pectoris with some benefit. *Myoston*, *cutonon*, *kallikrein*, *angioxyl*, etc., all have essentially the same action, but their precise use and limitations have not been accurately determined.

A few minor glands and organ that remain to be considered are not very important. In most cases the endocrine nature of these is doubtful and there is no evidence at present in support of the efficacy of any of these substances in the realm of organotherapy. The spleen, the kidneys, the heart, the mammary glands come under this group and their role in this branch of therapeutics is purely speculative or empirical.

ORIENTAL SORE. See leishmaniasis, page 1403.

OSTEOMALACIA. This is a chronic disease usually affecting females, characterised by decalcification of bones resulting in bending, fracture and other deformities. It is more common in women than in men and occurs usually during pregnancy or when the diet is deficient in calcium and phosphorus. Defective hygienic conditions and lack of proper nutrition are said to predispose and the disease is not exclusively limited to the poorer classes. In the tropics, the disease is commonly seen in *purdah* women who are debarred from enjoying the beneficial effects of the actinic rays of the sun. Fehling draws a relationship between the occurrence of the disease and the ovarian function and in many cases improvement followed oophorectomy. Endocrine dysfunction has also been suggested as responsible for the disease and defective suprarenal function also has been held to be a causative factor in the disease. Defective calcium metabolism is always associated with parathyroid dysfunction and this should be fully investigated in all cases. Infective causes are stated to predispose and in a few cases a severe attack of puerperal, typhoid, or scarlet fever, etc., has preceded the development of osteomalacia. Repeated pregnancies are also said to predispose. The essential pathological changes consist in the absorption of the calcium salts in the affected part of the bones leaving them fibrous and decalcified and new bone is not formed. The pelvic bones are markedly affected and are seat of deformity, though other bones such as vertebræ, ribs, etc., are also

involved. The muscles covering the bones degenerate and atrophy. The patient often complains of pain of an aching character in the pelvic region, back, chest, etc. Tenderness over the affected bones may be present, various deformities of the spine and spontaneous fractures of bones may be also met with. Fever, wasting, excessive perspiration and cardiac symptoms may also occur. Examination of urine usually reveals an excess of phosphates and calcium salts. The disease may run a course of several months and thus become chronic.

TREATMENT. Search for all septic foci in the body should be made and eradicated when detected. The general hygienic condition of the individual should be improved. An open air life and enjoyment of the beneficial effects of sunlight should be advised in these cases. The diet is most important and the selection of proper dietary is all that is required in the treatment. It should comprise foods rich in calcium, phosphorus and vitamins and these are abundantly contained in fresh milk, eggs, fish, meat and fresh vegetables particularly beans, peas, tomatoes, spinach, etc. Vitamin preparations especially containing vitamin D such as radiostoleum, ostelin, codliver oil, halibut-liver oil, etc., should be advocated. Parathyroid extract in combination with calcium therapy is of particular value in most cases. Physical therapy in the form of ultra-violet rays is beneficial in countries where natural sunlight cannot be always obtained. Aspirin, salicylates, application of heat and massage are useful for alleviation of pain and cramps. Calcium lactate has been advocated in 1 dr. doses three times daily with milk. The prolonged intake of phosphorus has given encouraging results and this may be given in solution in almond oil (1 in 1000) in daily doses of one tea-spoonful after food or phosphorous pill (1 in 100) may be given in doses of 1 or 2 gr. three times daily after food. Preparations of suprarenal gland have also given good results in some cases. If the disease progresses in spite of medicinal treatment oophorectomy is advised. Artificial abortion is justified in earlier months of pregnancy in cases of deformed pelvis with small and narrow outlet and moreover it has been found that pregnancy usually leads to a rapid development of the disease.

OXALÆMIA. It is said to result from three sources, namely, the food, intestinal fermentation and the tissues. Oxalophoric foods or foods containing considerable amount of oxalates are rhubarb, sorrel, tea, coffee and chocolate. Some hold that pure proteins and gelatine do not give rise to oxalic acid. Probably all sugar-containing foods are capable of giving rise to oxalates in the body. Intestinal fermentation, especially in the presence of tapeworms, which contain much glycogen, may also lead to the formation of oxalic acid. In the treatment of oxalæmia, foods containing oxalates are better avoided and also sugar and articles of diet which are not pure protein, such as meat, should be restricted. Fish is better tolerated in these

cases. As the liver function is generally sluggish in this condition, it should be stimulated. The alimentary canal should be freed from animal parasites, and metabolism speeded up by respiratory exercises, ultra-violet rays and oxidising remedies. Insulin appears to be the most effective drug in the treatment of oxalæmia.

PELLAGRA. See page 1029.

PLEURISY. It is not infrequently met with in the course of a large general practice, and although many cases are easily dealt with, others are liable to cause trouble and anxiety. The vast majority of cases of pleural inflammation are undoubtedly infective in origin; seldom primary, apart from tuberculosis, but generally secondary to some focal infection of the lungs (tuberculosis, pneumonia, bronchitis, abscess, gangrene, etc.). Certain cases arise (a) as a result of direct extension of disease from adjacent organs other than the lung, or from serous membranes (pericarditis and peritonitis); (b) *via* the blood stream, as a part of a general infection (septicæmia, pyæmia); (c) in the course of infections of undetermined origin (rheumatic fever, scarlet fever); (d) by the agency either of organisms or of chemical toxins in chronic disorders of metabolism (gout, diabetes, chronic nephritis); (e) by metastasis from more distant focal infections (tonsillitis, appendicitis, oral sepsis); (f) trauma (wounds, contusions, fracture of ribs); (g) from new growths of the lung; (h) as complications (bronchiectases, hydatids, etc.); (i) terminal, often in elderly subjects.

The most frequent causal agent is the tubercle bacillus. Non-tuberculous exudative pleurisy, which occurs in about 18 per cent. of all cases, is most frequently due to the pneumococcus or streptococcus. A ready clinical classification is discoverable in the nature of the effusion. Thus a dry pleurisy connotes a fibrinous exudate; a pleurisy with simple effusion is one that is sero-fibrinous and empyema is one that is definitely purulent.

TREATMENT. *Acute dry pleurisy.* The usual symptoms are pain in the chest aggravated by coughing or attempts at deep breathing with slight or moderate fever. The characteristic physical sign is a fine friction sound, audible over the area affected.

General management. Complete rest in bed, plenty of fresh air in accordance with the state of the patient; a dose of calomel is administered at the beginning followed by salts in the morning. In the earliest stage, small doses of tincture of aconite or veratrum viride, 2 min., every quarter of an hour during one hour, afterwards repeating the dose hourly, until the skin begins to act freely and the temperature abates. Such remedies should be discontinued as soon as the circulation becomes relieved.

Pain. (a) *Local applications.* Mild cases are relieved by thermogen wool used dry or rendered more potent in action by sprinkling with warm salt and water, by the employment of the official cataplas-

ma kaolin. Failing this, turpentine or belladonna stupes, or hot linseed meal poultices find some advocates. Strapping the chest, which in former days was normal routine except for cases in which pain is intense, is less to be recommended since it tends to embarrass the sound side, prevents effective auscultation, and during removal is apt to cause pain and disturbance to the patient. Dry cupping has again come into favour. For very intense pain, a good procedure is to introduce into the pleural sac a small quantity, say 200 c.cm. of filtered air which, by separating the inflamed pleural layers, acts as a cushion and gives instant and complete relief. (b) *Drugs*. At the beginning, for slight pain, Dover's powder 10 gr. is excellent; aspirin 10 gr. with or without pyramidon (5 gr.) may be given. Internally an alkaline diaphoretic and diuretic is of use, e.g., potassium citrate 20 gr., ammonium acetate solution 2 dr., syrup of lemon 1 dr.; camphor water $\frac{1}{2}$ oz. six hourly. If the pain increases and the patient becomes restless and irritable, it may be necessary to have recourse to veramon 6 gr., by mouth, repeated if necessary or to a hypodermic injection of morphine $\frac{1}{6}$ to $\frac{1}{4}$ gr.

Insomnia. If no cause is obvious, in mild cases 15 gr. each of potassium bromide and chloral hydrate will suffice; in moderate cases, allonal one to two tablets or medinal 5 to 10 gr., in the worst cases omnopon $\frac{1}{3}$ gr. orally or hypodermically.

Cough. This is usually dry, persistent and ineffective and requires the exhibition of a suitable tincture, such as glycerine 20 min., syrup of lemon 15 min., water to 1 dr., to which may be added, if necessary, heroin hydrochloride $\frac{1}{20}$ gr. or morphine hydrochloride solution 3 min. In dry chronic pleurisy resolution may be hastened by counter irritation in the form of mustard plaster or blisters, or by painting the chest wall with equal parts of liniment or tincture of iodine. Internally a mixture may be prescribed containing the following: Potassium iodide 10 gr., sodium bicarbonate 20 gr., sodium salicylate 10 gr., ammonium carbonate 3 gr., chloroform water up to $\frac{1}{2}$ oz., thrice daily.

In acute pleurisy with simple sero-fibrinous effusion, fever, cough and pain may subside after a week or so, and a slight serous exudate becomes absorbed. The process may be quickened by painting the chest with iodine, or by dry cupping. If the exudate does not exceed moderate limits, treatment is similar to that for acute dry pleurisy. A light diet with limitation of total fluids is advisable, the bowels being kept open with concentrated salines. Effusion extending above the fourth rib anteriorly, if left alone, naturally tends to take longer to absorb than those of less amount, disappearance of the fluid being accompanied by crackling or creaking friction sounds. For many months, at the base of the affected lung resonance is impaired, and breath sounds are but feebly audible. If after three weeks the fluid level stands at the same height, or is increasing, particularly above the fourth rib in front or if displacement of organs causes circulatory or respiratory

embarrassment, after determination of the nature of the fluid by an exploratory puncture, syphonage or aspiration should be undertaken, unless the fluid is hæmorrhagic. Tapping too low on the left side may damage the spleen, causing bad hæmorrhage. Needling a solid lung may cause catastrophe. In exploring the chest a local anæsthetic should always be used. The anæsthetic may be novocaine, percarine, phenolaine, or any other compound. The method of withdrawing quantities of fluid with a 20 c.cm. syringe should not be indulged in; some air is bound to enter each time the syringe is removed, this air may be troublesome or even a danger later.

Usually after the withdrawal of a small quantity of fluid or auto-serotherapy, absorption begins to take place and the patient may be left alone, but in some cases a second tapping may be necessary. There are several points in favour of leaving the fluid, firstly, antibodies may be present in the fluid, and secondly the mechanical effect. If a lung has been forcibly collapsed with a pressure of fluid, it does not expand freely at once if all the fluid is drawn off. There are those who suggest that the fluid should be drawn out and replaced by air on the assumption, firstly, that the fluid is toxic, and, secondly, that the lung should be kept collapsed. If the pleural exudate were secondary to pulmonary disease this would be justified on the analogy of the artificial pneumothorax treatment; but in most cases the lung does not appear to be diseased at the time of the effusion, pulmonary disease not appearing in most cases till some years after the effusion, during which time the patient has usually had perfect health. The assumption that air replacement is advisable in all cases would seem to be based on a false analogy. Hæmorrhagic effusions are met with in tuberculosis, influenza, neoplasm and other infected conditions of the pleura, and probably the frequency of incidence is in the reverse order to which they are mentioned. The pleura has strong antibacterial powers for dealing with infection; it is on this account that one so frequently finds that fluids which contain organisms become absorbed without going on to empyema.

PNEUMONIA. It is a disease which affects persons of all ages and stations of life. While the diagnosis as a rule affords no difficulty the prognosis and treatment call for the greatest skill and judgment. In the primary form of the disease, the infection is a self-limited one. Besides natural variation in the virulence of the infecting organism the general resistance of the patient plays an important part in the progress of the disease.

The two main types of pneumonia are: (1) Croupous or lobar pneumonia, and (2) lobular or broncho-pneumonia. Lobar pneumonia may be defined as an acute infectious disease caused by the pneumococcus of Frankel, and locally resulting in an inflammatory consolidation of a large area of the lung. The disease is now looked upon as being

primarily a form of septicaemia, the involvement of the lung being merely a local and predominating manifestation of the infection. Recent serological investigations have shown that there are four clearly defined types of infection, of which two are common, and the type 3, although the most virulent is the rarest. In type 4 the disease is said to run rather a mild course. In a typical case of pneumonia the diagnosis is not difficult, but in children, especially in apical pneumonia, the meningeal symptoms may mask the real trouble. The rapidity and type of respiration is the best guide.

Lobular, or broncho-pneumonia. The condition may be defined as an inflammation of the capillary or terminal bronchioles and the alveoli which constitute the corresponding pulmonary lobules. There are two forms of the disease, primary and secondary. In the former the pneumococcus is usually found, but in the latter the streptococcus, micrococcus catarrhalis, and Pfeiffer's bacillus are often predominant, a mixed infection indeed is usual. Broncho-pneumonia is not a self-limiting disease like lobar pneumonia and after a variable period the temperature falls by lysis.

TREATMENT. I. *General.* Fresh air, a minimum of disturbance and adequate nursing are essential. The propped up posture usually gives greater comfort. Gentle tepid sponging 2 to 4 times a day or as required. The diet should contain plenty of fluids; milk, citrated and diluted with water, imperial drink, barley water, horlick's malted milk, weak tea, etc. are given. The total milk in the day should not exceed two pints. Glucose or lactose may be added to each feed with advantage. Oral hygiene is important. The mouth should be cleaned with listerine or weak sodium bicarbonate solution. The bowels are kept regular with enema.

II. *Specific therapy* (see serum therapy, page 803). Fresh interest has recently been aroused in this subject by the use of Felton's concentrated anti-pneumococcal serum. Serum is of value only in types I and II cases which are usually responsible for from half to two-thirds or more of the total cases of primary pneumonia. It should be given in all severe cases (I and II) seen early in the diseases especially during the first 3 days. For therapeutic use the serum is supplied in phials containing 10,000 to 20,000 protein units each of types I and II in a volume of 5 or 10 c.cm. respectively. It is essential that the serum should be administered intravenously and in most cases a morning and an evening dose suffice. Dose 20,000 to 40,000 units. This serum is difficult to prepare and very expensive and uncertain in its effect. The dose required costs £10 to 20 or about Rs. 200.

III. *Symptomatic treatment.* (a) Pain. Morphine $\frac{1}{6}$ to $\frac{1}{4}$ gr. combined with atropine $\frac{1}{100}$ gr. is given during the first three days of illness to relieve pain. It should be avoided in the presence of marked cyanosis or generalised bronchitis with abundant secretion.

Other measures for the relief of pain consist of the application of anti-phlogistine or cataplasma of kaolin. (b) For cough a sedative linctus along with a hot drink and steam inhalation is helpful. In early stages a simple alkaline diaphoretic mixture—potassium acetate 20 gr., potassium citrate 30 gr., ammonium acetate 2 dr., spt. of nitrous ether 15 min. and water 1 oz. is helpful; it loosens the sputum and promotes diuresis and elimination of toxins. In later stages and when there is much bronchitis a stimulant expectorant mixture consisting of sodium bicarbonate 10 gr., ammonium carbonate 5 gr., tincture of scilla 10 min., chloroform water 1 oz. is given. (c) To produce sleep give in the early stage, omnopon 1 gr. or Dover's powder 10 gr., later chloramide and potassium bromide 20 to 30 gr. of each., paraldehyde 1 to 2 dr., medinal 6 gr. (d) Stimulants. Digitalis 10 to 15 min. of the tincture 6 hourly. The early administration of digitalis is a safeguard to the heart. The action of strychnine on the respiratory and vasomotor centres makes it a valuable drug in the stage of falling blood pressure; give subcutaneously in doses of 1/60 gr. 6 hourly alone or combined with atropine 1/100 gr. Adrenalin 0.2 c.cm., pituitrin 0.3 c.cm. may be given intramuscularly when the pulse begins to flag. Camphor in oil or cardiazol are very valuable cardiac stimulants. Dose 1 c.cm. every 4 to 6 hours. Glucose acts as a stimulant to the exhausted heart muscle in acute failure and may be given intravenously—50 c.cm. of a 20 per cent. solution with 10 units of insulin subcutaneously and repeated in 12 hours if necessary. Alcohol is given when indicated and not as a routine. Oxygen is administered with a catheter at the earliest evidence of cyanosis. Tonics are indicated during convalescence, e.g., perchloride of iron sol. 10 min., strychnine hydrochloride sol. 3 min., glycerine 30 min. and water to 1 oz. Cod liver oil may also be given.

POISONING. General directions. (1) In all cases where the poison has been taken by mouth, immediately empty out the stomach either by a stomach tube, or emetics. The stomach tube is contraindicated in poisoning with corrosives, strong alkalies and acids; it should be used cautiously in irritant poisoning. Emetics should only be used when no means of washing out the stomach are at hand; where poison has been taken immediately after or along with full meals, emetics should first be used followed by a stomach tube. Emetics are also contraindicated in corrosives, strong acids and alkalies; when much diluted they do not act promptly. (2) Do not wait for symptoms to appear even in suspected cases; act promptly and wash out the stomach at once. (3) Always keep the contents of the stomach and first washings (with plain water) for chemical examination. (4) Stomach washings should be thorough and repeated at intervals when symptoms reappear.

THE FOLLOWING INSTRUMENTS AND ANTIDOTES SHOULD ALWAYS BE KEPT READY FOR TREATMENT:—*Instruments.* Stomach tube (this should be in-

spected frequently as rubber is liable to perish and become unserviceable), mouth gag, rubber catheters, hypodermic syringe, tourniquet, scalpels, rectal tube and saline apparatus.

Emetics. Apomorphine hydrochloride 1/10 gr. tablets, zinc sulphate 30 gr. in 4 oz. warm water; copper sulphate 10 gr. in 4 oz. warm water; mustard $\frac{1}{2}$ oz. in 8 oz. of tepid water; ipecacuanha wine 6 dr.

Stimulants. Strychnine hydrochloride 1/30 gr. tablets; digitalin 1/100 gr. tablets; ether in glass ampoules; adrenalin, braudy; coffee; ammonium carbonate, sal volatile.

Opiates. Morphine hydrochloride 1/3 gr. tablets; tinct. of opium 30 min. or more.

Antidotes. Atropine sulphate 1/60 gr. tablets; pilocarpine nitrate $\frac{1}{2}$ gr. tablets; pituitrin 1 c.cm. ampoules; amyl nitrite capsules; gold chloride one per cent. solution; potassium permanganate crystals; tea; tannic acid; carbonates of sodium and magnesium; olive oil; castor oil; lime water; sulphates of sodium and magnesium; strong ammonia solution; ferrous sulphate; tincture of perchloride of iron; vinegar, citric acid; starch; sodium bicarbonate, dilute sulphuric acid and tinct. of iodine; potassium bromide; chloroform; antivenine; oxygen.

Warmth. By hot bottles or friction to the extremities.

Demulcents. Milk, white of egg, barley water, olive oil (avoid in phosphorus and cantharides cases), linseed, tea.

Saline injections. Normal saline, either by the rectum or sterilised and given intravenously or subcutaneously.

ACIDS. *Hydrochloric, nitric and sulphuric.* Do not use the stomach tube or emetics, but give alkalis, such as calcined magnesia, lime water, if not available give chalk, whiting, sodium carbonate, or potassium carbonate dissolved in plenty of water; magnesium carbonate may also be given dissolved in water or soap and water in large draughts followed by demulcents, opiates and stimulants, if required. To relieve thirst give pieces of ice or ice cream. Rectal feeding to maintain nutrition. Tracheotomy may be required to relieve dyspnoea.

Carbolic acid. Use a soft stomach tube gently and carefully and wash out successively with magnesium sulphate or sodium sulphate $\frac{1}{2}$ oz. in a pint of warm water, until there is no smell of carbolic acid in the washing. Leave some of the solution in the stomach. Follow this up by demulcents, stimulants, warmth and artificial respiration. Intravenous or rectal saline, if necessary.

Oxalic Acid. Do not use the stomach tube or emetics, give chalk, whiting or lime with plenty of water. Give milk freely and follow with a full dose of castor oil and stimulants.

Hydrocyanic acid or cyanides. Prompt action essential. Place the patient in the fresh air. Give adrenalin 4 dr. (1 in 1,000) by mouth, empty stomach and wash out with pot. permanganate solution. 15 gr. of sulphate of iron with 20 min. of tinct. ferri perchlor. in a little water adding 2 dr. of magnesium carbonate. Mix and administer and repeat

if necessary. Artificial respiration, cold douche (from a height) to head and spine. Ammonia inhalations. Strychnine hydrochloride 1/15 gr. and ether over the heart area; atropine sulphate 1/60 gr. hypodermically. If the body surface is cold, vigorous friction and hot applications. Intravenous injection of glucose or sodium thiosulphate (10 per cent. sol.) 5 c.cm.

ALKALIES. *Caustic potash, caustic soda, ammonia.* Do not use the stomach tube or emetics, but give weak acids, such as vinegar diluted in water or citric acid, tartaric acid, lime juice, $\frac{1}{2}$ dr. to one pint of water. Repeat. Followed by demulcents, opiates and stimulants.

INORGANIC POISONS. *Antimony.* Wash out the stomach, give strong tea, tannic acid 30 gr. in warm water, repeating as often as vomiting occurs. Demulcents, stimulants, opiates, warmth. Pituitary extract and saline injection if needed.

Arsenic. Wash out the stomach thoroughly. Give freshly prepared ferric oxide. (Mix one and a half ounces of tinct. ferri-perchlor. in a wine-glass of water with a solution of sodium carbonate $\frac{1}{2}$ oz. in half a tumblerful of water, strain the precipitate and administer the precipitate suspended in a glass of water). Repeat, if necessary. Demulcents. Stimulants. Opiates. Ice to suck. Warmth to extremities. Saline injections or saline per rectum. Sodium thiosulphate 5 c.cm. (10 per cent. sol.) intravenously.

Copper salts. Give large quantities of milk and eggs. Then wash out the stomach. Demulcents, opiates, and stimulants.

Iodine. Wash out the stomach with a soft tube. Sodium bicarbonate 2 dr. in half a tumbler of water. Starch, bread, rice-water, milk and flour, morphine. Stimulants.

Lead salts. Wash out the stomach. Give magnesium or sodium sulphate $\frac{1}{2}$ oz. in 8 oz. of water or dilute sulphuric acid 30 min. in 8 oz. of water. Demulcents. Morphine.

Mercury and its salts. Give large quantities of milk and eggs before attempting to wash out the stomach. Demulcents. Tincture of opium and stimulants. Repeat stomach washing and continue it. Rectal irrigation with saline, mouth wash with astringents. Alkaline normal saline intravenously, if necessary. Sodium thiosulphate 5 c.cm. (10 per cent. sol.) intravenously once every day when acute symptoms subside.

Phosphorus (red paste matches). Wash out the stomach thoroughly with potassium permanganate solution. (1 gr. to 1 oz.) and leave about 10 oz. in the stomach or give copper sulphate 2 to 3 gr. in 4 oz. of water every five minutes until vomiting is induced; then every 15 to 30 minutes and then wash out the stomach with potassium permanganate solution or weak hydrogen peroxide. Old French Turpentine 40 min. emulsified with mucilage and water every 15 minutes for the first hour, then three times daily. Magnesium sulphate $\frac{1}{2}$ oz. as a purge. Demulcents. Normal saline with sodium bi-

carbonate intravenously to combat shock and diminished alkalinity of blood. Avoid oils and fats.

Silver salts. One ounce common salt in 8 oz. of water. Then wash out and follow with white of egg and milk.

Zinc salts. Large quantities of milk and white of egg, large quantities of sodium or potassium carbonate dissolved in warm water. Tannic acid, strong tea, demulcents and opiates, if necessary.

ORGANIC POISONS. *Aconite.* Wash out stomach with dilute potassium permanganate solution. Digitalin 1/100 gr. or better 1/50 gr. Atropine sulphate and also strychnine. Maintain recumbent position. Stimulants. Artificial respiration. Friction. Warmth. Brandy diluted with water per rectum.

Alcohol. Wash out stomach. Ammonium carbonate 30 gr. in 5 oz. of water. Strong coffee, strychnine hydrochloride 1/60 gr. Keep the patient roused with cold douches. Digitalis. Warmth. Artificial respiration. If required, oxygen inhalation.

Antipyrin group (antipyrin, antifebrin, phenacetin) Wash out stomach. Recumbent position. Warmth. Stimulants. Digitalis. Strychnine hydrochloride. Artificial respiration. If necessary, oxygen inhalation.

Belladonna, atropine, datura, hyoscine. Wash out stomach with dilute potassium permanganate solution. Pilocarpine 1/3 gr., repeated every two hours until skin becomes moist. Stimulants, tea, coffee, tannin. Warmth. Artificial respiration. Catheterise, if urine retained. If delirium is great, give sedatives and ice bag to head.

Cannabis indica. Wash out stomach with dilute potassium permanganate solution. Purgatives. Brandy. Tannin.

Cantharides. Apomorphine 1/10 gr. and strychnine hydrochloride 1/60 gr.; give alkalies freely. White of eggs. Barley water, gruel. Stimulants. Morphine. Avoid oils and stomach tube.

Chloral. Wash out stomach. Strychnine hydrochloride 1/60 gr. Warmth and friction are essential. Hot coffee. Stimulants. Artificial respiration. Oxygen.

Chloroform. (By inhalation). Pull out the tongue. Swab any mucus from the back of the throat, place the head lower than the body. Artificial respiration. Atropine sulphate. Strychnine 1/60 gr. with digitalin and ether hypodermically. Brandy and coffee per rectum. Massage the heart per abdomen. Intracardiac injection of adrenalin solution. Oxygen inhalation. Wash out stomach well, stimulants for the heart and respiration as above.

Cocaine. Wash out the stomach with dilute potassium permanganate solution. Strychnine and digitalin hypodermically, adrenalin intramuscularly, ammonia or amyl nitrite to inhale. Recumbent position. Artificial respiration. Strong coffee. Bromides or morphia, if convulsions.

Croton oil, colchicum and violent purgatives. Wash out stomach with milk or olive oil. Demulcents. Stimulants. Opiates.

Digitalis. Wash out stomach with dilute potassium permanganate solution, give strong tea or coffee. Tannic acid 10 gr. in 2 oz. of water by mouth repeated frequently. Recumbent position. Warmth Stimulants. Atropine injection for slowness of heart.

Fungi. Wash out stomach with dilute potassium permanganate solution. Atropine 1/50 gr. Stimulants. Warmth. Castor oil. Opiates.

Food-poisoning. As for fungi, but avoid atropine.

Kerosine oil, paraffin, petroleum. Wash out stomach. Strychnine. Warmth. Hot coffee per rectum. Demulcent. Castor oil. Artificial respiration.

Oleander. See digitalis, page 246.

Opium. Wash out stomach with tepid water tinted with potassium permanganate ($\frac{1}{2}$ gr. to 1 oz.) until the pink colour is retained in the return washings. Leave about 10 oz. in the stomach. Every 15 min. if morphia is taken hypodermically, wash out the stomach with permanganate solution. Repeat washing after half an hour. If symptoms reappear, wash out again. Atropine sulphate 1/30 gr. repeated, if necessary. Strychnine and ether hypodermically. Keep the patient roused with cold douche, or walking to and fro between two assistants (in mild cases only). Forced walking contraindicated in collapsed or comatose cases. Ammonia or smelling salts to nostrils. Artificial respiration. Hot coffee by mouth, or per rectum. Warmth. Oxygen.

Tobacco. Wash out stomach. Recumbent position. Strychnine. Strong tea. Stimulants. Warmth. Artificial respiration.

Strychnine, nux vomica. Administer ether or chloroform until introduction of stomach tube is possible. Wash out stomach with tannic acid or potassium permanganate solution. Leave a mixture of chloral hydrate 30 gr. and potassium bromide 1 dr. in the stomach or give apomorphine hydrochlor 1/10 gr. for emesis. Chloroform inhalation or chloral hydrate per rectum to control spasms, if necessary. Absolute quiet in a dark room essential. Warmth. Artificial respiration. Oxygen.

Turpentine. Wash out stomach. Magnesium sulphate 1 oz. in water. Morphine. Demulcent drinks.

Sulphonal, trional, veronal, medinal, luminal. Wash out stomach, leaving one pint of hot coffee with an oz. of castor oil (or give emetic). Stimulants. Warmth. Recumbent position. Artificial respiration. Subcutaneous saline. Catheter, if necessary.

Gas poisoning (carbon monoxide, carbon dioxide, marsh gas, coal gas, sewer-gas). Fresh air, inhalation of oxygen, ammonia to nostrils. Stimulants. Warmth. Strychnine. Digitalin. Artificial respiration. In carbon monoxide poisoning attempts should be made to cause the patient to breathe in the expired air of the medical attendant through a tube made of stiff paper. Venesection and transfusion of blood may be tried.

POLIOMYELITIS, ACUTE. (Infantile paralysis). It is an acute specific fever characterised by lesions in the grey matter of the anterior horns of the spinal cord. Von Heine (1840) discovered that the lesion was localised in the spinal grey matter. Landsteiner and Papper (1909) indicated that the disease was due to a filterable virus and transmitted the disease to monkeys. Infection is usually acquired by the nasopharyngeal route and the virus is transmitted from patients as well as by carriers, milk and fomites. The histological features of the cord lesions are perivascular infiltration of the grey and white matter with degeneration of the ganglion cells of the anterior horn. A single attack gives permanent immunity to the individual. The incubation period is 3 to 10 days. The onset is usually sudden with headache, malaise and gastro-intestinal disturbance; the temperature rises high. This prodromal stage is usually very short. Muscular paralysis is noted about the second or third day and usually does not progress from the start, but in some cases spreads rapidly. Various types of the disease are described, of which the commonest is the spinal variety. Leg muscles are commonly affected; in some cases one arm and the other leg are affected, but all four limbs may be paralysed; reflexes are lost; a maculo-papular eruption may be seen on the affected limb. Besides this spinal type Wickman described certain other varieties, *viz.*, abortive spreading (ascending or descending), meningeal, cerebellar, cerebral, and mixed types. The cerebrospinal fluid is clear and under pressure and there is an excess of cells present; the protein is increased; the sugar and chlorides are normal, and no organisms are found. The blood examination shows leucocytosis.

TREATMENT. Absolute rest in bed is essential. Paralysed limbs should be wrapped up in cotton wool and well supported. If the serum of a convalescent patient is available it should be given early. About 30 c.cm. of blood are taken from the convalescent, the serum is separated and warmed to body temperature. Lumbar puncture is then performed on the patient, 10 to 15 c.cm. of the spinal fluid are removed and the serum is injected intrathecally. Attempts are being made to prepare a protective vaccine on the lines of the anti-rabic treatment. Hexamine is often given with alkalis by mouth, but its value is doubtful; aspirin may be given for pain and sedatives for restlessness. The muscles should not be massaged during the active stage of the disease. After a month or so gentle massage and electrical treatment may be applied.

Prophylaxis. The patient should be isolated for 3 weeks after the temperature is normal. Contacts should gargle twice a day with potassium permanganate solution (1 in 5,000).

PREGNANCY TESTS. *Aschheim-Zondek* "Pregnancy test. The test depends upon the fact that the urine of a pregnant

woman contains a substance which induces the formation of hæmorrhagic follicles in the ovary of the sexually immature female mouse.

Female mice, three to four weeks old and weighing about 6 to 10 gr. are used in the experiment. The age factor is important as the ovarian cycle in the mouse commences at about the sixth week of life. Five animals are used in each test. The urine for injection should be fresh and a morning specimen. Aschheim and Zondek recommended that each of the five mice should receive a different dose; thus the first would receive six doses of 0.5 c.cm.; the second six doses of 0.4 c.cm. and so on. It has been found that the mouse receiving the largest dose gives a weaker response than others receiving smaller doses. The injections are completed in 48 hours as follows: first day in the morning and evening; second day in the morning, mid-day and evening; third day only in the morning. *Condition of the ovary.* On the morning of the 5th day a naked eye examination of the genital apparatus of the animals is undertaken. Three types of reaction are observed in the ovary. These are called by Aschheim and Zondek as the anterior pituitary reaction (*Hypophysen Vorderlappen Reaktion*). I. This consists in the formation of large mature follicles in the ovary. II. This consists in the formation of hæmorrhagic follicles. III. This consists in the formation of *corpora lutea*. Reactions II and III separately or together indicate a positive result whereas reaction I alone implies a negative one. *Condition of the uterus.* In reaction I the uterus appears to be considerably enlarged in size and distended with fluid. The ovary is sometimes found to be full of corpora lutea with the formation of hæmorrhagic follicles and the uterus closely resembles one of an untreated animal. *Condition of the vagina.* The vagina of the animal in reaction I is found to be open. A smear is characteristic of œstrus.

Apart from pregnancy, the reaction I is obtained in certain other conditions such as after the menopause (25 per cent. of cases), castration and in cases of genital carcinoma.

Hofman's hormonal pregnancy reaction. The test differs from the original Aschheim Zondek test in that the blood serum is used instead of urine. Sometimes, a hormonal blockage in the kidney results, which gives negative pregnancy reaction, and so Hofmann tried the test with blood serum. The blood serum can be withdrawn any time during the test, whereas it is sometimes difficult to procure the morning specimen of urine. Rabbits were used as test animals because the pregnancy test can be completed in less than four days with rabbits, whose ovulation mechanism differs from that of mice. In order to eliminate certain sources of error involved in the rabbit test, such as pseudo-œstrus, infantilism, dermoid cysts, an exploratory laparotomy is performed to inspect the ovaries of the animals, immediately before the test. *The technique of the test* is as follows; 25 c.cm. of blood, which may be withdrawn from the patient at any time, is centrifugalised and the serum shaken with ether. A female rabbit weighing not less than 2,300 gm. is

laparotomized and the ovaries are inspected. Then approximately 13 c.cm. of serum is slowly injected into the marginal vein of the ear. If the animal does not tolerate it well, the injection should be interrupted and continued about an hour later. Twenty-four hours later, the ovaries are inspected and the presence of blood clots indicates pregnancy in the woman from whom the blood specimen was taken.

Biochemical test. This test is based on the facts that the prehypophyseal hormone increases the cholesterol content of the blood and that the urine of a pregnant woman contains the prehypophyseal hormone. The injection of urine of pregnant women into guinea-pigs of either sex produces within the first 24 hours an increase of cholesterol in the blood amounting to from 30 to 50 per cent. The reaction is positive at various stages of pregnancy. In a control series of experiments it was found that urine of non-pregnant women did not produce this increase of cholesterol in the blood. *The technique:* 10 c.cm. of urine obtained from the fasting patient by catheterization is mixed with 25 c.cm. of sulphuric ether. After the mixture has been shaken and decanted, 10 c.cm. of it are injected into a guinea-pig. After 24 hours, blood is withdrawn from the heart of the animal and the cholesterol content of the blood is determined. This test of hormone hypercholesterolaemia is considered positive if the blood cholesterol of the guinea-pig is increased to 25 per cent. The test has several advantages over the Aschheim-Zondek reaction. The test animal is easier to procure as it may be male or female, sexually mature or immature and of any age or weight. The technique is simple and the test can be performed in 24 hours.

Chemical test. (a) To one c. cm. of urine add one drop of a 0.5 per cent. solution of hydrogen peroxide followed by 5 drops of a 1 per cent. aqueous solution of phenyl hydrazine hydrochloride, 5 drops of a 5 per cent. aqueous solution of methyl cyanide and 5 drops of concentrated HCl. Place the mixture in a water bath for 25 minutes. A russet colour and flocculent precipitate denote a positive reaction whilst a negative reaction is indicated by a straw colour and a powdery precipitate or the complete absence of a precipitate. (b) A second method said to be more sensitive is as follows. To 1 c.cm. of urine add 1 drop of a 0.5 per cent. solution of hydrogen peroxide and allow to stand for 3 minutes. Then add 5 drops of 1 per cent. solution of phenyl hydrazine hydrochloride, followed by 5 drops of a 5 per cent. aqueous solution of potassium ferricyanide. Allow the mixture to stand at room temperature for ten minutes; next, place it in a boiling water bath for 15 minutes. Add 1 drop of concentrated HCl followed by an excess of sodium hydroxide; then titrate with dilute hydrochloric acid until the colour changes from orange through green to blue. Much less diluted HCl was required to produce the final colour in pregnancy urine than in the urine of women who were not pregnant. The reagents must be fresh.

PRURITUS. It is a subjective sensation of itching. The causes are manifold. (1) Hysterical pruritus is seen in young girls and also in older women about the menopause. Other symptoms of hysteria such as anaesthesia of the soft palate and of the cornea are also evident. (2) 'Nervodermite' is seen in the middle-aged women, and the parts affected are nape of the neck, labia, perineum and thighs. (3) In psychological cases though pruritus has long ceased, the patient is still under the impression that he or she is suffering from it. (4) Senile pruritus. (5) Cases of dermatographism. (6) Toxic pruritus of diabetes, gout, hepatic affections, Grave's disease, visceral carcinoma, malaria, nephritis, focal sepsis and also pruritus due to drugs and food is known. (7) A few external causes are: (a) Parasitic disease, e.g., pediculosis, scabies, ringworm. (b) Pruritus ani and vulvæ may be due to worms, portal congestion due to hepatic disease or local obstruction from tumours in the pelvis and from pressure of the uterus in late pregnancy, local fissures or secondary eczema.

DIAGNOSIS. (1) History. (2) Local examination of the part. (3) Regions of the body affected. (4) Laboratory examination.

TREATMENT. *General.* Investigate the cause and treat accordingly. Nerve sedatives are helpful in the nervous group of cases. Women nearing the menopause are best treated by radium which accelerates the cessation of menstruation. In toxic cases, remove the cause first. Investigate if there is intestinal stasis and if so treat by the combined fast and purge method (preferably with the salines). Eradicate septic foci in the body. If an allergic state is suspected, do a Walker's food test and correct dietetic errors. If no definite cause is ascertained try symptomatic treatment with soothing lotions and other general sedatives.

Local. Application of hot compresses followed by dusting inert powders. Soothing lotions, e.g., carbolic acid (1 to 2 per cent.), dilute hydrocyanic acid used as lotion or ointment, 1 to 3 per cent., camphor in oil, 1 to 10 per cent. menthol as ointment, 10 per cent. Bayer's cycloform ointment; 1 to 3 per cent. ichthyol may be added to the above lotions or ointment.

A useful prescription is, carbolic acid (1 in 80) 1 oz., liq. carb. detergens (1 to 6 per cent.) 15 min. Spa treatment, if available, is very beneficial in some cases. Regulation of habits should form a part of the treatment. Calcium and parathyroid are very useful in many cases and particularly in those of dermatographism. Adrenalin is also useful in such cases for temporary alleviation.

PYORRHOEA ALVEOLARIS. It is a disease characterised by a progressive inflammation and ulceration commencing at the gum margin and invading the periodontal membrane. There are various methods of treating pyorrhoea which should be used in combination with full co-operation of the patient. The methods usually employed are:

(1) Scaling of the teeth to remove all tartar especially that adherent to the roots. (2) Massage of the gums with glycerine and tannic acid is useful. The procedure is to wrap a piece of muslin round the finger and dip it in the above. The gums should be vigorously rubbed both transversely and vertically and on both surfaces. This should be done for a few minutes twice a day for about 3 weeks at least after the scaling. It may then be replaced by a solution of salt water, a teaspoonful of salt to a tumbler of water. (3) Mouth washes. Their main purpose is to flush out the mouth and to remove debris. The idea of killing bacteria with strong antiseptics is fallacious. If antiseptics are used they must be very well diluted. The following gargles are usually used; saline, potassium permanganate, hydrogen peroxide, chinisol, listerine, alum and potassium chlorate.

The patient should brush his teeth at least twice a day (morning and night) and rinse the mouth thoroughly after each meal.

GENERAL TREATMENT. (a) *Regulation of the bowels*, (b) *tonics*, (c) *sufficient fruits in diet*.

VACCINE THERAPY. It has little if any value in the treatment of pyorrhœa.

PYREXIA. (See page 202). If one cannot remove the cause of the fever, that is to say, deal with the cause radically, it is best only to try to keep the temperature within bounds. To attempt to force down a temperature too zealously may do more harm than good. The principles of treatment in any case in which fever is a prominent symptom are: (1) Removal of the cause if possible. (2) Maintenance of the patient's strength until the disease has run its course. This is mainly a question of general management and diet. The diet should be light and nourishing. In this country milk is usually the chief article of a liquid diet. Two or three pints a day should be the maximum allowance, given in 6 to 8 oz. feeds at a time. The milk may be flavoured in various ways with tea, coffee, cocoa, etc. to avoid monotony. The milk may be supplemented by broths, fruit juices and lemon drinks sweetened with sugar. Water should be given freely. If the patient is able to take solids, the range of choice in diet is much widened. Foods rich in starch and sugar are the best. These include cereal foods (bread, rice, cornflour, arrowroot, etc.) and fruits. Alcohol may be used, but most febrile patients do quite well without it. The common practice in this country is to use brandy. (3) Measures to modify the fever. (a) By lessening heat production. We have no means of materially lessening the production of heat. (b) By acting on the heat-regulating centres. The antipyretics of the coal tar group (antipyrin, aspirin, pyramidon, etc.) act in this way. But their routine use is condemned. (b) By increasing heat loss. This is the only legitimate way of reducing the temperature in cases of fever. This may be effected more actively either (i) by promoting perspiration and so

increasing the loss of heat by evaporation or (ii) by the direct removal of heat from the body by hydrotherapy.

The production of sweating by diaphoretic drugs has long been one of the main objects of treatment of acute fever. The following is often used (potassium acetate 15 gr., liq. ammonium acetate 2 dr., spirit of nitrous ether 15 min., lemon syrup 1 dr., camphor water up to 1 oz.). The direct removal of heat by hydrotherapy is very effective. This consists of an ice bag on the head, sponging, bath, wet pack and iced rectal saline.

TEMPERATURE NORMAL. Mouth 96.7° to 99°F., Rectum 97.2° to 99.5°F. (most reliable), Axilla and groin 0.4°F. below the rectal.; temperature in a stream of urine 0.3° to 0.5°F. below rectal. In the tropics temperature is about 1°F. higher than in a temperate climate. The temperature is maximum in the evening (between 5 p.m. to 8 p.m.) and minimum in the early hours of the morning. The daily temperature range in health is 1° to 1.5°F.

A temperature of 100°F. is regarded as slight fever, 102°F. as moderate fever, 104°F. as high fever and 105°F. or upwards as hyperpyrexia.

TYPES OF PYREXIA. (I) *Continued or continuous fever*. Diurnal variation often does not exceed the normal diurnal variation; seen in typhoid fever, diphtheria, influenza, rheumatic fever, pneumonia, glandular fever, plague, undulant fever, yellow fever, cerebrospinal fever, trench fever, relapsing fever, rocky mountain fever, and kala-azar. (II) *Remittent pyrexia*. Here the temperature never attains normal though the diurnal variation is greater than the average diurnal variation. (III) *Intermittent pyrexia*. Temperature sometimes is normal and sometimes raised a degree or two, generally towards the evening. Types II and III seen in malaria, latent tuberculosis, visceral syphilis, subacute septic conditions, enteric group of fevers, pernicious anaemia and trypanosomiasis.

QUINSY. See page 1473.

RABIES. See page 1004.

RADIOTHERAPY. See page 136.

RASHES DUE TO DRUGS. Erythematous rashes, generally localised masclar eruptions confined to the arms, face and trunk, sometimes widespread and resembling measles and scarlatina.

(a) Animal sera—5 to 10 days after injection; the rash appears with malaise, fever and joint pain.

*(b) The coal tar products—antipyrin, phenacetin. The synthetic salicylates produce macular rashes extensively distributed over the trunk and extremities.

(c) Quinine, copaiba, cubebs, belladonna, opium and its derivatives—blotchy macular eruption on trunk and extremities.

(d) Allonal, luminal, veronal, etc. Arsenic, bromides, iodides, phenolphthalein, chloral and turpentine, produce macular, papular or diffuse scarlatiniform rashes involving the whole body.

Acute exfoliative dermatitis—arsenic, ar-sphenamine, bismuth.

Urticarial eruptions—animal sera, arsenic, iodides, bromides, quinine, phenacetin, phenolphthalein (these may also produce eruptions of erythema multiforme type).

Vesicular eruptions—arsenic, bromides, iodides, quinine, antipyrine, and chloral.

Bullous eruptions—iodides, bromides, chloral, antipyrine, phenolphthalein, synthetic salicylates.

Pustular eruptions—iodides, bromides, chloral, antipyrine, arsenic, ar-sphenamin, synthetic salicylates, turpentine.

Acneform eruptions—iodides, bromides, chloral, turpentine.

Vegetating granulomatous conditions—arsenic, iodides, and bromides.

Ulcerative and gangrenous—iodides, bromides, arsenic, chloral and quinine.

Hæmorrhagic (patches of ecchymosis or purpuric spots)—animal sera, arsenic, ar-sphenamine, antipyrine, bromides, copaiba, ergot, iodide, quinine, synthetic salicylates.

Keratoses with pigmentary changes—arsenic.

Pigmentation of the skin—arsenic, bismuth, silver salts.

RAT-BITE FEVER (Sodoku). (See page 652). It is a relapsing type of fever caused by the *Spirillum minus*. It is conveyed to man by the bites of rats, cats and other infected animals. The bite usually heals up and nothing further happens till 2 to 6 weeks afterwards, when the site of the bite becomes inflamed and there is some local lymphangitis. The temperature rises with rigor and prostration which lasts for 3 to 6 days only. Paroxysms of fever recurring at intervals of 5 or 6 days are characteristic features. With each paroxysm, there are rash, leucocytosis and eosinophilia.

Diagnosis. (1) History of a bite. (2) Peculiar temperature chart. (3) Animal inoculation with blood or gland. (4) Spirochaetes in the peripheral blood especially by dark ground illumination. (5) Leucocytosis (about 15,000) and eosinophilia. (6) Positive agglutination reaction to the spirillum. (7) Negative Wassermann reaction.

TREATMENT. (1) A course of six injections of novarsenobillon will cure the disease in doses of 0.3 to 0.45 gm., though one or two injections may cause disappearance of the parasites from the peripheral blood. The injections should be given at the onset of a spell of fever. (2) General and symptomatic treatment is also given. (3) Canterisation of the wound soon after the bite may prevent the infection.

REFRIGERATION. Refrigeration or thermosteresis is the process of abstracting heat or of making or keeping cool; when carried to its

limit, congelation or freezing ensues. The milder degrees are produced through the action of water of varying degrees of low temperature, applied in various ways. In more intense forms of refrigeration—congelation or freezing—volatile liquids like ether, ethyl chloride, etc., or of carbon-dioxide snow or liquid air are used. Local freezing causes an occlusion of blood vessels with subsequent anæmia, necrosis and atrophy of the epithelium in proportion to the intensity of the application.

Liquid air. Dried and purified atmospheric air is liquefied by repeated compression (at a pressure up to 2,000 pounds per square inch) and a cooling device. The temperature of the liquid air is -422.5°F (-252.5°C). It is marketed in what is called 'Dewar bulb', a flask so blown that one flask is inside another with a vacuum between. Liquid air is applied by means of pledgets of absorbent cotton wrapped around wooden applicators. In very small lesions a larger surface than would otherwise be necessary must be frozen because very small pledgets would not hold enough liquid.

Carbon-dioxide snow. The carbonic acid gas is liquefied under pressure (900 pound per square inch) with a cooling device similar to that used in liquefying air. When the liquid gas is allowed to escape its temperature falls to -23.8°F . (-31°C). To make snow for freezing purposes various methods are used. Hubbard apparatus is very convenient for the purpose. The temperature of the snow is -108.4°F . (-78°C), but it can be safely handled and moulded if the fingers are protected by chamois or leather gloves.

If liquid air could always be obtained it would be prepared because of the ease of its application, the rapidity of its action and its comparative painlessness. The uncertainty of the supply and its high cost make the use of liquid air almost prohibitive. The advantages of carbon-dioxide snow are: it can be easily obtained, it can be used on small lesions as, unlike liquid air, no larger surface than is necessary need be frozen as the mass or crayon of snow may be pared down to any size.

The indication for the use of carbon-dioxide snow: (1) to produce simple inflammatory reaction; (2) to produce destruction of certain tissues by interstitial scar tissue formation; (3) to produce immediate destruction of tissues by freezing. In affections of the skin carbon-dioxide snow has a wide range of usefulness. Lupus erythematosus, nevi, angiomas, chronic localised eczema, epitheliomas especially of the rodent-ulcer type, keratosis senilis, warts, papillomas, hypertrophied scars, keloid, etc., have all been cured by freezing.

RELAPSING FEVER. (See page 651). It is a febrile disease characterised by initial fever which ends by crisis in about seven days and is followed by a similar attack in about a week. The causal organism is the *Spirochæta recurrentis*, which is found in the blood during the pyrexial periods. Fever which is conveyed by lice is called

'Louse Relapsing Fever' and the fever which is conveyed by a tick is called 'Tick Relapsing Fever.'

DIAGNOSIS. (1) Clinically, the temperature chart gives a clue to the nature of the disease when a relapse occurs. Onset is acute with headache, pains in the body and vomiting. Spleen and liver are enlarged and tender. Jaundice may be present. (2) Examination of blood for spirochaetes during pyrexia: (a) fresh blood—by dark ground illumination, (b) dry film—stained by Leishman or India ink and (c) culture. Inoculation of blood into susceptible animals such as rats, squirrels, monkeys, etc. Spirochaetes appear in the blood of the mouse in about twenty-two days and persist for about two days. (3) The leucocytes are increased during the fever especially the large mononuclears. (4) Agglutination test is often positive. (5) Spirochaetes are often found in the urine.

TREATMENT. (1) Rest in bed. (2) An initial purgative (a dose of salts). (3) Novarsenobillon (0.4 gm.) intravenously when the temperature is rising. One injection is usually sufficient to prevent relapses but is advisable to give a course of 6 injections. If the injection is contra-indicated, stovarsol is given instead by mouth. Six tablets (4 gr. each) are given daily for two days.

RESPIRATION. The number of respirations in the resting adult is commonly about 17 or 18 per minute. This is influenced by various conditions of the body and also by age. A new-born child breathes about 14 times a minute, a child of five about 26 times, a man of twenty-five about 16, and of fifty about 18. The frequency is increased by any muscular effort even that of standing.

When breathing quickly, a man takes in and gives out at each breath about 500 c.cm. of air measured dry and at 0°C (*tidal air*). By means of a forcible inspiratory effort about 1500 c.cm. of air can be taken in (*complemental air*). At the end of a normal expiration a forcible contraction of the respiratory muscle will drive out about 1500 c.cm. more (*supplemental air*). *Vital capacity* is the sum of these three amounts and, is, on an average, about 3500 c.cm., i.e., it is the maximum amount of air that can be inspired after a powerful expiration. The *residual air* is the air which remains in the lungs after maximal expiration. It amounts to about 1,000 to 1,500 c.cm. *Alveolar air* does not refer to the air which is present in the anatomical alveoli, but is used to describe the air in the depths of the lungs, which is more or less in contact with the respiratory epithelium and can thus carry out gaseous interchanges with the blood. It is a physiological entity and consists of the supplemental air, and the residual air and amounts to about 3,000 c.cm. The *dead-space air* is found in the air passages, nasopharynx, trachea and bronchi. It does not carry out any interchange with the blood, and amounts to about 150 c.cm. The volume of the physiological dead space is not

constant but varies with the alterations in the state of the bronchial musculature and is increased in exercise.

Intrathoracic pressure. The pressure in the pleural cavity is sub-atmospheric and is 5 mm. Hg. during expiration, 10 mm. Hg. during inspiration. The pressure in the lungs is about 1 atmosphere as they are in free communication with the outside air. The negative pressure in the thorax is diminished by any factor decreasing the elasticity of the lung tissue. Thus, in an old man, where the elastic tissue is degenerated, the alveoli are enlarged, giving rise to a condition known as *emphysema*.

Chemistry of respiration. As a result of the oxidation processes associated with life and activity the tissues of a man of 70 kilo. body weight consume on an average during working hours about 400 c.cm. oxygen per minute. The tissues produce a large amount of carbon-dioxide. The oxygen required by the tissues is taken from the blood and the CO₂ formed is, in return, passed out in the blood. Hence the venous blood contains more CO₂. In the passage through the lungs the blood is arterialised, oxygen passing into it and CO₂ out, owing to an exchange with the air in the alveoli. The composition of the inspired and expired air compares as follows :

	Inspired air	Expired air
Oxygen	20.05 vol. per cent.	16.4 vol. per cent.
Nitrogen (including argon)	79.01 „ „	79.5 „ „
Carbon-dioxide ...	0.04 „ „	4.1 „ „

Under normal circumstances, inspired air contains a variable amount of aqueous vapour and has a variable temperature. Expired air is nearly saturated with aqueous vapour and in the trachea has approximately the temperature of the body, 37°C. The tension of aqueous vapour amounts to 47 mm. Hg. The oxygen tension of the alveolar air is 100 mm. Hg. and of CO₂, 40 mm. Hg.

By *respiratory quotient* is meant the ratio of CO₂ evolved to O₂ absorbed, and its absolute amount depends on the nature of food-stuffs or constituents of the body which are undergoing oxidation. If these were entirely carbohydrate the *respiratory quotient* (R.Q.) would be 1. If fat alone were being utilised it would be 0.71, with protein alone 0.81. In man on a mixed diet, the R.Q. at rest is somewhere about 0.85. The R.Q. is affected when the pulmonary ventilation is altered either voluntarily or secondarily to a rise of body temperature or fluctuation of the H-ion concentration of blood. (1) *Voluntary hyperpnoea* washes out excessive CO₂ and R.Q. may rise above one. (2) in *acidæmia*, there is hyperpnoea, and the R.Q. rises. The same applies to the rise of body

temperature. (3) In *alkalæmia*, the breathing is depressed, CO_2 is retained in the body and R. Q. falls. (4) During violent exercise, lactic acid enters the blood stream and breaks up the plasma NaHCO_3 and liberates large additional volumes of CO_2 ; the R. Q. then exceeds 2.

ARTIFICIAL RESPIRATION. Under various conditions the respiratory movements may stop and it may then be necessary to cause air to enter the lungs by some artificial means. The most controllable method by which air may be forced in and drawn out of the lungs at suitable intervals, is by means of air pumps, but when these cannot be used, quite efficient ventilation can be maintained by simpler means. The best method in man, is that described by Sharpey-Schafer. The subject is placed in the prone position, with the head slightly to one side, the mouth is cleared and the tongue pulled well forward. The operator, kneeling either at the side, or astride, places the palms of his hands flat on the subject's trunk just over or below the lowest ribs and then by leaning forward presses gently forwards and upwards for about two seconds. He then leans back a little to release the pressure for two seconds and repeats. In this way air is forced in and out and it is possible to maintain normal ventilation in an unconscious subject for long periods without undue fatigue on the part of the operator.

With patients under an anæsthetic for surgical operation and lying in the supine position, quite good results can be obtained by applying intermittent pressure on the epigastrium, by which means also the diaphragm is made to ascend. It cannot be too strongly insisted that pressure on the upper ribs is almost useless. In both of these methods, where possible, the subject is made to inhale a mixture of oxygen and 7 per cent. carbon-dioxide for the stimulation of the respiratory centre.

RESPIRATORY EFFICIENCY TESTS. The tests are difficult and complicated owing to close relationship of the cardiovascular and respiratory systems. These are of value in determining whether apparently healthy children or adults are up to the normal standard, whether young adults are fit for occupations involving a special strain on the respiratory organs such as flying, the strenuous exercises of athletes, etc. These tests also reveal diseases of the lungs and ascertain the degree of pulmonary damage in doubtful cases. The tests also determine whether persons are fit to stand operations on the chest or elsewhere in the body. *The vital capacity test.* This measures the maximum volume of air which is breathed out after a full inspiration. Thackrah examined the capacity of the lungs by using a large graduated glass jar, inverted over and filled with water. The person tested blew through a tube, the lower end of which was immersed in water under the jar. The largest vital capacity measured was 6,150 c.cm., the average for healthy men ranged from 3,600 to 6,000 c.cm. and for females about 2,160 c.cm. Hutchinsonson, using his spirometer, showed that the vital capacity is closely related to the standing height and modified by weight and age. A relationship also has been brought out between vital capacity and the surface area of the body, the

average for healthy males being 2,660 c.cm. per square metre of body surface. It is considered that the vital capacity of a person less than 90 per cent. of the normal is pathological. The statistics for vital capacity in normal healthy athletes give an average figure of 4,856 c.cm., the maximum and minimum being 5,750 and 4,000 c.cm. respectively. Flack gives a figure of 4,000 c.cm. as the average capacity for a fit flying officer. The vital capacity is lowered in diseases of the lungs and pleura and when the readings are normal, pathological changes in the lungs are usually not suspected. The degree of diminution of the vital capacity in pulmonary tuberculosis depends upon the activity of the disease rather than upon the extent of the lesion. Hutchison found that the vital capacity in the early stage of pulmonary tuberculosis is on an average 78 per cent. of the normal and in advanced stages about 38 per cent. and extensive pleural adhesions were not found to lower the vital capacity. The vital capacity is lowered in pleural effusion, lung abscess (16 per cent.), bronchiectasis (36 per cent.), asthma (34 per cent.), carcinoma of lung (50 per cent.), chronic bronchitis (32 per cent.), pneumothorax and cardiac enlargement (41 per cent.). *The manometer test.* Hutchison measured both the expiratory and inspiratory force of breathing by this test. The manometer is attached to the nose of the individual breathing in and out of the apparatus and displacing a column of mercury. The test is usually performed with the person tested sitting with the nose clipped and the height of the mercury column blown is noted. The abdominal muscles take part in the test. The average inspiratory pressure was found to be 51 mm. and the expiratory to be 63 mm. of mercury. Flack gives the average expiratory figure for a fit flying officer as 110 mm. Hg. The average figure of athletes is found to be 78 mm. Hg. The test does not afford any clue as to the presence of diseases such as bronchitis, emphysema or artificial pneumothorax. *The endurance or "Fatigue test."* Flack devised this test where the person tested blows up a column of mercury to a height of 40 mm. and sustains it there with the breath held as long as possible. The pulse rate is recorded every 5 seconds during the test. The test determines the efficiency of the expiratory muscles and the pulmonary circulation. Flack found that in a fit flying officer the column is sustained for 52 to 60 seconds and the pulse rate varies very little during the test. The average sustention time was found to be only 33 seconds. The figure however varies with individual cases. In respiratory diseases such as pulmonary tuberculosis, bronchitis, emphysema, bronchiectasis, asthma and pneumothorax the sustention time is lower than the normal figures. Strictly speaking the test is not of particular value as a respiratory efficiency test. *Bronchial spirometry* has been unsuccessful because of its technical difficulties. Bluhm in measuring respiratory efficiency has considered both basal metabolic rate and blood circulation through the lungs; the latter is only affected when there is gross destruction of pulmonary tissue and not by pneumothorax or

thoracoplasty. The working test for pulmonary efficiency depends on the comparison of oxygen consumption after the performance of a standard amount of work. The subject of the experiment ascends flights of steps placed in a circle for 20 rounds, the rate of walking being fixed by a metronome at 88 steps a minute. The relative oxygen debt (Hill) is equivalent to the increase per minute in oxygen consumption following the period of work. Normal persons sometimes show little or no increase, but most results lie between 10 and 25 per cent. The test cannot be used for people who are confined to bed.

RHEUMATISM, ACUTE. It is an acute specific disease characterised by fever, pain in the joints and a special tendency to cardiac damage. It is one of the dreaded diseases specially of temperate climates and is rare in the tropics. The occurrence of the disease in the tropics is disputed though juvenile types have been reported in India. The disease has been found to exist in all its forms, namely, articular, cardiac and choreic. The articular form of the disease is mostly subacute in nature. The essential cause of the disease is obscure though it is an old-recognised one and has been described by Sydenham as far back as the seventeenth century. It was not until the year 1816 that the modern conception of the pathology of acute rheumatism was brought to light. Later on it was recognised that rheumatism was essentially a disease of childhood and girls are slightly more susceptible than boys. There is a well marked family incidence, but the most important known factor is environment, as acute rheumatism is a disease of the relatively poor, cold and damp were the first suggested causal factors. Chemical abnormality such as the accumulation of an excess of lactic acid or uric acid in the system has been suggested. The bacteriology of the disease started with Mantle's discovery of a diplococcus in the blood of a rheumatic child and later on Poynton and Payne after a series of most careful and consistent investigations discovered a diplococcus which was suggested to be the causal organism. It has been suggested that the lesions of rheumatism are not due to any specific organism and are not the result of a toxæmia but are really allergic manifestations due to a peculiar tissue reactions in certain individuals. The latest view is that of Schlesinger, Singy and Amis who believe that they have recovered a virus from cases of rheumatism in children.

The onset of the disease is abrupt and acute with a sense of chill and later on a rise of temperature. The temperature is usually remittent or intermittent in nature. Sweating is generally profuse and has a characteristic acid smell. The urine is scanty, high coloured and presents a trace of albumin on examination. Vague pains are complained of in the muscles and joints and are made worse by exercise and wet weather, and are usually relieved by warmth and sunshine. Of the joints affected, the knees and ankles are the commonest. The affected joints are swollen and red and synovial effusions may appear specially

in the large ones. The first definite sign of rheumatism in a child is cardiac involvement with a quickened pulse. The heart sounds change in character; the first sound at the apex becomes soft, blurred and accompanied by a systolic murmur and the second sound at the base may be intensified. As the heart adapts itself to myocardial damage enlargement of the organ of a permanent nature may appear. The blood shows considerable leucocytosis, sore throat is a constant accompaniment of the disease. A type of secondary anaemia is also seen among the victims.

TREATMENT. Three great essentials are recognised in the treatment. Absolute rest in bed should be enjoined from the onset of the disease to avoid excessive cardiac damage later on. The patient should on no account try to make any unnecessary effort or movement. In case of severe carditis the rest should be prolonged to months and the return to activity should be carefully graduated. The diet should be liquid during the acute stage of the disease and should include milk diluted with water, barley water, fruit juice, etc. The Imperial drink is very useful during the course of the disease. Intake of fluid should be free to compensate the loss of water from the body by sweat and to facilitate the excretion of the toxin from the system. A thorough search should be made for the detection of septic foci of infection in the body and when detected should be eradicated. At the same time the general condition of the patient should be improved. Of the reputed drugs, salicylic preparations deserve the name of specific remedies. The drugs cut short the course of the disease, cause the temperature to come down, lessen the inflammatory reaction of the joints. They also lessen the tendency to recurrences and sometimes cause the disease to abort at an earlier stage. The preparation most commonly used is the salicylate of soda. It should be given in sufficient quantities and should be evenly distributed in 24 hours. To a child of 10 years about 10 gr. of sodium salicylate can be safely administered every hour without any untoward symptoms intervening. During the regime, the child should be at complete rest, have a considerable amount of fluid to drink, a regular action of the bowels and be given twice as much of the bicarbonate as of the salicylate of sodium to prevent acidosis. About 180 gr. of sodium salicylate may be safely given to an adult patient in 24 hours. The quantity of the drug should be gradually cut down when the pain of the joints diminishes and the temperature comes down. There is an additional value in this method of treatment from the point of view of diagnosis, for if a patient suffering from acute arthritis with fever does not improve after 48 hours' treatment with full doses of salicylates, the case is certainly not one of rheumatic fever. Salicin is considered to be less depressing and is sometimes recommended for children. The old alkaline treatment has been incorporated with the salicylate treatment. In the earlier stages of the disease to relieve severe pain and induce sleep, nothing is better than the opium preparations. Antipyrine and

phenacetin should be avoided in children. Cases accompanied by hyperpyrexia may be treated by prompt application of a cold pack. During the active stage of the disease small blisters may be applied to the precordium and later on, iodide of sodium may be given internally. The administration of digitalis in cardiac cases is often attended with poor results. Strychnine, adrenalin and pituitary may be given if the blood pressure is very low. Recently blood transfusion has been advocated.

Bee venom has been found to be efficacious in the treatment of chronic rheumatism. It can be used in the form of an ointment for local application. Salicylic ointment is at first applied to the skin to render it more absorbent and then the ointment containing venom is used. The ointment is applied for 8 days, stopped for 4 days and continued for a longer period if necessary.

During the acute stage of the disease, the local treatment of acutely inflamed joints should comprise the use of splints for fixing the joints to ensure absolute rest and later on when the inflammation abates, careful massage attended with gentle passive movements should be encouraged. The use of the time-honoured oil of winter-green for massage of these joints should be resorted to. Convalescence is generally slow. A change of climate, rest, nourishing diet and tonics should be recommended for a speedy recovery.

SANDFLY FEVER. See page 989.

SCHISTOSOMIASIS. See page 332.

SCIATICA. See page 1414.

SEA-SICKNESS. The ætiology of sea-sickness is uncertain and complex. Various factors have been brought forward to explain its causation. The derangement of the labyrinthine function is considered to be the primary cause of sea-sickness. The symptoms associated with it are either secondary or accessory to the vestibular disturbances. Ketosis is a contributory factor; it sets in prior to the onset of vomiting and is relieved by combined glucose and alkali treatment. This predominating ketosis is also seen in subjects who have starved or undergone salicylate treatment prior to sailing. The sympathetico-tonic subjects suffer most from this condition; gastric stasis and pyloric spasm in them are both due to sympathetic over-action. Poor ventilation and high humidity also act adversely by increasing both the lassitude and headache so common in sea-sickness. Movements of the abdominal viscera like the derangement of the stomach with sinking sensation, nausea and vomiting and the changes of pressure affecting the liver by causing alternate congestion and anæmia are held to be probable causal factors in sea-sickness. The movement of the ship reinforces visceral reflexes and hence the use of an abdominal binder restricting movements of the viscera is advised. The unusual susceptibility of passengers to

the odour of the galley or of burnt engine oil on board-ship is one of the psychical factors responsible for the disease. External visual reflexes are also held to be potent factors.

TREATMENT. The pre-embarkation treatment should be started two to three days before sailing. It consists in administering cholagogue cathartics such as blue pill (4 gr.) overnight to be followed by a saline in the morning; diet should be plain and simple and alcoholic drinks are not to be indulged in to excess. Alkaline drinks with glucose should be freely taken to avoid ketosis. Susceptible passengers should take part in deck games, dancing and other forms of exercise having a general hygienic value. These modify the primary and secondary reactions in the disease. Here the object is to counteract the action of the vestibule by engaging other parts of the body in voluntary action. The prone position of susceptible persons in fresh air on the deck and well wrapped up against cold is generally beneficial. A tight abdominal binder or a bath towel kept in position by safety pins adds to physical treatment. Closure of eyes, wearing coloured glasses or bandaging one eye may be all helpful factors in the treatment of the disease.

Diet. Sometimes the thought, sight or suggestion of food is repellent to the patient. In such cases it is better to allow the patient to take any sort of food he likes and never to force him to eat. Alkaline drinks with addition of glucose are very beneficial in these cases, particularly in those where a tendency to vomit supervenes. Free fluid intake should always be encouraged.

Drugs. Of the sedatives, chlorotone, chloralamide, barbiturates and the bromides deserve mention, but the possible abuse of them should always be borne in mind and hence they should be only used in cases of necessity. Vertigo is a common and troublesome symptom is sea-sickness; luminal ($\frac{1}{2}$ gr.) is used as a vestibular sedative and may be given twice a day before embarking and should be continued for the first few days of the voyage. With the onset of symptoms, the drug is given hourly for four hours and the daily dose may then be increased to two or three grains for several days. The susceptible subjects are generally of the vagal type with a tendency to collapse and in these cases oxygen inhalation with vaporized ephedrine or adrenalin is very beneficial. Hypodermic injections of strychnine sulphate 1/32 gr. and atropine sulphate 1/100 gr. are also helpful in them.

SEROUS FLUIDS. Technique of exploratory punctures. (1) *Paracentesis thoracis.* The dull area, on percussion, is generally selected as the site for puncture. In extensive pleural effusions, the best site for puncture is in the mid-axillary line in the sixth interspace or in the eighth interspace in the posterior axillary line. The skin should be thoroughly sterilised with absolute alcohol or tincture of iodine. A local anæsthetic like 2 per cent. novocaine is injected and the skin along the

lower border of the upper rib is incised with a scalpel. Less than 1 inch of the needle of a sterilised 20 c.cm. syringe or a trocar (size 12 to 15) is pushed into the pleural cavity and care should be taken not to irritate the substance of the lung. With the same technique, the trocar from a Potaine's aspirator may be used for the purpose. Aspiration should be slow and it should be stopped if the patient gets a severe paroxysm of cough, pain or oppression in the chest, a feeling of faintness or expectorates blood-streaked sputum. After withdrawing the cannula or the needle of the syringe, a silkworm gut suture may be required if the skin wound is large or if it is a punctured wound it may be sealed with sterile cotton and collodion or tincture benzoin compound. The aspirated fluid, collected in a clean sterile and dry flask, may be sent for cultural examination.

2. *Puncture of the pericardium.* In cases of pericardial effusion, the fluid collects chiefly at the posterior and lower part of the cavity. The usual spot for puncture is the fifth intercostal space just outside the nipple line. This is usually $\frac{1}{2}$ to 1 inch inside the lateral border of relative dullness and no apex beat should be palpated at this point. With the same aseptic precautions as for draining the pleural cavity, the trocar is slowly pushed in, tilting it upward and medially towards the apex of the heart. In cases of marked effusion, as much as 200 to 500 c.cm. of pericardial fluid have been removed. The procedure is said not to be attended with much danger but drugs such as strychnine, atropine, adrenalin, etc., should be at hand for emergency use.

3. *Paracentesis abdominis.* The best site for puncture of the abdominal wall for withdrawal of ascitic fluid is midway between the umbilicus and the pubes. The bladder should, in all cases, be empty and the patient should be in a sitting posture. Aseptic precautions and other procedures are the same as in thoracentesis. The fluid should slowly drain through the cannula and the patient should have a tight abdominal binder around the abdomen as soon as the fluid leaves the abdominal cavity. The danger of the operation lies in injuring a coil of intestine, which is very rare.

Examination of the aspirated fluid. Non-purulent fluid. (1) Specific gravity can be determined by the urinometer. (2) Sero-mucin test of Rivalta. One drop of glacial acetic acid is added to 100 c.cm. of distilled water and 1 or 2 drops of the puncture fluid is poured into it. If the fluid is an exudate, a bluish-white cloud appears and if a transudate, no such cloud appears. A positive Rivalta reaction is seen in pneumothorax. (3) *Cytodiagnosis.* Citrated or oxalated fluids are preferred to clotted specimens. The fluid is centrifugalised for about 10 minutes and a drop of the sediment is uniformly spread in a thin layer over a clean and dry glass slide. Methylene blue or Wright's stain is used to stain the smear. A differential count of lymphocytes, endothelial cells and polymorphonuclears, may be made as in a blood film. Tuberculous effusions are usually non-purulent with lymphocytes

predominating. The bacilli are never detected by ordinary microscopic examination of the smear. Culture, in Corper's crystal violet potato medium, of the sediment of a centrifuged specimen, in a suspected case, gives a satisfactory growth of the tubercle bacilli in two weeks to two months. Biological test consists in injecting the sediment into the groin of two guinea pigs. Guinea pigs develop tuberculosis in one to three months.

Characters of the aspirated fluids. (1) Clear serous transudate is light yellow or greenish in colour with specific gravity below 1015 and albumin content under 3 per cent. The Rivalta reaction is negative and the stained smear of sediment shows few cells, mostly endothelial and no bacteria. (2) Serofibrinous exudate is yellow in colour and cloudy due to the presence of fibrin with specific gravity above 1018. The Rivalta reaction is positive with albumin content over 3 per cent. Microscopical and cultural examinations of the smear and centrifuged sediment are of importance in these cases. Infection with tubercle bacilli is highly suggestive where lymphocytes predominate and here cultural examination and animal inoculation of the centrifuged sediment are of immense value. The presence of an overwhelming number of polymorphonuclears strongly suggests an early pyogenic infection. A cultural examination should be undertaken to demonstrate influenza bacilli, streptococci, pneumococci, etc. (3) Purulent fluid. Here a Gram-stained smear shows pus cells, pneumococci, streptococci and staphylococci. If a direct smear shows no bacteria, culture for tubercle bacilli.

Rarer fluids. (1) *Syphilitic fluids.* Smears show equal numbers of lymphocytes and endothelial cells. The Wassermann reaction is positive on both the fluid and blood. (2) *Fluids in hydatid disease.* The fluid is clear with proteins less than 1 per cent. and specific gravity below 1010. Microscopic demonstration of the typical curved hooklets in the centrifuged sediment confirms the diagnosis. (3) *Chylous fluids.* The true form is due to erosion of lymphatic channels by filarial parasites, malignant growths, tubercle bacilli and Hodgkin's disease. The fluid has a smell of fatty foods. The pseudochylous fluid is thought to originate from an albuminous degeneration of the endothelium, the exact mode of production being unknown and is met with in chronic nephritis, tuberculosis and malignant growths. It is pure white in colour and has no characteristic smell. (4) *Hæmorrhagic fluid* is of rare occurrence and is met with in cases of thoracic aneurisms, pulmonary tuberculosis, hæmorrhagic diseases and trauma.

SYNOVIAL FLUID. Normal characters. It contains about 50 white cells per c.cm. with a differential count of polymorphonuclears + 5 per cent., monocytes + 58 per cent., macrophages + 30 per cent. and endothelial cells + 8 per cent. A few red cells are found in the fluid in recent traumatic cases and the icterus index is over 6.

Collection of fluid for examination. The skin of the most dependent part of the fluctuating swelling should be thoroughly swabbed with tincture of iodine to make it aseptic. A sterilised 20 c.cm. record syringe is used to withdraw the fluid. A local anæsthetic like ethyl chloride or 1 to 2 per cent. novocaine may be used before the puncture is made. The fluid is examined for: the leucocyte count, an icterus index estimation, Wassermann reaction, estimation of sugar content, pH estimation and cultural examination. Direct smears do not show tubercle bacilli or gonococci even if the infection is acute.

SNAKE-BITE. See page 1079.

SORE-THROAT. *Diphtheritic cases.* The diagnostic features are: The knee-jerks are liable to disappear and albumin is often present in the urine, these are very early manifestations of the disease. The character of the patch should always be observed. Frequent throat swabs are to be taken for bacteriological examinations. The sub-maxillary glands are often enlarged on the affected side only while in non-diphtheritic cases they are bilaterally enlarged.

In diphtheritic cases give the patient a mixture containing biniodide of mercury. The following is a convenient way of prescribing it: Perchloride of mercury 1 gr., potassium iodide 30 gr., glycerine 2 dr. and water to 8 oz. Each ounce of the mixture contains less than 1/8 gr. of perchloride of mercury and a tablespoonful is a perfectly safe dose for an adult. The glycerine is added to make the mixture adhere to some extent to the fauces and thus secures a local as well as a constitutional effect. The biniodide of mercury is also a very powerful bactericide and is especially inimical to the Klebs-Loeffler bacillus. For detailed treatment see pages 799 and 1343.

Acute tonsillitis. The common recognised types are acute catarrhal, lacunar, and parenchymatous. It may be a primary infection or secondary to nasopharyngeal infections. The causal organism is generally a hæmolytic streptococcus.

TREATMENT. Swab both the tonsils all over with tincture of iodine (not Mandle's pigment). Spray the throat with hydrogen peroxide in warm water (1 in 4) or a warm alkaline spray or douche with a Higginson's syringe, a solution containing carbolic acid 1 gr., sodium bicarbonate 5 gr., and water to 1 oz. Internally, sodium salicylate or aspirin 5 gr. each, may be given every four hours or a powder containing salol 5 gr., phenacetin 3 gr. may be given every two hours. Small doses of aconite often bring the temperature down. A useful prescription is tincture of aconite 1 min., antipyrin 1 gr., caffeine citrate 5 gr., and water to 1 oz., one dose to be taken every hour till six have been taken.

PERITONSILLAR ABSCESS (Quinsy). Strictly speaking, this is a suppuration of the tissue of the soft palate outside the capsule of the tonsil, but many of them are actually intratonsillar ones. The palate is

congested and bulged; there is also pain, with dysphagia and high temperature.

Treatment. It is surgical and indicates evacuation of the pus contained in the abscess.

VINCENT'S ANGINA. This is an infection of the tonsils by the fusiform bacillus and a spirillum; deep ulceration of the tonsils is a marked feature. There is sore throat on one or the other side, the temperature is not high and the mouth has a characteristic unpleasant foetor. For diagnosis a bacteriological examination of a throat swab is necessary.

Treatment. Gargles and throat sprays containing hydrogen peroxide in warm water to which a teaspoonful or two of glycothymoline is added are very useful. Local application with a swab of fresh salvarsan or neosalvarsan powders applied 2 to 3 times a day to the ulcerated parts is most beneficial. Application of equal parts of ipecacuanha and Fowler's solution is also useful. Local applications of perborate of soda, methylene blue, and trichlor-acetic acid are also used. For obstinate cases, intravenous injections of neosalvarsan are indicated.

Other causes of sore throat are: acute septic pharyngitis, hospital sore throat, Ludwig's angina, herpes of the pharynx (rare) and pemphigus. These are treated on the lines indicated above.

SPRUE. See page 879.

SPUTUM. *Collection of the specimen.* As secretions of the naso-pharynx and mouth are likely to contaminate the sample, it is desirable as a preliminary measure to cleanse the mouth with some antiseptic lotion. It should be coughed up into a sterile wide-mouthed bottle and submitted for ordinary microscopical and cultural examinations. The sample should be examined within two hours of such collection. In case of a child, washings from the fasting stomach may be examined for tubercle bacilli or the child may be induced to cough by tickling the throat and the particle of phlegm may be swabbed off from the posterior pharyngeal wall.

GENERAL CHARACTERS. (1) *Amount.* In measuring the twenty-four hours' sample, the quantity of supernatant saliva and other secretions should be deducted, leaving behind the purulent material only. From 4 to 20 oz. of sputum are expectorated in case of bronchiectasis, discharging abscess and pulmonary tuberculosis with cavity formation. As the lesion in the lungs heals up, the amount of sputum brought out also decreases but the latter gives no idea of the extent of pulmonary disease. (2) *Odour.* Ordinarily sputum is odourless. It has a very foul offensive smell in cases of lung abscess, bronchiectasis, tuberculous cavities and particularly in gangrene of the lungs. (3) *Types.* (a) Mucoid sputum is transparent and glairy and is met with in most acute pulmonary infections and after attacks of bronchial asthma. (b) Mucopurulent sputum consists of masses of opaque pus of varying colour, floating in mucus. The purulent material is increased and

marked in bronchiectasis, pulmonary abscess and tuberculous cavities. Pus and mucus are intimately mixed in cases of pulmonary abscess. (c) Distinct purulent sputum is found at the height of acute infections of the respiratory passages and particularly in bronchiectasis cases. If expectoration of homogenous material is sudden and acute, it is a case of ruptured abscess of the lung or empyema. (4) *Layer formation* of sputum is characteristic in bronchiectasis, lung abscess and gangrene. The topmost layer is one of frothy pus, the intermediate is of watery mucus and the lowest layer consists of pus. (5) *Blood-stained sputum*. Expectoration of blood-stained sputum, though highly suggestive of a grave pulmonary lesion, should never be confirmed unless the surrounding regions such as the mouth including the gums, nasopharynx, etc., are thoroughly investigated. The prognosis is usually grave if the amount of blood brought out exceeds one drachm. In hæmoptysis, the blood is bright red and frothy and the sputum is tinged with blood for days together even after the cessation of hæmoptysis. Microscopical demonstration of tubercle bacilli or a large number of spirilla in sputum confirms the diagnosis. Moreover, the sputum will also contain pus in cases of bronchiectasis, lung abscess, gangrene, etc. A radiogram of the chest in these cases also helps the diagnosis considerably. In old people carcinoma of the lungs should be borne in mind.

MICROSCOPIC EXAMINATION OF SPUTUM. The examination of an unstained film under the low power lens of a microscope is important as it gives much valuable information. The film should be moderately thick. A drop of strong caustic soda will liquefy purulent material of the sputum and will facilitate the demonstration of elastic fibres, ray fungus, blastomycetes, heart-failure cells, dust cells, Curschmann's spirals or Charcot-Leyden crystals. The presence of *elastic fibres* has prognostic importance. These indicate damage of pulmonary tissues and are abundantly found in progressive pulmonary tuberculosis, ulcerating bronchiectasis, abscess and gangrene. The sputum is boiled with an equal volume of 10 per cent. sodium hydroxide, centrifugalised and the sediment is submitted for microscopical examination. *Fungi* such as streptothrix, leptothrix, the actinomyces, are sometimes accidentally found in the sputum of patients suspected clinically to be suffering from pulmonary tuberculosis. The symptoms of such patients clinically resemble those of tuberculosis but the sputum shows no tubercle bacilli. The *heart failure cells* are phagocytic histiocytes from the alveolar walls of the lung. They are large cells with the nucleus situated eccentrically and containing yellow granules. The sputum in these cases is brown due to the presence of pigments, hæmatoidin and hæmosiderin. They are abundant in pathological cases only, such as, mitral stenosis and pulmonary infarcts. The *dust cells* are found in the brownish-black sputum of people living in the dusty atmosphere of big cities. These look like heart-failure cells and the pigment is due to carbon particles. The *Curschmann's spirals* are dense fibres of mucus which appear in

the sputum only after asthmatic attacks, though eosinophilia is more diagnostic in these cases.

DEMONSTRATION OF TUBERCLE BACILLI. Technique of staining a film. The smear should be moderately thin. Carbol fuchsin should never be boiled but should be heated till it steams. The stain is then poured over the slide to cover the smear. After three minutes, the stain should be washed off with water. It is then decolourised with acid alcohol (concentrated hydrochloric acid 3 c.cm. and alcohol 95 per cent. 97 c.cm.) until it is pinkish-gray on washing with water. Loeffler's methylene blue is used as a counterstain and kept for half a minute. It is then washed with water, dried and examined for tubercle bacilli under the oil immersion lens of the microscope. Under the microscope the bacilli appear as small red rods, a few are curved and others are slightly beaded. The presence of bacilli of this nature is diagnostic, but in the event of none being seen, several smears should be examined. When sputum is not available, throat swabs and gastric washings should be examined for bacilli.

Culture and animal inoculation of sputum for diagnosis of tuberculosis. Ordinarily stained smears of sputum do not show tubercle bacilli if these are less than 100,000 per c.cm. of sputum whereas the presence of 10 to 100 bacilli per c.cm. of sputum produces a positive culture or tuberculous lesions if inoculated into a guinea pig. The medium used in cultural methods is 0.5 c.cm. of sterile citrated blood or 0.5 c.cm. of fresh egg yolk treated with 6 per cent. sulphuric acid. The sulphuric acid destroys all bacteria except tubercle bacilli. After incubation of sputum at 37°C. for 45 minutes, the sulphuric acid is neutralised with sterile 1.3 per cent. sodium bicarbonate in 3 per cent. glycerine. The growth is watched at weekly intervals for three weeks till positive culture is obtained. A smear of such a culture may be stained with carbol fuchsin to demonstrate tubercle bacilli under the microscope.

Whooping cough organisms in sputum (early diagnosis). The special culture medium used is the glycerine-potato-blood agar medium of Bordet-Gengou with a pH 5. A small Petri dish is held vertically before a child's mouth during a coughing attack. The cough should be deep and expulsive. Droplet infection of the medium in the Petri dish takes place and the plate is incubated for 48 to 72 hours. *Bacillus pertussis* colonies appear as tiny pearls surrounded by dark zones. Under the microscope, a smear, when stained, shows Gram negative small organisms resembling pneumococci. The organisms are generally detected in the catarrhal stage of the disease at a period of greatest infectivity.

Vincent's organisms in sputum. Collection and technique of staining. In all chronic pulmonary diseases, sputum should be examined to detect Vincent's organisms. Thorough aseptic precautions of the mouth including the gums, teeth and tonsils should be taken before the collection of the sample and the specimen should in all cases be

examined within half an hour of collection. The smear should be thin and free of purulent materials. It is stained with steaming carbol fuchsin for three minutes. The stain is then washed off, dried and the film submitted to microscopical examination. The bronchial spirochætes, if present, appear as pinkish red organisms. Negative findings have no value and even in positive cases, contamination from the oral cavity should be borne in mind. In pathological cases they are present in numbers as secondary invaders and are commonly met with in chronic bronchopulmonary diseases and pulmonary hæmorrhage.

Pyogenic organisms in sputum. Gram's stain is used in finding the organisms in acute infections. The organisms commonly found are pneumococcus (Gram positive); Friedlander's bacillus (Gram negative); streptococcus (Gram positive); micrococcus catarrhalis (Gram negative); influenza bacillus (Gram negative); Bordet-Gengou bacillus of whooping cough (Gram negative); these appear as tiny bacilli resembling influenza bacilli.

STOOLS. *Functional test for gastro-intestinal motility.* The patient swallows a 10 gr. capsule of carmine and the stool is watched for a change of colour. It should normally become coloured red in 24 to 48 hours and the colour should continue for 48 to 72 hours after taking the carmine capsule.

Collection of fæces. About half an ounce of formalin should be added to the collected stool to destroy the disagreeable odour. For cultural examination and detection of occult blood in the fæces, formalin should not be added.

GENERAL CHARACTERS. *Colour.* The normal colour of stools varies from yellow to brown. Pale-coloured stools indicate poor digestion with deficiency of bile and pancreatic secretions. The colour also varies due to intake of different foodstuffs and drugs. Tarry-coloured stools are found in lesions of the upper gastro-intestinal tract. Fæces tinged with fresh red blood indicates a lesion in the lower gut and particularly of the rectum. *Form.* Normal stools should be semi-formed with undigested food particles in them. Loose stools indicate deficient absorption of the fluid matter from the fæcal mass in the large intestine or a rapid evacuation of the intestinal contents. Narrow and ribbon-like stools indicate a spasmodic condition of the gut. Scybalous masses are the result of a spastic condition of the colon. *Mucus and pus.* A naked eye detection of mucus and pus in the fæces indicates colitis or enteritis. In acute diarrhoeas, mucus is intimately mixed with fæcal matter. Pus in stools is usually found in inflammatory conditions of the gut. *Chemical tests:* *Occult blood.* Benzidine-acetic acid solution is the reagent ordinarily employed for the test. It is prepared by dissolving powdered benzidine in 3 c.cm. of 80 per cent. acetic acid. A small portion of the fæces is smeared on the centre of a white paper and a drop of the reagent is poured over it. The development of green or blue colour in less than one

minute indicates the presence of blood in the stools. A deep blue colour within 3 seconds indicates over 5 per cent. of blood; a pale blue colour in 3 to 5 seconds indicates 1 to 5 per cent. of blood; a pale blue or green colour within 15 to 60 seconds indicates less than 1 per cent. of blood and a pale blue colour after 30 seconds is of doubtful value. Another most sensitive test to detect occult blood in faeces is to use a saturated solution of benzidine in glacial acetic acid with hydrogen peroxide. It is added to a boiled solution of faeces when the blue colour develops. The test will give a positive reaction to blood in a dilution of 1 in 3,000,000. Unlike the former test, dietary precautions are to be observed in these sensitive techniques as this is likely to yield false results. Extra-gastro-intestinal sources of bleeding should be looked for and excluded before a test is done and a diagnosis given. Repeated examinations of stools are helpful in these cases to confirm a diagnosis. The test is positive in cases of peptic ulcers, carcinoma of the gastro-intestinal tract, ulcerative colitis, dysentery, typhoid fever, intestinal tuberculosis, acute abdominal emergencies such as mesenteric thrombosis, volvulus and intussusception, cirrhosis of the liver and general hæmorrhagic diseases such as purpura, scurvy, leukaemias, etc. *Biliary pigments.* The reagent used in the test is a saturated aqueous solution of mercuric chloride (mercuric chloride 101 gr. in 4 oz. of distilled water) or concentrated nitric acid. To a quantity of faeces about 3 to 4 times its volume of mercuric chloride solution is added and the two are mixed with a glass rod. The development of red colour denotes urobilinogen (urobilin) and a green colour, bilirubin. The colour generally appears in less than an hour but may require more time if the quantity of bile is small. Urobilin, the decomposed product of bilirubin, is the normal pigment of faeces. The test is required to ascertain the amount of bile present in the stools. Absence of bile gives rise to bulky, offensive, pale-coloured stools.

MICROSCOPIC EXAMINATION OF STOOLS. The smear on a glass slide should be from a fresh specimen and mixed with an equal amount of water. The film should be a thin one. The objects seen under the microscope are: vegetable fibres; spirals or cells; triple phosphate crystals; connective tissue strands and muscle fibres; epithelial cells and leucocytes; worms and their ova; occasionally amoebæ and flagellates; red blood cells and bacteria. For details of examination of faeces for intestinal parasites and their ova see page 1384.

INFANT'S STOOLS. The following should be noted: (1) *Number.* More than 4 evacuations should be considered pathological. (2) *Colour.* Normal colour is brown but infants fed solely on milk have pale yellow or green stools. Green stools in diarrhoeas indicate that the bile could not undergo a change in the gut. (3) *Consistency.* It varies and depends on the nature of feeds given to the infant. Foamy stool is due to carbohydrate fermentation. (4) *Odour.* A sour odour is due to carbohydrate fermentation while a foul putrefactive smell indicates protein

putrefaction. (5) *Curds*. The appearance of curds in infant's stools is thought by some to be normal. Protein curds are hard, tough and leathery; fat curds are buttery in consistency. (6) *Mucus*. It indicates an inflammatory condition of the gut and the amount varies with the severity of the lesion. (7) *Blood*. Intimately mixed with fæces and associated with loose stools, blood is seen in cases of infectious diarrhoea, dysentery, ulcer, intussusception, tuberculosis and scurvy. Stools smeared with fresh blood outside indicate a lesion of the rectum such as fissure, ulcer, polypus, etc.

CULTURAL EXAMINATION. Cultures from fresh specimens only are desirable. Nutrient broth is the medium used for it. The pathogenic organisms found are *B. dysenteriae* of Sonn, Flexner, Hiss, Russell, *B. paratyphosus* B and C; *B. morgani paracoli*; *B. dysenteriae*, schmitz, etc.

PARASITES AND THEIR OVA IN THE STOOLS. The examination of stools is never complete unless a naked-eye examination for a part or whole of a parasite (*e.g.*, tenia and oxyuris) or their larvæ (*e.g.*, strongyloides) or a microscopical examination for their ova is undertaken. In positive cases, detection of parasites may be difficult at times but the ova are generally present in all specimens submitted for microscopical examination. In anæmic patients particularly, the examination of the stool for parasites and their ova should be a routine procedure. *Collection and examination of fæces*. The specimen for examination should be collected in a wide-mouthed bottle with a little addition of formalin and water. The formalin destroys the disagreeable odour and dilution with water helps emulsification of the sample facilitating the detection of ova under the microscope. To search for the adult worms, *e.g.*, tapeworm segments and oxyuris, it is advisable to give a dose of salts at night and examine the stool the following morning. The liquid stool is poured on to a sieve and water poured on it; the fæcal matter is washed away leaving the worms and undigested residues of food. The contents of the sieve are transferred to a black or dark-brown dish or simply a large Petri dish with a piece of black paper underneath, when the worms, if present, can be easily picked up. *Microscopical examination*. To examine stools for ova, it is desirable not to administer any purgatives, as ova are better demonstrated in formed stools than liquid one. *Simple smear*. A thin smear of stool is made on a clean dry glass slide and the whole area is examined under the low power lens of the microscope. Ova and larvæ are seen, when these are present in overwhelming numbers.

McVall's method. The method is generally adopted for hookworm ova. A thick smear of stool with water is made on a glass slide and left for five minutes. The whole is then gently immersed in a bowl of water. The floating coarse particles and debris are washed away, leaving the ova on the slide.

Willis method. About half a gramme of fæces is poured in a small tin container and a thorough emulsion of it is made with saturated salt

solution. The container is filled to its brim with salt solution and a clean glass slide is put over it in contact with the stool emulsion for nearly ten minutes. The slide is rapidly lifted up and then examined under the low power focussing on the upper surface of the film and not on the slide. Almost all nematode ova (excepting unfertilised ascaris ova) float in saturated salt solution and hence are present in the film on the slide. This method is not useful for detecting strongyloides larvae unfertilised ascaris ova and ova of flukes and tapeworms.

Rivas method. About 2 gm. of stool is emulsified in 10 c.cm. of 5 per cent. acetic acid solution. The homogenous suspension is allowed to settle for two minutes; 5 c.cm. of the supernatant fluid is removed with a pipette and an equal quantity of ether is added to it. It is then centrifuged. Four layers of ethereal extract, detritus, acetic acid and sediment are formed in succession. The layers of ether, detritus and acetic acid are carefully poured off and the sediment at the bottom of the tube is submitted for microscopical examination.

Direct Centrifugal Floatation or D.C.F. method. This delicate method has been devised by Clayton Lane to detect hookworm and other ova which float in saturated salt solution and is of special value for diagnosing mild infections. The stool is first emulsified in water and centrifuged. Saturated salt solution is then added to the sediment and the tube filled to the brim with the solution. A special square cover-glass is placed on the top of the tube touching the salt solution and is held in place by four horns of the specially designed centrifuge bucket. The tube is centrifuged again at high speed and the cover-glass is lifted off and placed on a slide on two little plasticine cones with the film side downwards like a hanging drop preparation and is examined under the low power of the microscope.

SUDDEN DEATHS. Apart from sudden deaths after violence, accidents and poisoning, the statistics of the different pathologists of the world show that the majority of such accidents is due to sudden stoppage of the heart, profuse hæmorrhage from various causes and arterial embolism and thrombosis in different parts of the body. Of the diseases of the heart, valvular diseases including the aortic and the mitral valves, atheroma of the coronaries, syphilitic involvement of the coronaries, myocardial fibrosis, fatty infiltration, cardiac failure from high blood pressure, aneurysms of the aorta, both ruptured and unruptured, account for a large number of cases. Respiratory diseases including hæmoptysis in pulmonary tuberculosis, cancer of the lung, obstruction of air passages due to foreign body, diseases like diphtheria, malignant growths like carcinoma, pneumonia, pulmonary embolism are responsible for others. Other common causes include intracranial hæmorrhage, intracerebral hæmorrhage, tumours of the brain, oedema of the brain, ruptured cerebral aneurism, brain abscesses, cerebral embolism, acute infections and septicæmia, heat stroke, heat exhaustion, operative shock, allergic

and anaphylactic shock, deaths during anæsthesia, abdominal emergencies such as perforated peptic ulcers and perforated appendix with peritonitis, obstruction, etc.

SYPHILIS. This is a specific disease of wide distribution caused by *Treponema pallidum* (*Spirochæta pallida*). It may be acquired where the causal organism is propagated by inoculation or conveyed from person to person by contagion or it may be inherited where the disease is conveyed to the child by either or both the parents. The treponema of syphilis is a spiral curved organism 5μ to 15μ in length and is actively motile in fresh specimens. It survives for a short time only outside the body and is killed by weak antiseptics. The parasite has been cultivated by Noguchi; no race is known to be immune from the disease but infection confers immunity to a great extent and in fact a second attack is unknown in untreated cases.

In the majority of cases the disease is transmitted by sexual union (90 to 95 per cent.) though the term venereal disease strictly speaking is not correct as there are other modes of inoculation (5 to 10 per cent.). Accidental infections are known to occur in surgical and obstetrical practice. A characteristic local sore may not appear and a chancre on the lip or fingers affords the most common example of the extragenital variety. Wet nurses are very often infected on the nipple and relatives of a syphilitic child may be similarly accidentally infected. The treponema gains entrance to the body through a small break in the continuity of the skin or the mucous membrane. In acquired syphilis the chief site of infection is the genito-urinary tract; less frequently on the mucous membranes or mucocutaneous junctions such as the lips and rarely on the unbroken skin surface. After inoculation the organisms multiply at the site and produce a chancre, a manifestation of slowly developing tissue reaction. The organisms spread to other sites of the body by the perivascular lymphatics from the original infected site and afterwards multiplying further, they are carried to the various tissues or organs of the body through the blood.

Incubation period is from ten days to ten weeks and on an average is about three weeks. There is a general infection of the body within a few days of inoculation possibly within twenty four hours. If untreated, the primary lesion lasts from 3 to 4 weeks and the healing of the lesion occurs with marked induration of the part. The serum from the primary chancre contains a considerable number of spirochaetes and the organisms may even be found in the scars of the primary lesion. A generalised infection becomes apparent after an interval of 6 to 8 weeks. Manifestations in such cases may be severe or be very slight. Evidence is entirely lacking whether the body can overcome the infection entirely by its own resistance. The acute secondary stage lasts for several months but rarely a year and the

manifestations in some cases disappear for ever while in others only for varying periods.

Clinical features of acquired syphilis. The chancre or the primary lesion appears after the incubation period. Though these chancres have certain characteristic features it is difficult to diagnose the disease at this stage from clinical features only and microscopic examination is necessary. On an average in about three weeks from the time of appearance of the chancre, the blood becomes positive to Wassermann reaction though it may be positive earlier, and for treatment and prognosis it is usual to classify cases as of those with sero-negative W.R. and those with sero-positive W.R. The classification of syphilis into 3 or even 4 stages is becoming obsolete because it is now known that no one stage is characterised by definite group of symptoms nor there is any line of demarcation from one stage to the other. At any time from about one month to several months after the appearance of the chancre but usually about six weeks from the time of appearance of the sore there appear the manifestations which are called secondary syphilides. Along with these, there may be mild constitutional symptoms such as fever, malaise, headache and generalised pain all over the body. The commonest manifestations during this time are those on the skin and the mucous membrane. Skin lesions are dull red or copper coloured, circular or oval in shape with indurated margin and there is absence of itching. The organisms of syphilis are found in the serum exudate of these lesions and Wassermann reaction of the blood is almost always positive. The types of skin eruptions are varied in character and these may be macular, papular and papulo-squamous; pustulation is not common. Different varieties are present at the same time and this polymorphism is characteristic of the disease. During the early stage of eruptions, these are distributed all over the body in a symmetrical form. Mucous patches and moist papules are also met with at this stage of the disease at particular regions of the body. The mucous membrane of the mouth and tongue may be involved. Condylomata about the genitalia and moist papules are seen in persons with unclean personal habits. The late secondary manifestations are of papulo-squamous type; some are nodular lesions in the skin like tuberculoma or psoriasis and in comparison with earlier lesions these are not symmetrical. Another characteristic but not common lesion at this stage is leucoderma of the neck specially found in young females with dark hair. With treatment these symptoms disappear quickly, but even when untreated they disappear in time. With the subsidence of the secondary syphilitic manifestations the disease passes into a latent stage. During the latent period usually extending to a few years the only evidence of the presence of the disease is the generalised enlargement of the lymph nodes and a positive Wassermann reaction of the blood.

In the next tertiary stage, the slow infiltrating lesions usually of the cardiovascular system are met with. The gummatous lesions of the skin and subcutaneous tissues are formed. These are painless swellings ultimately breaking down in the centre and giving rise to ulcers with punched out edges and wash leather bases. The periosteum of the bones is thickened and sclerosis is marked. The main viscera involved during this stage in addition to heart and blood vessels are the liver, the kidneys and the stomach; other viscera are also involved though very rarely. Any structure in the body can be affected during this stage. Neurosyphilis was considered to be the terminal stage of the disease, but it is now clear that the central nervous system may be involved any time, even during the early stage of the disease. The affection of the central nervous system is slow and insidious and symptoms manifest themselves late. The examination of the cerebro-spinal fluid is advised in all cases of early syphilis from six months to one year's time and in late cases before any treatment is started or as early as possible thereafter. According to the anatomical structures involved neurosyphilis may be meningeal, vascular, hemiplegic, monoplegic, aphasic, parenchymatous, (G. P. I., tabes dorsalis, meningo-vascular gumma of the brain, spastic paraplegia); in many cases one may merge into another.

Congenital syphilis. In case of congenital syphilis, the foetus is infected by the passage of the treponemata from the maternal circulation through the placenta. It is rare to find an infected foetus before the fourth or fifth month of gestation and this is an important fact in connection with the treatment of infected mothers in pregnancy and also in antenatal work in getting children free from syphilis out of infected mothers. The possibility of a child being infected in utero lessens as the years increase between the birth of the child and the time the mother got infected (Kassowitz's law). The disease may lead to mis-carriages, premature birth and of birth of still-born infants. Sometimes a living child may be born which dies in very early life (within two years). Subsequently a child may be born with evident manifestations of syphilis or may be born without any outward signs or symptoms but may later develop symptoms. There is no primary stage in congenital syphilis. Lesions ordinarily met with are fissured ulcerative lesions of the skin near about the mouth, genitalia and anus; snuffles or serous or mucopurulent discharge containing treponemata which is highly infectious; bullous skin eruptions chiefly met with about the buttocks, soles and palms; epiphysitis; enlargement of the liver and spleen. Near about the age of 7 or 8 years or even later interstitial keratitis is very suggestive of congenital syphilis. Other classical signs are undue prominence of the frontal or parietal bones, eighth nerve deafness (detected often by marked shortening of bone conduction while air conduction remains very acute), high arched palate, saddle nose, Hutchinsonian teeth, peg-shaped upper central incisor

teeth with or without notching and involving the permanent teeth only and sabre-shaped tibia.

Hutchinson's triad, diagnostic of congenital syphilis, are interstitial keratitis, deafness and pegging of the incisor teeth. Visceral lesions are less common in congenital syphilis though involvement of the liver and spleen is met with, cardiovascular involvement is almost absent in congenital syphilis; the central nervous system is affected like the acquired type. It must be remembered that congenital syphilis is easily preventable if treatment of the pregnant mother is carried out in time.

TREATMENT. The treatment of syphilis should be started immediately the diagnosis is made. It is now generally realised that the earlier the course of treatment is started the better are the chances of a permanent cure. Early treatment is also of value in cutting short the period of infectivity as it has been found that *T. pallida* cannot be demonstrated in a lesion twenty-four hours after an arsenobenzol injection. Again it should be remembered that mere disappearance of the signs and symptoms of the disease does never guarantee a cure. The treatment should therefore be an intense and prolonged one as soon as a definite diagnosis is made as it is difficult to gauge with accuracy the ultimate effect of courses of treatment served. Harrison advocates a treatment with both arsenobenzol and mercury for some time after the blood sera gives a negative Wassermann reaction. Mercury being a comparatively feeble antisypilitic drug, reliance cannot be wholly made on it without arsenobenzol compounds. Mercury may well suffice for a continuation treatment after a thorough course with arsenobenzol compounds has previously been given. Relapses have been recorded even after a course of arsenobenzol and mercury had cleared up all symptoms and rendered the blood sero-negative. In addition to mercury and the arsenobenzol compound, bismuth and iodides are considered to be helpful and effective anti-syphilitic drugs in the treatment of the disease. As patients may show idiosyncrasy to one or the other of these drugs, the course should therefore, be modified without following a scheduled routine treatment blindly.

General treatment. The maintenance of the general health and the increasing of the body resisting powers of the patient are most essential along with the specific treatment of the disease. Living in a hygienic environment, keeping regular hours and taking regular exercises, go a long way to help this specific treatment. Avoidance of overwork and worries and abstinence from alcohol should always be aimed at. Sexual excesses should be avoided. The diet should be variable according to the stage of the disease. It should be plain, nourishing and should contain all the proximate principles of food. During the active stage of the disease a bland non-irritating liquid diet is advisable. The bowels and the skin should be kept freely active. Sulphur water has been utilised in the treatment of syphilis

and is a valuable adjuvant to the treatment. In debilitated anæmic individuals, iron, arsenic and strychnine are effective tonics.

Local treatment. In uncomplicated chancres 33.3 per cent. calomel ointment may be applied or the part may be kept dry by dusting with equal parts of calomel and calamine powder, morning and night. The treatment of a chancre of the lip includes the application of a 10 per cent. calomel ointment or 15 per cent. ammoniated mercury ointment. Before the application of the ointment or the powder the part should be bathed with some antiseptic lotion such as eusol, weak biniodide of mercury (1 in 10,000), or weak carbolic lotion (1 in 60). When a chancre is attended with considerable amount of sepsis the condition should be treated on ordinary surgical lines with good drainage, hot fomentations applied twice daily and canterising the focus with pure carbolic acid or acid nitrate of mercury. In sub-preputial chancre with much retention of septic discharges an operation of dorsal slitting of the foreskin or circumcision may be necessary. Gargles with chlorate of potash, alum sulphate, borax or a weak solution of peroxide of hydrogen, are of much value where the mucous membrane of the mouth is involved. Condylomata should be dusted with a powder containing equal parts of calomel and calamine and the surrounding parts should be kept scrupulously clean. In lesions of the skin, specially in pustular conditions such as rupia, hot antiseptic baths containing sanitas or potassium permanganate are effective therapeutic measures in cleansing the parts. The local treatment of ulcerated gummatous conditions in the tertiary stage of the disease consists in cleansing the parts with mild antiseptic lotion and applying hot fomentations afterwards.

Specific treatment. Syphilis is one of the few infectious diseases for which specifics are known; and in this instance there are four; mercury, bismuth, arsenic, and potassium iodide. (For the therapy of these drugs, see pages 736, 708 and 653).

The health organisation of the League of Nations published lately the results of an inquiry into syphilis treatment carried out in five countries (Denmark, France, Germany, Great Britain, United States of America); 98 clinics in these countries have contributed to the inquiry and 13,198 case records of primary and secondary syphilis have been analysed.

Guided by the principles revealed by the study of these records, the experts who have collaborated have adopted the following recommendations which are of great interest to syphilologists, public health officers, and private practitioners:—

1. Treatment should be recommended as early as possible in the sero-negative primary stage. In this connection, the fullest possible use should be made, for purposes of diagnosis, of the microscopical

examinations of the secretion from primary lesions or from lymph glands.

2. It should be emphasised that, prior to the institution of either of the systems of treatment outlined below, there should be an adequate physical examination to determine the absence or otherwise of any indication for caution in respect of the dosage.

3. It is essential that, in carrying out the treatment, a strict supervision of the patient be exercised, especially in respect of mucous membranes, skin, kidneys and liver.

4. Observation, clinical and serological, after completion of treatment should be adequate and in any case for not less than three years.

5. Adequate examination of the spinal fluid, at least before dismissal from observation, is essential.

6. The principles to be followed in carrying out the actual treatment should be as follows :—

(a) To employ a comparatively heavy individual dosage of the arsenobenzene and of the bismuth or mercurial compounds, the doses being administered in comparatively rapid succession, especially at the commencement.

(b) To maintain persistent attack on the disease, avoiding intervals of such length as to afford the parasite an opportunity of recovery.

(c) To administer approximately as much treatment to primary as to secondary cases.

7. The material studied does not enable clear decision to be made as to the relative merits of intermittent treatment with courses of injections in rapid succession separated by rest intervals of some weeks, and continuous treatment, or between the simultaneous employment of both arsenical and bismuth or mercury and the system in which bismuth and mercury are withheld until a number of arsenical injections have been administered.

Nevertheless it seems practical from the results of the analysis and from the personal experience of the experts to formulate a system of intermittent treatment and one of continuous treatment either of which can be expected to yield satisfactory results in ordinary cases of early syphilis.

It seems possible that the intermittent treatment which is suggested below may in effect be continuous or practically continuous, owing to the continued absorption of bismuth from the sites of the injections for some weeks after any temporary suspension of the treatment.

1. *Males*: For adult males of average weight aged less than 50 years and in whom there is no contraindication, a number of courses of injections is given on the plan described below. It should be said that, at the beginning of this course, some administer at once the full weekly dose (0.60 to 0.75 gm.), while others divide it into two doses (*e.g.*, 0.30 and 0.45 gm.) so far as the first week is concerned.

Weeks.		'914' (gramme)	'606' (gramme)	Insoluble compound of bismuth containing bi-metal; (gramme)	
1st to 8th	...	0.60 to 0.75	0.4 to 0.5	and	0.20 to 0.24
9th		0.20 to 0.24
10th		0.20 to 0.24

By insoluble bismuth is here meant compounds of a very slight solubility in water. They should therefore be given in suspension, those of extremely slight solubility (the oxychloride, etc.) usually in a watery suspension, those that are more soluble (the subsalicylate, the iodobismuthate of quinine, the alkaline tartrates, etc.) suspended in a vegetable oil. If a *liposoluble* compound (e.g., the camphocarboxylate, etc.) is preferred, it is desirable that the injection be given twice weekly in half doses.

The dosage of all bismuth compounds should be calculated according to their content in bismuth metal.

As an alternative to bismuth, a course of mercury may be given, either in the form of inunctions (40 days at 3 gm. of unguentum hydrargyri) or 70 mg. calomel or 120 mg. salicylate of mercury, etc., suspended in a suitable base.)

It is recommended that: (a) in cases which remain or become serologically negative, during or by the end of the first course, four such courses be administered, with intervals of three to five weeks between any two courses.

(b) In cases which have not become sero-negative by the end of the first course, in addition to the amount of treatment shown in (a), further courses should be administered until the patient has received as a minimum three beyond that which has ended with negative serum reactions. At the option of the individual clinician, this treatment may be prolonged as may be considered necessary.

(c) Cases presenting signs of clinical relapse of an early type should be dealt with on principles similar to those enunciated in (b).

2. *Females*: For females (non-pregnant), treatment should be administered on the plan outlined for men with the exception that the single dose of '914' should be reduced by 0.15 gm. and that of '606' by 0.1 gm.

In the event of any reduction in the amount of treatment being indicated it is recommended that this be effected by reducing the number of arsenical injections rather than by reducing the individual dose or increasing the intervals.

As an optional scheme more in harmony with the trend towards longer courses, three series of ten to twelve injections each of arsenical drugs may be given. To secure an overlapping of the heavy metal and the arsenical, believed by some observers to protect against neuro-relapses, begin the bismuth, two, three, or even four injections before the end of the longer arsenical course, continue it through the period

in which the arsenical is suspended, and on into the beginning of the next arsenical course. The bismuth is then suspended while the arsenical course is completed.

The following is the plan of alternating continuous treatment for early syphilis (League of Nations) :—

	'606' (gramme)	Intermittent treatment.	Serol test.	Remarks.
Day		*		
1	0.3 to 0.6		1	'606' dosage for first 3 injections at level of 0.1 gm. for each 25 lb. (11.3 kg.) body-weight. Average subsequent dosage, 0.4 gm., men ; 0.3 gm., women, the fourth and subsequent injections in the first course at weekly intervals. In average patient, all lesions heal rapidly and blood serological reaction becomes negative during first course. If '606' cannot be used, substitute 8 to 10 doses 0.3 gm. silver arsphenamine (silver salvarsan), silver arsenobenzol, etc., or 10 to 12 doses '914' (0.45 to 0.6 gm. maximum for women and 0.6 to 0.75 gm. for men). This applies also to subsequent courses.
5	0.3 to 0.6			
10	0.3 to 0.6			
Week				
3	0.4			If mercury is used ; note overlap (bismuth and arsenic) of week at end of first and start of second '606' courses.
4	0.4			
5	0.4			
6	0.4			
7	0.4			'606' starts, bismuth stops. Watch for provocative serologic reaction after first dose of '606'. Try to prevent short lapses in treatment, especially at this early stage.
8		Bismuth 4 doses, 0.2 gm. and potassium iodide, or unguentum mercury and potassium iodide.	1	
9				
10				
11				
12	0.4		1	Bismuth is better than mercury. Use if possible. Examine cerebrospinal fluid if patients' co-operation can be secured at about this time. If found to be abnormal, continue or intensify treatment as required, re-examining fluid within six months.
13	0.4		1	
14	0.4			
15	0.4			
16	0.4			
17	0.4		1	
18-23		Bismuth 6 doses or unguentum mercury and potassium iodide.		
.				

'606' (gramme)	Intermittent treatment.	Serol. test.	Remarks.
24 0.4			
25 0.4			
26 0.4			
27 0.4			
28 0.4			
29 0.4			
30-37	Bismuth 8 doses or unguentum mercury and potassium io- dide.		
38 0.4		1	
39 0.4			
40 0.4			
41 0.4			
42 0.4			
43 0.4		1	
44-53	Bismuth 10 doses or unguentum mercury and potassium io- dide.		Note that bismuth or mercury courses are gradually get- ting longer—4, 6, 8, and now 10 weeks.
54 0.4		1	The average sero-negative, sero-positive primary or early secondary patient should have at least 5 courses of '606'.
55 0.4			
56 0.4			
57 0.4			
58 0.4			
59 0.4		1	
60-69	Bismuth 10 doses or unguentum mercury and potassium io- dide.		It is safer to finish treatment with bismuth or mercury rather than with '606'.
70-122 proba- tion.	No treatment.	6-11	

123 complete physical and neurological examination, lumbar puncture, and if possible, fluoroscopic examination of heart and great vessels.

The bismuth salt advised for this system is bismuth salicylate in oil suspension, in full adult dosage with due regard for weight. Other preparations of bismuth may be used only with due regard for an equivalent metallic content and for their rate of elimination. The mercurial inunction is 40 per cent. metallic mercury in a suitable fatty

base, dose 4 gm. per inunction, five to six inunctions per week. The use of iodide is optional, depending on indications. The use of insoluble mercurials intramuscularly in this system is not recommended.

It should be further understood that when heavy metal is employed after the last '606' course, the heavy metal courses are to be separated by rest intervals of six to eight weeks between each series of ten weeks injections, or each course of 40 inunctions.

In case of primary syphilis which has remained sero-negative throughout, a minimum of five courses of '606' or '914' should be given. Cases of sero-positive primary syphilis should receive the full treatment called for by this system. In cardiovascular and visceral syphilis small doses are preferable and either arsenic or bismuth should serve the purpose best combined with the administration of iodides. The treatment thus suggested should never be rigidly followed but should be modified according to the reaction of the patient and the diseased tissues. The after treatment of the late cases should be on similar lines as that of persistent sero-positive syphilis. It is better to saturate the patient with the drugs over a prolonged period than to overtreat him with intense therapy for a short period. The treatment should continue for a minimum period of two years and the patient should be under observation for four years during which the blood and the cerebrospinal fluid should be examined from time to time. Short courses of oral medication with mercury and iodide during the course are of definite benefit in these cases.

Neurosyphilis. The treatment of neurosyphilis presents difficulties which are not met with in other systemic cases. No therapeutic agent is as yet known capable of regenerating damaged nerve tissues and even the common anti-syphilitic remedies can hardly penetrate the diseased tissues to effect a cure. In these cases, vigorous and prolonged therapy with antisyphilitic drugs is indicated. The administration of iodides should be encouraged during and subsequent to the treatment with arsenic and bismuth. During a course of treatment for 2 months Lees recommends intravenous administration of '914' in doses of 0.3 gm. at weekly intervals for 3 doses and intramuscular injection of sulpharsenol commencing with doses of 0.15 gm. to 0.6 gm. at weekly intervals for 9 doses. Combined with the arsenic therapy about 9 doses of bismuth are given at weekly intervals commencing at doses of 0.4 gm. and rising to 0.5 gm. After the treatment the patient should rest for a month and then a subsequent treatment should be modified according to the clinical signs and symptoms and the effect of treatment on the blood and the cerebro-spinal fluid. Dercum holds that by draining off the cerebrospinal fluid and thereby lessening the intrathecal pressure; the passage of substances from the systemic circulation to the choroid plexus is facilitated. In this method, within two hours of an intravenous administration of '914', spinal drainage is undertaken and such drainage is carried out once weekly throughout a course of 7 to 9

injections. Shift and Ellis advocated a combined intravenous and intraspinal therapy in neurosyphilis with a view to obtaining a maximum therapeutic effect on the diseased parts. About 40 c.cm. of blood are withdrawn from a patient an hour subsequent to the intravenous administration of '914'. The blood is allowed to clot, the serum is centrifuged and ultimately removed. About 10 c.cm. of this serum are diluted with 18 c.cm. of normal saline and the whole is inactivated by heating to 50°C. for half an hour. A quantity of the spinal fluid is withdrawn by a lumbar puncture and the prepared salvarsanised serum is allowed to flow slowly into the spinal canal by gravity. The foot of the patient's bed is kept elevated for one to two hours afterwards. The injection of salvarsanised serum may be repeated at intervals of two or three weeks and a course consists of seven to nine such injections. Purves-Stewart advocates the introduction of salvarsanised serum or other anti-syphilitic drugs by the cisternal route. It is suggested to be a more efficient method than the intraspinal one though the technique is rather difficult. Tryparsamide is highly reputed in all early cases of meningo-vascular syphilis, in early cases of general paralysis of the insane and in hemiplegias, it is considered to be a most potent drug in controlling the serological changes and rapidly improving the clinical condition of the patient in neurosyphilis. Though the drug is not a strong spirochaetocidal agent it has a high degree of penetration and a powerful stimulative effect on animal economy and animal resistance. The dose of tryparsamide should not exceed 3 gm. weekly for average patient and it should not be repeated more frequently than once a week. The routine course consists of eight intravenous injections given weekly, the first dose is 1 gm., the second of 2 gm. and the remaining of 3 gm. each; along with it, eight weekly intramuscular injections of bismuth or mercury are also given. As many as twelve courses spread over a period of 3 to 4 years may have to be given in resistant cases. The only contra-indication of the drug is diseases affecting the optic nerve. Besides the treatment with drugs other forms of therapy have also given encouraging results.

Protein shock therapy. It has been observed that considerable improvement or even cure is effected by artificial inducement of fever or leucocytosis by inoculation with bacterial or saprophytic organisms, milk or various other chemicals. Typhoid vaccine, *Bact. coli* vaccine, milk, etc., have been used for this purpose. Sulphur has also been injected intramuscularly to produce fever and this has produced beneficial effects in neurosyphilis. The preparations in common use are sulfosin and consul. The latter is given intramuscularly in doses varying from 1 to 5 c.cm., but the malarial treatment seems to be far more effective than the treatment with sulphur.

Malaria therapy. This treatment started from the observations that were made for over a century that intercurrent infections, such as artificially produced abscesses or fever have a beneficial effect on

the symptoms of general paralysis of the insane. Now-a-days malarial therapy is being largely practised in the treatment of neurosyphilis. The syphilitic patient chosen for this treatment, should be fairly healthy where the treatment can be carried out without danger and the attack can be controlled by antimalarial drugs. About 2 to 4 c.cm. of blood are taken from the vein of a patient suffering from an attack of benign tertian malaria. The blood is injected subcutaneously between the scapulæ on the back of a syphilitic patient. After an incubation period of one or two weeks the patient develops an attack of malaria. The patient is allowed to have eight to twelve pyrexial attacks before quinine is administered to control them. In a few cases the patient may not react to malaria. To control the pyrexial attacks after eight to twelve of them have occurred quinine is administered. When the malarial treatment is finished a patient improves in health and puts on weight. Once a syphilitic patient has been inoculated with benign tertian malaria, his blood can be used as a stock, and from him blood can be transmitted to other syphilitics. This transmission from patient to patient does not make the treatment less effective. It is suggested that in neurosyphilis, especially in advanced cases of general paralysis of the insane, the malarial therapy followed by tryparsamide is most beneficial in many cases.

Congenital syphilis. The treatment should be continued for 3 years. In the first year, if the baby has cutaneous lesions a perchloride of mercury bath, 20 gr. in 2 gallons of warm water, is recommended; 10 to 20 gr. of mercury ointment or unguentum cinereum is rubbed gently for half an hour every other day. After that, mercury in form of grey powder, $\frac{1}{2}$ gr. three times daily in milk, should be given internally for two months. Colloidal iodine, $\frac{1}{2}$ to 1 dr. twice daily, should then be prescribed for one month. In the second and third year, mercury is given internally for 3 months, colloidal iodine for 1 month with a period of rest for 1 month, subsequently mercury is given for 4 months, iodine for 1 month, with a rest for 2 months. Children over 7 years of age may be treated with proportionate dosage of arsenobenzol, bismuth or mercury. The average commencing dose of an arsenic preparation during the first year of life is from 0.025 to 0.05 gm., each week. The dose is much less in debilitated marasmic children and is generally 0.0075 gm. or even less. During the second year of life, the dose may be increased from 0.05 to 0.075 gm. of '914' in cases of healthy children. Bismuth is generally given biweekly in doses varying from 0.025 to 0.05 gm. Mercury may be given instead in doses commencing from 1/20 gr. each week.

Pregnancy complicated with syphilis. The antisymphilitic treatment is well borne by the syphilitic mother. An increased strain is generally put on the excretory organs during the course of treatment and the urine should be carefully watched from time to time to detect traces of albumin. Many pregnant women do not tolerate iodides and treatment should

therefore include the administration of '914', bismuth and mercury. The whole course of treatment generally covers a period of six months, divided into periods of three months. During the first three months, 4 doses of '914' each of 0.45 gm. are given at weekly intervals and then after a period of rest for a month, another 5 such doses are given at weekly intervals. Four doses of bismuth, each 0.4 gm. are given at weekly intervals during the period of rest from the arsenic. In the next three months of treatment, 8 doses of bismuth each 0.4 gm., are given at weekly intervals with a period of rest for a month in between the injections during which 4 doses of '914' each 0.45 gm. are given during the intervals. In every case treatment should be modified according to the tolerance of the patient. The dosage and the time intervals of administration of different drugs should be accordingly modified. In all cases it is necessary to continue the treatment after the puerperium on the same lines as for the routine treatment in systemic cases. It is suggested that the patient should receive courses of antisypilitic treatment in her subsequent pregnancies even though clinical examinations give negative results.

Prophylaxis. The prophylactic treatment resolves itself into the two factors, namely, the reduction of the number of infection-carriers and the prompt disinfection of those who have been exposed to risk of contagion. All persons after exposure should submit to abortive treatment. The disease can be successfully treated if seen early and cures can be guaranteed in those cases. Infection carriers generally result from failure to cure. Women are more liable to be infected than men. Disinfection of the exposed parts carried out in an efficient manner often succeeds if performed within four hours of exposure. The general line of treatment laid down is that the genitals, pubis, and lower abdomen should be well washed with soap and water. The part should be dried and swabbed well with perchloride of mercury lotion (1 in 2000) and particular attention should be paid to the mouth of the prepuce, corona, and frenum, all of which are liable to be abraded during intercourse. An application of 33 per cent. calomel ointment in lanolin is considered to be highly beneficial in disinfecting the parts. Stovarsol tablets each 4 gr., 4 such every morning before breakfast for 4 days and repeated in the second and third week after exposure to infection are also of value. Apart from these drugs protection is also afforded by the careful use of a condom or sheath during intercourse.

SYSTEMIC DISEASES, ORAL MANIFESTATIONS OF. The oral cavity serves as an index of generalised infection of the body. The altered character of the oral mucosa from the normal pink colour to a general pallor is strongly suggestive of anæmia. Similarly, a purplish colouration of the mucous membranes, particularly of the lips and tongue strongly suggests an insufficient oxidation of blood hæmoglobin (anoxæmia) in serious chronic diseases of the heart and lungs. Dryness of the mucous membranes is an indication of a depletion of body

fluids or dehydration, seen in severe untreated diabetes, uræmia, prolonged vomiting from various causes and also in persons with nasal obstruction who are popularly known as mouth-breathers. Brownish pigmentation of the oral mucosa is seen in Addison's disease. Ulcerations, exudations and deposits on the gums, tongue and elsewhere often appear as local manifestations of general infections, toxæmias, chemical poisoning, dietary deficiencies or serious diseases of the hæmopoietic organs.

A coated tongue is seen in fevers and in gastro-intestinal disorders, especially associated with gastric hyperacidity. Gastric hyperacidity tends to smooth the tongue with atrophy of the papillæ. A disturbance in motility or sensation is usually associated with disorders of the nervous system, organic or functional (hemiplegia and hysteria) and certain malignant growths involving the organ.

Syphilis, tuberculosis and actinomycosis produce ulcers with marked induration. In syphilis, both the primary and secondary manifestations are seen in the mouth. The papillæ of the tongue become more prominent and an exudate is usually found in the faucial tonsils in follicular tonsilitis, scarlet fever, etc. In Vincent's angina, a punched out ulcer with a dirty exudate around the tonsil is seen with tender and painful lymph nodes below the angle of the jaw.

Many diseases of the skin also affect the oral mucosa and among these are lichen planus, lupus erythematosus, erythema multiforme, pemphigus and angioneurotic oedema. Papules of the buccal mucosa with circular or conglomerate patches on the tongue or lips suggest lichen planus. Lupus erythematosus appears as greyish or reddish spots or patches which may ulcerate. Pemphigus of obscure origin, occurs as blebs and ulcers on the mucous membranes and resists all treatment with a tendency to frequent recurrences. In measles, Koplik's spots usually appear first in the mouth as small bluish-white spots, each on a red base later becoming whitish and numerous.

The salicylates and their derivatives, barbituric acid compounds, phenolphthalein, potassium iodide all produce rashes involving the mucous membrane of the mouth. Benzol, bismuth, lead and mercury cause characteristic intraoral changes. Lead produces a bluish deposit on the gums. Bismuth and mercury produce severe stomatitis with violet or black pigmentation and later ulceration.

Intraoral changes are chiefly associated with endocrine dysfunctions such as hypothyroidism and Addison's disease. In the former, the tongue is thickened and in the latter, pigmented areas are seen on the oral mucosa.

In deficiency diseases marked changes are met with in the oral cavity. In scurvy, the gums become hypertrophied and soft, and often bleed considerably; a sore tongue with atrophy of papillæ and redness is characteristic of pellagra; swelling and multiple superficial ulcerations appear later, simulating those of pernicious anæmia.

Pernicious anaemia shows pallor of mucous membranes of the oral cavity and tongue. In tropical sprue, the tendency to ulceration and atrophy of the tongue is more marked. Polycythaemia is evidenced by cyanosis of the lips and tongue. Bleeding and swollen gums resembling scurvy are seen in purpura. A general anaemia of the oral mucosa and haemorrhage from the gums appear as early signs in fatal leukaemias.

TETANUS. Tetanus or lockjaw is a specific disease caused by the toxins of the tetanus bacillus, an anaerobic organism. The bacilli occur in the intestines of animals, such as the horse and cow. Man is infected through a wound contaminated with soil containing the spores. The bacilli remain localised, but give rise to exotoxins. These are absorbed from the end plates of motor nerves and pass up through the perineural lymphatics. The incubation period is about 12 days, but may be as short as 2 days or prolonged to several months.

Diagnosis. (1) History of wound. (2) Clinically, trismus, stiffness, opisthotonus, spasms, etc., are characteristic in a typical case. The mind remains clear and the patient is in great agony. It is easily differentiated from strychnine poisoning in which the jaw and neck are not affected, there is complete relaxation between spasms and the body temperature is normal. (3) Moderate leucocytosis. (4) Cerebrospinal fluid comes out under pressure.

TREATMENT. (1) The patient is kept in a dark and quiet place. (2) Antitetanic serum is given early, desensitising the patient if necessary (see also serum therapy, page 791). An intravenous injection of 20,000 units diluted with an equal volume of warm normal saline is given slowly. A lumbar puncture is then made under general anaesthesia and 20,000 units of concentrated serum is given intrathecally. These intravenous and intrathecal injections are repeated during the next two days; on the 4th day 10,000 units are given intramuscularly and repeated if necessary. (3) Chloretone 40 gr., olive oil 1 oz., may be given per rectum. Chloral hydrate 15 gr. and potassium bromide 20 gr. given 4 hourly by mouth when the patient can swallow. (4) Chloroform is administered if spasms are severe. (5) One c.cm. of 25 per cent. solution of magnesium sulphate per 25 lb. body weight given intrathecally sometimes produces good results. (6) Rectal saline and glucose.

Prophylaxis. Serum in doses of 500 units subcutaneously or intramuscularly repeated three times at weekly intervals.

Curare treatment. The chief effect of curare is to paralyse the voluntary movement by blocking the passage of impulses from the peripheral nerves to the muscles. Along with the antitoxin treatment and the administration of sedative drugs *per rectum* such as paraldehyde, avertin, etc., dose of 32 mgm. of the drug for adults is injected subcutaneously and is generally repeated at six hourly intervals. In severe cases, four such doses would bring about an improvement in the condition clinically, but repetition of treatment might be necessary on recurrence.

of symptoms. No unpleasant symptoms or serious after-effects follow these injections. Observations on the effects of curare treatment in tetanus are hopeful but dosage at present is a difficult problem and will remain so until a standardised preparation of the drug is available.

TRYPANOSOMIASIS. African sleeping sickness. It is a disease endemic in tropical Africa and is characterised by pyrexia with enlargement of lymphatic glands, followed by nervous changes and increasing torpor. It is produced by infection with a trypanosome, which is a flagellate protozoon. Man is infected by the bite of the tsetse fly. There are two main types:—*T. gambiense* and *T. rhodesiense* occurring in different parts of Africa.

Diagnosis (1) Clinically there is irregular pyrexia and enlargement of superficial glands (especially the cervical) in the early stage, due to invasion of the blood and lymphatic glands. There may be splenic enlargement, oedema of feet and rash on the body. If untreated the disease gradually passes after months or years into the second stage of drowsiness. In the third stage the patient is bed-ridden and comatose. (2) Blood. (a) Trypanosomes in the centrifuged deposit. (b) Excess of globulin in the serum. (c) Secondary anæmia. (d) Aldehyde test may be positive. (3) Gland puncture shows trypanosomes. (4) Guinea-pig inoculation. (5) Cerebrospinal fluid in the second stage shows: (a) excess of cells (50 or more per c.mm.), (b) excess of protein and (c) presence of trypanosomes.

TREATMENT. (1) Atoxyl 3 to 7 gr. in 10 per cent. solution are given intramuscularly once a week for a month and then at monthly intervals till all signs disappear; test vision from time to time. (2) Soamin may be used similarly. (3) Tryparsamide, another arsenical preparation is especially useful for advanced cases. It is given intravenously or intramuscularly in doses of 1 to 3 gm. in 10 c.cm. of water every week, until a total of 20 to 100 gm. has been given according to the severity of the case; the average dose is 0.04 gm. per kilo. of body weight. Visual disturbances are a signal for stopping injections, but they are only temporary. Good results are also sometimes obtained by intravenous injection of tartar emetic and this drug was largely used in former days; it has now been superseded by a new organic preparation. (4) Germanin or Bayer '205', is administered by intravenous injection in doses of 15 gr. in a 10 per cent. aqueous solution weekly till 45 to 60 gr. have been given. This is particularly useful in early cases, but in later stages tryparsamide is best.

Prophylaxis. Injections of germanin before going into a fly area afford protection. Patients must be isolated and measures taken to destroy the tsetse flies. (See also page 466).

SOUTH AMERICAN TRYPANOSOMIASIS. It is a form of human trypanosomiasis met with in south America caused by *Trypanosoma cruzi* and disseminated by certain bugs. It is characterised by acute fever

with adenitis and involvement of the spleen, thyroid, nervous system and heart muscle. Unfortunately treatment is not very effective in this condition

TUBERCULOSIS. See page 945.

TYPHOID FEVER. See page 830.

ULCER. An ulcer is a defect of the body surface due to loss of epidermal covering. It may or may not be the outcome of an infective process, its shape and size may vary, it may or may not be painful, and may be acute indolent or indurated. In acute infective processes it tends to spread. This is seen in chancroids, syphilomas, tuberculomas, malignant growths, because of malnutrition of the tissues. The specific ulcers need different treatment.

Disinfection is rather difficult in infective ulcers because no antiseptic is yet known which will destroy the bacterial cells only without killing the tissue cells at the same time. The use of strong antiseptics, adds injury to the devitalised tissues suffering from deficiency of nutrition as in cases of thrombosed or varicose ulcers. In all infective ulcers drainage should be the chief measure for removing infection without damage to the tissues. Drainage is indicated in profusely secreting ulcers with signs of acute inflammation. Hydrogen peroxide along with hot boric acid lotion may be used as a cleansing agent and this may be changed every two hours during the day and if possible every four hours during the night until healthy granulating tissue has developed and the infiltration of the edges of the ulcers has disappeared. A hot 10 per cent. magnesium sulphate solution compress is held to be superior to the boric acid dressing as the hypertonic solution, by inducing exosmotic currents, cleanses the ulcers and relieves the pain of the patient. A constant bath in a warm (95° to 100°F.) dilute solution of potassium permanganate is a valuable means of rendering it inoffensive if the ulcer is foul-smelling. When the odour is overcome, hot boric dressings may be used. Moist dressings are beneficial in ulcers surrounded by dermatitis. Eczematous ulcers require uncovered compresses. For moistening these a solution of aluminium subacetate (diluted 1 in 10) is a most useful primary dressing to be followed as soon as the ulcer appears clean. Adherent dressings often delay healing by injuring the healthy granulating tissues, hence moist dressings are preferable and require renewal at intervals of not more than 3 to 4 hours. Some protection against physical injury and infection should always be aimed at after an ulcer is fairly clean and healthy. Wire-gauze screens protect ulcers and promote healing by exposing them to dry air and sunlight. The screen should be nicely shaped so as to fit the wound. Absorbent dressings, as they act like a foreign body when in contact with the ulcers, should be discarded. It generally keeps the skin edges waterlogged and the epithelium does not grow well over the ulcerated surface. For epithelization to be complete and satisfactory, the clean wound should be covered with a dry

adherent scab which will be spontaneously detached after healing is complete. Surgical paraffin (melting point 50°C.) is preferred by many for dressing these ulcers. The paraffin film by providing a more physiologic condition for healing aids the growth of epithelium over the wounded surface. Being perfectly bland, the paraffin does not kill cells as do most antiseptic dressings and moreover the living cells are not injured when this paraffin is removed from the ulcer. The raw surface is at first painted with sterile liquid petrolatum before the application of the paraffin ; over this a thin layer of sterile cotton is applied and next the melted paraffin is laid over it by a series of gentle pats. The paraffin should completely seal the wound. A second film of paraffin may be painted over the first one. The dressings might require changing at intervals of 24 to 48 hours or even longer. A mixture of paraffin, one part and petrolatum two parts may be used but it is less efficient because it does not retain the wound secretions. In painful ulcers a 10 per cent. ethylamino-benzoate (anasthesine) may be incorporated with advantage. In ulcers resulting after deep burns such as from electric currents, silver foil has been advocated as a suitable dressing. It clings closely to the surface, is bacteriostatic and helps in the accumulation of wound secretion which serves as a culture medium for the proliferating cells. In this treatment keloid formation seems to be less marked than in others. Indolent ulcers require a stimulative treatment for rapid healing by increasing the blood supply and stimulating the proliferation of cells. The application of irritant drugs is indicated only when the ulcer-bed is well filled and their use should be discarded as soon as exuberant granulation tissues develop. Radiant energy is most beneficial in extensive ulcers, particularly associated with poor blood supply. This can be achieved with direct exposure to the heat of the electric cradle or continuous exposure to ultraviolet rays of the sun. The latter rays are considered to have a considerable amount of antiseptic value while excessive exposure should always be avoided lest it might produce necrosis of the tissues. Balsam of Peru is particularly valuable in the treatment of bed sores. It is not only a good stimulant to healing but is also bacteriostatic and keeps dressings from sticking. It may be used in the form of a paste with zinc oxide or mixed with castor oil in equal parts. A useful prescription of Balsam of Peru paste includes balsam of Peru 10 gm., zinc oxide 40 gm., castor oil 50 c.cm. Compound tincture of benzoin forms a varnish after evaporation of the alcohol which is protective and such treatment is particularly suitable for small indolent sores.

In certain intractable ulcers periarterial sympathectomy becomes necessary for prompt healing. The growth of epidermis should be stimulated for the proper healing of an ulcer and reducing agents have a special reputation for this purpose. Of drugs similarly reputed a 5 per cent. scarlet red ointment applied to the growing epithelial margin for a couple of days deserves mention. Gauze impregnated with compound scarlet red ointment containing oxyquinoline sulphate 0.6 gm.

chlorbutanol 2.4 gm., liquid paraffin 4 c.cm. and 5 per cent. scarlet red ointment 120 gm., is specially recommended by Bettman (1931) for preparing ulcers for skin grafting later on. Thiocresol compresses advocated by Reimann (1930) are of proved value in extensive ulcers. Thiocresol should be freshly prepared in a 1 in 10,000 dilution. A stock solution of thiocresol contains thiocresol 0.1 gm., alcohol 50 c.cm., 5 c.cm. of this should be mixed with 100 c.cm. of distilled water to make 1 in 10,000 dilution. The solution is poured on sterile gauze and placed directly over the wound. This dressing is best alternated after forty-eight hours with simple dressing such as compresses of physiologic solution of sodium chloride. The most important conditions retarding healing are exuberant granulation, a callous ulcer margin and ulcer completely encircling a limb. Exuberant granulations may be destroyed by curetting or sometimes require trimming with scissors. Cauterization with silver nitrate applied once or twice a week very often restrains such growth. The visible epithelial margin should never be touched with caustics. This procedure generally retards healing for some time. Cauterization with stimulating astringents like copper sulphate or zinc chloride is preferable to silver nitrate in cases of anæmic ulcers with pale flabby granulations. This should be followed by dry treatment such as dusting with thymol iodide and a compression bandage. A firm strapping with elastic adhesive plaster serves the purpose very well. Treatment of callous ulcers presents difficulties. Hydrotherapy in the form of hot circular compresses may produce a macerating effect on the tissues and increase the blood supply to the part and thus expedite healing. Local hypodermoclysis with physiologic solution of sodium chloride may assist this softening effect by its lymphagogue action. Along with the hot compresses preferably during the night alternated with a pressure bandage during the day is of advantage. Irradiation treatment with Roentgen rays in fractional doses, an occasional erythema dose of ultraviolet rays, or daily graduated doses of the sun rays deserve a trial.

When the above treatment fails surgery should be adopted as a last resort. Incisions are to be made through the indurated margin, radiating from the centre of the ulcer, penetrating the deep fascia and extending for one or two inches beyond the margins of the ulcer. After complete excision of the ulcer and as soon as healthy granulation tissues have developed, skin grafting should be undertaken for the rapid healing of the wound. Sometimes amputation is required when an extensive ulcer encircles a limb and when plastic operations fail.

Varicose ulcer has been treated with the topical application of 6 per cent. gentian violet. After thorough washing and subsequent drying of the ulcer, a 5 per cent. aqueous gentian violet solution is sprayed on with an atomizer or is sometimes directly applied over the ulcer. A dry sterile dressing is then employed after the gentian violet has dried. This treatment is repeated every other day until a firm

crust has formed and finally complete healing occurs. Varicose ulcers have also been successfully treated with warm saline dressing Unna's paste, Dakin's solution, ultraviolet light, scarlet red ointment and 70 per cent. alcohol.

Bed sores. Factors which usually predispose to development of bed sores are prolonged pressure, maceration and trauma to the part. Prolonged pressure especially over the bony prominences such as the sacrum, shoulder blades, heels, ankles and elbows, should be avoided or minimised by a water bed or a cushion filled with water at 95°F. To improve circulation in the tissues of the back, massage is beneficial and some recommend 50 per cent. alcohol for rubbing. The direction of massage should be from the base of the skull downwards and afterwards the patient's skin should be dusted with talcum powder or zinc stearate. When the skin is dry and rough, an ointment consisting of zinc stearate 5 gm., tincture of benzoin 5 gm., 5 per cent. scarlet red ointment 0.25 gm., hydrous wool fat 30 gm., liniment of camphor 180 c.cm. and mutton tallow 500 gm. may be used. Daily cleansing the sores with alcohol kills the cells. The ulcers require stimulation for which balsam of Peru serves the purpose best. It should be mixed with castor oil to prevent the burning sensation, especially when it is applied to sensitive ulcers. A 5 per cent. scarlet red ointment is an ideal stimulant for the growth of epithelium. Thiocresol compresses have of late been advocated to stimulate healing of extensive ulcers. A freshly prepared 1 in 10,000 solution of the 2 per cent. alcoholic solution, 5 c.cm. is mixed with 100 c.cm. of distilled water and is applied on the gauze which is then covered with waterproof material. This dressing is changed every two hours. To avoid excessive irritation, it should be alternated with compresses of physiologic solution of sodium chloride at intervals of forty-eight hours.

Absorbent materials should be used to prevent damage to the skin due to constant wetting with sweat, urine, faeces, etc. All forms of trauma should be avoided, as trauma, however slight, permits invasion of bacteria. In threatened bed sores with signs of cutaneous erythema, the skin should be hardened with a 5 per cent. solution of silver nitrate in distilled water. The following solution is useful for painting when there are small breaks in the skin: alum 30 gm., water and alcohol each to be added 250 c.cm. For unavoidable bed sores a useful preparation is a 5 per cent. aqueous solution of tannic acid sprayed on the uncovered area of the skin and later on dried by a current of warm air. Moist treatment is only indicated in cases of spreading infections and where pus is retained. In these cases warm boric acid compresses and irrigation of the ulcer with a solution of chlorinated soda are most beneficial.

URINE. The examination of the urine may give important information concerning disturbances of metabolism, as well as regarding

diseases of the kidney or urinary passages, and even with regard to functional abnormalities of the liver, or of the heart and circulation.

The examination of the urine should include the following:—

The volume excreted per day, the specific gravity, the colour and the reaction. In addition it should be tested for the presence of albumin and sugar (cloudy urine must be filtered before these tests are made). Urine which contains pus cells or bacteria is usually turbid, and sometimes cannot be cleared by filtration. Under these conditions it must be shaken with kaolin and then filtered. According to its colour the urine should be tested for the presence of bile pigments, blood pigments, urobilin and porphyrin. Finally the urinary sediment should be examined microscopically. In certain cases the examination must include tests for other substances (*e.g.*, in diabetes for acetone and di-acetic acid), and the quantitative estimation of albumin, sugar, nitrogen, etc.

VOLUME. The normal male voids approximately 1500 to 2000 c.cm. per day, and the female 1000 to 1500 c.cm. A daily volume of less than 500, or more than 2000 c.cm. is usually to be regarded as abnormal.

While in the normal individual the urine is excreted principally during the day and only a small quantity at night, it is often observed in patients with heart disease, pyelitis, or vascular disease of the kidneys, that a far larger amount of urine is excreted during the night (nycturia).

SPECIFIC GRAVITY. It is measured by dipping a dry hydrometer into the urine cooled to room temperature. The hydrometer is read at the lower level of the fluid meniscus. The specific gravity is dependent upon the amount and the weight of the dissolved substances.

The specific gravity of the urine ranges normally between wide limits, approximately 1.01 to 1.025. With increased fluid intake large quantities of urine of low specific gravity are excreted, upon a small fluid intake or with a considerable loss of water in the form of perspiration during vigorous exercise, or *via* the bowel in diarrhoea, small quantities of urine are passed having a high specific gravity.

From the specific gravity of the urine the total concentration of solids in grammes may be calculated by multiplying the last two figures of the specific gravity by Haeser's coefficient 2.3. For example, a urine of specific gravity 1.015 contains 34.5 (15×2.3) gm. solids per litre, which, with a total urinary volume of 2,000 c.cm., represents the elimination of 69.0 gm. of solids per day.

COLOUR. The colour of the urine which is normally yellow, is fainter with a dilute urine, and darker and more reddish-yellow, if the urine is more concentrated. Bright yellow urine of high specific gravity is often found with diabetes mellitus. The urine is a dark, yellow-brown (the colour of beer) and has a yellow foam if bilirubin be present, *i.e.*, with icterus; reddish-yellow or reddish-brown if it contains urobilin, a reddish colour with porphyrinuria, a smoky red, *i.e.*

red and at the same time slightly cloudy and iridescent, if blood be present therein. The original normal colour of the urine deepens somewhat upon standing in air and may change to a greenish-brown following the use of phenol, lysol, naphthol, hydroquinine, salol, or with alkaptonuria or melanuria.

REACTION. The reaction of the normal, freshly voided, human urine is acid, principally due to the presence of disodium acid phosphate. Occasionally the reaction of the normal urine may be amphoteric changing blue litmus faintly red, and red faintly blue. This is the case if large quantities of the dibasic phosphates are present together with diacid phosphates. When only the dibasic phosphates, or with these tribasic phosphates are present the reaction is alkaline.

ALBUMIN. Albumin may be demonstrated in the urine by the following tests (turbid urine must be filtered before testing).

1. *Heat and acid.* The urine is heated in a test tube to boiling and one or more drops of dilute acetic acid are then added (instead of dilute acetic, concentrated nitric acid may be used). If a precipitate develops during heating which disappears on addition of the acid, it is composed, not of albumin, but of the phosphates or carbonates of calcium or magnesium which are easily soluble in acid. If there remain even a slight clouding, or if such appears for the first time upon the addition of acid, albumin is present. If the urine is very dilute or poor in salt the addition of a small amount of salt greatly enhances the accuracy of the test. For estimation of the albumin content the Esbach albuminometer may be employed. This method is complicated by the fact that Esbach's reagent (picric acid and citric acid) may sometimes cause a precipitate in normal albumin-free urine, since the picric acid produces an insoluble compound with potassium salts, urates, quinine, urotropin and other substances. As a result the Esbach method may give too high a value following the use of urotropin, or may give a positive reaction in urine that contains no acids. The use of Tsuchiya's reagent avoids this difficulty. 1.5 gm. phosphotungstic acid dissolved in a mixture of 5 c.cm. concentrated HCl and 95 c.cm. of 95 per cent. alcohol.

2. *Heller's test.* Concentrated nitric acid is layered beneath the urine in a test tube by means of a pipette. In the presence of albumin there develops at the boundary between the two fluids a cloudy ring.

3. *Sulpho-salicylic acid test.* If 20 per cent. sulpho-salicylic acid be added to the urine, there develops a definite clouding with small traces of albumin.

ALBUMOSE. Albumoses appear in the urine in many febrile infectious diseases (febrile albumosuria), in some types of poisoning (e.g., phosphorus poisoning), also in the presence of a purulent exudate as in empyema, meningitis (pyogenic albumosuria) in pneumonia, in the puerperium, with ulcerative processes in the intestinal canal. The

proof of the presence of albumoses is of very little diagnostic significance. To test for albumoses it is necessary first to eliminate any albumin which may be present. It can be separated from albumin by saturating the urine with crystals of ammonium sulphate, boiling and filtering. The precipitate on the filter paper is washed with water, when any albumose will be redissolved and carried through the filter paper. The Biuret test is then applied to this filtrate and if positive, indicates the presence of albumoses. With osteosarcoma and other diseases of the bonemarrow (*e.g.*, myeloma) there occurs a type of protein in the urine described by Bence-Jones. To demonstrate this protein the acid urine is heated to about 60°C. At this temperature a precipitate appears, this dissolves again on boiling to reappear as the mixture is again allowed to cool.

SUGAR. 1. *Fehling's test.* For this test two component solutions are prepared: (a) 34.64 gm. crystalline copper sulphate dissolved in water and diluted to 500 c.cm.; (b) 173 gm. of Rochelle salt (potassium sodium tartrate) and 100 c.cm. of pure sodium hydroxide diluted to 500 c.cm. with water. These two solutions are mixed in equal proportions before using. One c.cm. of the mixture should be completely reduced by 0.005 gm. of glucose. Two c.cm. of this mixture are placed in a test tube, diluted with an equal volume of water and boiled. In the absence of contamination no evidence of reduction should appear. One or two c.cm. of urine are added to the tube and the mixture is heated on a water bath. In the presence of glucose there appears a reddish-yellow precipitate of cuprous oxide.

The quantitative determination of the urinary sugar by Fehling's method is carried out as follows: 10 c.cm. of Fehling's solution, 10 c.cm. of concentrated sodium hydroxide and about 50 c.cm. of water are mixed in a basin. The urine is then added gradually from a burette until the blue colour of cupric oxide has completely disappeared. The percentage content of sugar is then calculated from the fact that the volume of urine added must have contained 0.05 gm. of glucose. If the sugar content is known to be high it is sometimes better to dilute the urine to 1 to 10.

2. *Benedict's test.* To about 5 c.cm. of the reagent in a test tube add 8 to 10 drops (no more) of urine, boil the mixture for 2 minutes and allow to cool. Dependent upon the amount of glucose present the mixture turns green, or a green, yellow, or red precipitate appears.

DIACETIC ACID. In the presence of diacetic acid, the urine gives a positive reaction to Gerhardt's ferric chloride test. The urine is mixed in a test tube with several drops of a solution of ferric chloride. This causes the formation (even in normal urine) of a greyish-white precipitate of phosphate of iron. If diacetic acid be present there appears in addition to this precipitate, a burgundy-red colour. Any specimen of urine which contains diacetic acid will always give a positive test for acetone. The reddish brown colour of the urine is

not produced by diacetic acid alone but also by antipyrin and certain other drugs, as well as by amino acids, with this difference, however, that the diacetic acid containing urine also gives a positive test for acetone. Salicylic acid produces a violet colour with ferric chloride.

If the patient has been taking drugs such as aspirin, salicylic acid, or salicylates, etc., misleading results may be obtained. The colour is, however, quite different from that given by diacetic acid, since it is much darker and of a more violet hue. To differentiate this, bring the urine to the boiling point. If the reaction is due to diacetic acid the heat will decompose the diacetic acid and the port wine colour will disappear. If it is due to coal tar drugs the colour will persist.

ACETONE. *Rothera's test.* Take about 2 inches depth of urine in a test tube and saturate it by shaking with finely ground ammonium sulphate crystals. To the solution add a few drops of a recently prepared 10 per cent. sodium nitroprusside solution and about as much ammonium hydrate as the amount of urine taken. The production of a permanganate colour at the junction of the fluids indicates the presence of acetone.

PUS. On adding liquor potassæ, a ropy gelatinous mass indicates pus. (The microscopic test is better).

INDICAN. To some urine add an equal amount of strong hydrochloric acid, then a few drops of hydrogen peroxide. Shake up the mixture with some chloroform. The indican is oxidized to indigo which imparts a blue colour to the chloroform.

BILE SALTS. Hay's test—Sprinkle flowers of sulphur on to the surface of urine in a test tube. If bile salts be present the particles of sulphur sink to the bottom of the tube.

BILE-PIGMENTS. Bilirubin is identified by Gmelin's test. Below the urine in a test tube is layered a small amount of fuming nitric acid. At the interface between the two solutions, in the presence of bilirubin, there is formed a ring of color which changes from green through violet to red and finally yellow. A blue ring may be caused by the presence of indigo, and a reddish-brown ring by urobilin and other substances. Gmelin's test may be carried out in another fashion. If the urine is filtered the greater part of the bile pigments remain upon the filter paper. If upon this yellowish filter paper is placed a small drop of nitric acid the characteristic rings of color form about it. Or several drops of urine may be placed upon an unglazed porcelain plate and touched with a rod dipped in nitric acid.

UROBILIN. It is demonstrated in the urine as follows :—

The urine is mixed with an equal volume of Schelsinger's reagent (zinc acetate 10 gm., alcohol 100 c.cm.) The turbid mixture is then shaken and filtered. In the presence of urobilin the filtrate shows a green fluorescence (best seen by looking down the test tube against a dark background). This test may be rendered more sensitive by mixing 3 drops of a 5 per cent. alcoholic solution of iodine with

10 c.cm. urine to convert all the urobilinogen to urobilin before the addition of the Schlesinger's reagent. Upon spectroscopic examination urobilin containing urine shows a single absorption band between the green and blue, sometimes only after the addition of zinc chloride and ammonia.

Diazo-reaction. *Solution A.* Saturated solution of sulphanilic acid in 5 per cent. HCl solution. *Solution B.* Half per cent. solution of sodium nitrate in distilled water. *Test solution.* Solution A 50 parts, solution B 1 part. To 5 c.cm. of urine add an equal volume of the test solution, shake thoroughly, add a strong solution of ammonia in excess, allowing it to run gently down the tube so as to overlay the mixture below. If the reaction be present a deep red band appears at the junction of the fluids, when shaken it yields a pink or rose coloured foam and after standing several hours, a green precipitate forms. Use fresh urine and see that the reaction is acid and the urine is filtered. Use a freshly prepared test solution.

ORGANIZED URINARY SEDIMENT. Leucocytes appear in small numbers in normal urine. If they are present in abundance the urine is cloudy. This finding indicates an inflammatory or purulent process in one portion of the urogenital tract (gonorrhoea, cystitis, pyelitis, nephritis), the more accurate localization of which often demands further investigation. With jaundice the leucocytes in the urinary sediment sometimes contain fine crystals of bilirubin.

With chronic gonorrhoea the urine contains fine shreds of mucus sometimes mixed with leucocytes, and occasionally intracellular gonococci, even though the original infection has taken place years before. These mucus shreds are discharged from the prostate or posterior urethra. Red blood corpuscles are present in the sediment with the most various hæmorrhagic conditions in the urogenital tract. Cells of renal epithelium are small, round or cuboid with a vesicular nucleus. They are usually poorly developed and often filled with fat droplets. Epithelial cells from the bladder, ureters or renal pelvis are indistinguishable from each other. Those from the superficial layers are flat and polygonal, from the deeper layers round or irregular in contour (pear-shaped) and contain a vesicular nucleus. With an inflammatory process involving the bladder or upper urinary passages large numbers of such epithelial cells, accompanied by leucocytes, are to be found in the sediment. It is, therefore, impossible by microscopic examination alone to ascertain exactly which portion of the upper urinary tract may be diseased. The vagina and prepuce are covered with pavement epithelium similar to that of the mucous membrane. The male urethra is lined with cylindrical epithelium. Gonorrhoeal pus sometimes contains such cells but is distinguished particularly by the presence of gonococci.

CASTS. Casts are formed in the renal tubules. They occur in large numbers in acute nephritis and in chronic nephritis with oedema and

less profusely with the contracted kidney and with those forms of albuminuria associated with circulatory failure or fever. With icterus bile-stained casts may be observed. In severe cases of diabetes mellitus large numbers of coarsely granular casts are sometimes found in the urine.

The following types of casts are distinguished. *Hyaline casts* which consist of a homogeneous transparent substance and are often indistinct in outline. *Granular casts* with fine granular matrix, are otherwise similar to hyaline casts. They occur, however, almost exclusively with true renal disease, i.e., with acute or chronic nephritis. *Waxy casts* are refractile, often yellowish, with a distinct contour which is sometimes irregular. They are met with chiefly in chronic renal disease and indicate a more severe degree of renal involvement. *Epithelial casts* are made up of desquamated epithelial cells from the renal tubules. *Red-blood cell casts* represent masses of red blood cells closely packed together. *Cylindroids* are long, irregular masses of mucus and are of no diagnostic significance.

MICRO-ORGANISMS may always be demonstrated in specimens of urine which have stood for any length of time. It is therefore, advisable to search for bacteria only in a freshly voided specimen or still better in one which has been obtained by means of a sterile catheter. With cystitis and pyelitis, bacteria, usually *B. coli communior* are found; more rarely staphylococci, streptococci and pneumococci. In foul-smelling urine *B. proteus vulgaris* is sometimes present, a short variable rod, which liquefies gelatine. In tuberculosis of the urogenital tract tubercle bacilli are to be found in the urinary sediment.

VACCINES. *General rules in the use of curative vaccines.* (1) Accurate diagnosis is essential in regard to the infecting organism or organisms and also in regard to the duration, course, and degree of a disease process. (2) Autogenous vaccines are preferable to stock vaccines. (3) Vaccines too old or too much heated should not be employed as there may be some change in the antigenic structure. As a general rule vaccines more than 3 months old should not be used. (4) When treating a case for a very long period the bacteriological diagnosis should be reconsidered in order to see if the flora has changed or become resistant to the action of vaccine administered. (5) Give the vaccine a thorough trial, specially in chronic cases. (6) Intercurrent illness, a long journey, a menstrual period, anticipation of a fatiguing or exciting time immediately after injection should lead to postponement of it. (7) Do not depend entirely on vaccine treatment but it should go hand in hand with other remedies recommended for any particular disease.

Dosage of autogenous and stock vaccines. For the amount and frequency of administration of a vaccine one should be guided by the clinical condition of the patient. There cannot be any fixed dosage in

the therapeutic use of a vaccine. The dose depends on the toxicity of the organism (of high toxicity 1 to 10 millions as initial dose, of low toxicity up to 100 millions), on the stage of the disease, whether acute, when very small doses are given, or subacute and chronic when large doses can be employed. The first dose is purely an experimental one and the subsequent doses must be controlled by the local, focal and general symptoms. The production of any marked reaction, either local or constitutional after any injection may be considered a contra-indication to any increase in dosage on the next occasion. A vaccine made with an organism of low toxicity may be increased by multiple progression whereas a vaccine made with organisms of high toxicity the increase should be by half arithmetic progression (e.g., 5-7½-10-15-20-30 millions). The time interval is another factor in the administration of vaccines. As a rule 2 to 5 days or 7 days interval between doses is given for chronic or subacute infections. But here again there is no hard and fast rule and one has always to be guided by the reaction of the patient. When stock vaccines are used the dose may be two or three times as large as those of autogenous vaccines and when used for prophylactic purposes they may be about five times the initial dose. It is convenient to prepare a vaccine of such a strength that the necessary first dose is contained in 0.1 c.cm.

Dosage, sex and age. Somewhat smaller doses should be used in females. In children under 6 years the adult dose should be divided by four, in children between 6 and 12 years it should be halved and from 12 to 16 years two-thirds of the adult dose should be given.

Prophylactic vaccines. Doses of most of the vaccines used for prophylaxis have been fixed more or less from previous experience. The least harmful and the smallest effective dose to protect a person from infection is administered.

General directions in the use of vaccines. Vaccines must be stored in a cool dark place. Vaccines should be well shaken before use and all aseptic precautions must be taken.

Administration. Vaccines may be injected intracutaneously, subcutaneously or in smaller doses intravenously.

The following vaccines are of proved value.

(A) *Prophylactic vaccines.* (1) *Cholera vaccine.* Dose—8,000 millions per c.cm. usually given in two doses of 0.5 c.cm. and 1 c.cm. at interval of a week. A single dose of 1 c.cm. may be used when necessary. (2) *Typhoid-paratyphoid (T. A. B.) vaccine.* Dose—Typhoid 1,000 millions, paratyphoid A. 750 millions, paratyphoid B. 750 millions in one c.cm. This vaccine is usually given in two doses of 0.5 c.cm. and 1 c.cm. at intervals of a week. A single dose of 1 c.cm. may be given when necessary. One dose of 1 c.cm. for re-inoculation. Sometimes Anti-T.A.B. and cholera vaccine are given together. (3) *Plague vaccine.* Three doses of 0.5 to 1 c.cm. at 8-day intervals. (4) *Anti-rabic vaccine.* Dealt with under the section on rabies. Only used for prophylaxis. (5) *Small-*

pox vaccine. Dealt with under the section of vaccination. Only used for prophylaxis. (See also page 778).

(B) *Vaccines used as therapeutic agents.* These may be either 'stock vaccines' or preferably prepared from the actual organism responsible for the disease and known as autogenous vaccines.

The following table is merely to be used as a guide to the initial doses of the vaccine for therapeutic use :—

Initial dose (millions)				Initial dose (millions)			
Bact. coli	20	N. pharyngis	20
C. diphtheriæ	10	Str. pneumoniae	10
Bact. Flexner	and	Flexner		Proteus group	20
group	20	Staphylococcus	50
N. gonorrhœa	25	Streptococcus	2
N. influenza	10				

Small-pox vaccination. The principle is to introduce *vaccinia virus* into the skin for inducing cow-pox and preventing small-pox. The material obtained from vesicles on a calf emulsified in glycerine or lanoline is used for the purpose. For detail see page 790.

VARICOSE VEINS. These are dilated, permanently lengthened and tortuous veins affecting mostly the superficial veins of the leg, spermatic veins and the hæmorrhoidal plexus in the rectum constituting piles.

The condition is due to some inherited weakness of the venous wall or irregularity in the arrangement of the valves or in cases of veins of the legs, some peculiarity in the lower fascial border of the saphenous opening. Besides these, other factors include persistent distension of a vein due to some pressure from above, such as, a pregnant or displaced uterus or a pelvic tumour; an abnormal communication between an artery and a vein may also result in a varicose condition of the latter. The tendency to varix increases with age and is favoured in old age on account of relaxation of the system resulting from sedentary habits.

TREATMENT. *Palliative treatment.* All sources of obstruction are to be removed. Massage is to be resorted to and the application of an elastic stocking or an India rubber bandage is useful in these cases. The bowels should be regulated and measures to promote general health should be adopted. Varicose ulcers and eczema are to be treated with soothing and drying ointments.

Injection treatment. The idea of injection treatment of varicose veins is to introduce some sclerosing solution of a drug to cause a chemical injury to the endothelium. It sets up a plastic thrombophlebitis without causing much pain to the patient whereby obliteration of the vein is also secured. The solution for injection should be cheap, easily dispensable, non-toxic, and should not produce any constitutional

disturbance. Further it should be sterile and antiseptic so that it does not produce any inflammatory changes at the site of injection. Prior to injection, the site is to be rendered surgically aseptic. The following solutions are used. (1) 30 per cent. lithium salicylate with 1 per cent. tutocaine (lithocaine). It is considered to be one of the best solutions and should always be freshly prepared before injection. The usual dose is 4 c.cm. The clot produced after injection is firm, hard and extensive with a minimum amount of local reaction. It produces local necrosis of subcutaneous tissues if the solution leaks outside and around the vein during the injection. (2) Quinine urethane solution contains quinine hydrochloride (B. P.) 60 gr., urethane 2 gr., and distilled water 30 c.cm. (Genevriev's solution). The dose varies from $\frac{1}{2}$ to 2 c.cm. Test for quinine idiosyncrasy should be made before the injection. The injection is painless and the sclerosis produced is extensive and permanent. A dose larger than 3 c.cm. should never be injected. The drawback of the injection is that untoward effects sometimes follow administration of quinine and an indolent ulcer may be produced if the solution leaks into the subcutaneous tissues. (3) Salt solution. The solution used consists of a 20 per cent. solution of sodium chloride to which 1 per cent. tutocaine has been added. This is suitable for small intradermal varicose veins only. Sometimes the solution is too strong for the veins, resulting in sloughing ulcers. (4) Sodium morrhuate. 5 to 10 per cent. solutions are used with the addition of 0.5 per cent. phenol as preservative. If 5 per cent. solution is used, $\frac{1}{2}$ to 1 c.cm. of it should be injected at different sites, three to four inches apart; the maximum dose should not exceed 5 c.cm. at one sitting. The tendency to production of an injection ulcer is less, but the end results are disappointing as they may show some degree of recanalization. (5) The 'twin injection' with quinine-urethane (2 c.cm.) and lithium salicylate 4 c.cm. injected from two separate syringes simultaneously at a distance of two to four inches in the same vein, are best practised on large tortuous veins. The results are satisfactory.

Contraindications to injection treatment are deep thrombosis of veins, phlebitis, pregnancy, advanced cardiac, pulmonary and renal disease, diabetes, marked cirrhosis of liver, generalised skin diseases. Complications of injection treatment are, injection ulcer, cellulitis, pulmonary embolism and infarction.

The results of excision of varicose veins have not been satisfactory in all cases. The scope of operation varies with the actual conditions present and the surgeon plans his operations on the merits of individual cases.

VERTIGO. The word vertigo means rotation and it is defined as a sensory disturbance with hallucinations of rotation, either of the patient (subjective vertigo), of his surroundings (objective vertigo) or both. Russell Brain holds that in vertigo the common factor in these hallucinations is the abnormal feeling of spatial disorientation,

no matter what plane they occur in and so he defines it as the sensation of a disordered orientation of the body in space. The nuclei and ganglia in the mid and hind brain are closely linked together and they all take part in the tone and position of the body, both static and kinetic. They are also in touch with the ear and eye and with the cornua of the spinal cord. The cerebellum and the nucleus of Deiters with their afferent vestibular influences are chiefly responsible for the symptom complex of vertigo. The cerebellum is essentially a co-ordinating centre for equilibration. Besides its afferent impressions from muscles and joints and the muscles of the head and eyes concerned in the maintenance of tone and balance of the body, the most important are those from the semicircular canals of the ear *via* the nucleus of Deiters. The semicircular canals form a sensitive register of stability and equilibrium. When stimulated, the labyrinths respond by external symptoms of vertigo, nystagmus and forced movements of the head and body.

ÆTIOLOGY AND CLINICAL TYPES: *Aural vertigo.* A systematic examination of the ear by the otologist is most essential. Wax in the external meatus, a blocked Eustachian tube, nasopharyngeal catarrh, middle ear disease, cholestromata, disease of the mastoid antrum, all should be borne in mind. A lack of patency of the Eustachian tubes with invagination of the tympana is a most potent cause of vertigo. Spasm of the tensor tympani or stapedius can also cause vertigo by disturbing the stapes. *Auditory vertigo* is not commonly produced by labyrinthine diseases but by other inflammatory causes and pressures from without or it may be entirely a reflex phenomenon. A patient with auditory vertigo experiences a sense of rotation either of himself or of his surroundings. As manifestations of cochlear disturbances, deafness and tinnitus might develop, nystagmus, forced movements, nausea and vomiting may also be seen. In Meniere's disease, the vertigo is severe and auditory in type. In the acutest form of the disease, the symptoms comprise giddiness, reeling, deafness, tinnitus, nausea, vomiting, cold clammy sweat, etc. Various causes have been brought forward to explain the syndrome but the ætiology is obscure. Meniere originally suggested that hæmorrhage into the labyrinth was responsible for the condition while others believe that this is due to a faulty water metabolism. The cerebral type of vertigo is less severe than the labyrinthine one. The common causes are cerebellar abscesses, tumours particularly in the posterior fossa, vascular cerebral lesions, etc. *Ocular vertigo* is due to a low degree of astigmatism, a strabismus of paralytic type and anomalies of muscle balance—heterophoria. A simple test of ocular vertigo is to ask the patient to open and close his eyes. If vertigo is present when the eyes are open, the vertigo is ocular and not aural. Cardio-vascular causes. Sudden cerebral hyperæmias or cerebral anæmia, organic heart disease with vasomotor failure, low blood pressure in convales-

cents, Stokes Adams' Syndrome and other arrhythmias are all predisposing factors of vertigo.

Miscellaneous causes. Vertigo is often complained of by neurasthenics and this is a common complaint of the female sex at the menopause. In disseminated sclerosis, a sensation of dizzy swaying is complained of. The vertigo which sometimes becomes severe and paroxysmal in nature is of pontine origin. Irritation due to intestinal parasites may be a reflex cause of vertigo. Of other reflex causes, diseases of the pelvic viscera in females deserve mention. The toxic causes responsible for the symptom are: intoxicants like tobacco and alcohol, drugs such as quinine, salicylates, the belladonna group and arsenic, bacterial toxins, syphilis, both the congenital and acquired types, herpes zoster of cranial origin. Mumps and influenza, as instances of acute toxic diseases, are known to cause severe vertigo. Epilepsy and migraine have also aura of vertigo. A small dose of quinine can differentiate an auditory vertigo from epileptic aura. It relieves the vertigo but not epilepsy. Finally, endocrine and vegetative disorders with unbalanced sympathetic and parasympathetic systems, should always be considered as potent causal factors of vertigo.

1. *Postural deviation.* The patient, with eyes closed and feet brought together, tends to fall towards the diseased side in irritative vestibular lesions. 2. *Kinetic deviation* (Barany's pointing test). The patient sits opposite to the physician and raises his arm, with the elbow straight, to touch the tip of the physician's finger with his own. He is then asked to repeat this with eyes closed. If the labyrinth on one side is paralysed, he tends to deviate or point past to the side of the lesion. 3. *Nystagmus.* Irritative labyrinthine lesions produce spontaneous vestibular nystagmus to the opposite side, that is, the eyes make a slow movement to the same side and a rapid twitch back to the opposite side. 4. *Rotation test.* The patient is seated in a chair which is very rapidly rotated for some time. The chair is then stopped and the patient looks in a direction opposite to that in which he has been rotated. Normally there is nystagmus in a direction opposite to that in which he has been rotated. 5. *Caloric test.* In this test, the tympanum should at first be inspected to see that it is not perforated and the external auditory meatus is free from wax and growths. The patient lies down and the external meatus is syringed with cold water (68°F). Cold air, blown through a coiled tube cooled by a spray of ethyl chloride, may also be used as a stimulus. Hot water (120°F.) is used when no response is obtained with cold stimulus. If the labyrinth is intact, the normal response to the stimulus is in form of a nystagmus away from the tested side. A hot stimulus generally results in nystagmus towards the tested side. If the nystagmus is not produced, there is a paralytic labyrinthine lesion.

TREATMENT. If the treatment is to be successful, a correct diagnosis of the underlying cause is most essential. The treatment of vertigo is therefore one of its primary cause. Luminal, in doses of 4

to 1 gr. thrice daily, is of particular benefit in auditory peripheral vertigo. In severe cases, alcoholic injections have been tried. Marked success has sometimes been achieved by the section of the auditory nerve. In case of blockage of the Eustachian tubes, inflation by an Eustachian catheter should be resorted to. Tweedie reports encouraging results by using small doses of iodides (1 or 2 gr.) thrice daily when inflation or dilatation methods failed to cure or improve the condition. Very small doses of sulphate of quinine ($\frac{1}{4}$ gr. thrice daily) are very effective in diminishing the sensibility of the labyrinth. In cases of head injury resulting in concussion, a dose of 1/96 gr. of perchloride of mercury often relieves severe tinnitus and vertigo. Amyl nitrite gives relief in giddiness of arteriosclerosis. A salt-poor diet with restriction of fluid intake (40 oz. in 24 hours) and iodides should be the real sheet anchor in the disease. In neurotic cases, bromides such as bromide of sodium (20 gr. at night) afford prompt relief. The belladonna group of drugs is very helpful in sea-sickness. Chronic infections of the nasopharynx, tonsils, teeth, accessory air sinuses should be dealt with on usual lines. Various operations are performed to rectify disorders of the outer and middle ear. Pericarotid sympathectomy may be helpful in angiospasm. In intracranial diseases as increased tension due to growth, operation for decompression and other intracranial surgery may be resorted to. In the vertigo of acute toxic cases, relief may be obtained by ice cold water bottles applied over the occipital region.

VISCEROPTOSIS. Visceroptosis or Glenard's disease, denotes a syndrome characterised by an abnormal descent of the abdominal viscera with signs of irregular abdominal pains and dyspepsia. The descent of viscera is usually due to a fall in intra-abdominal pressure and is often associated with impaired tone of the abdominal and pelvic muscles. When the intra-abdominal pressure is abnormally low, the organs drop directly due to gravity and the degree of ptosis of different viscera depends upon their weight and also upon the length and elasticity of their peritoneal attachments which act as true ligaments for the support of the organs. A considerable amount of stretching and even damage is done to the abdominal and pelvic muscles during pregnancy and parturition in women and if sufficient rest is not enjoined, later on the tone of such muscles is permanently impaired. Weakness of abdominal muscles is also commonly seen in individuals who are not used to moderate amounts of exercise daily for the upkeep of health. In cases of malnutrition in conditions like rickets and prolonged pyrexia, degeneration and even atrophy of muscles have been marked.

Sometimes the greater curvature of the stomach has been found after radiography to descend as low down as the true pelvis and the condition is then called *gastroptosis*. The condition has, however, been found to be congenital. Glenard has observed in *enteroptosis* kinks of

the intestine, especially at the flexures of the colon; pelvic cæcum and a low tranverse colon are often referred to as if they are invariably associated with constipation. In *hepatoptosis* the liver drops, rotates towards the right or sometimes falls forward so that its upper surface bulges in the epigastrium. In these cases the liver is not enlarged but is simply displaced. In case of a dropped spleen the organ can be shifted to its original position and such is also the case with the kidneys.

Various other causes have also been suggested for the displacement of abdominal viscera and the principal ones include a congenital mal-position, a pendulous abdomen with excess of intra-abdominal fat, and faulty postural habits. In all these cases the symptoms, if any, usually abate when the patient lies down and the organs resume their original positions.

The symptom is a vague pain experienced by the individual only when an erect position is assumed and is temporarily relieved when the lower part of the abdomen is compressed by some suitable means. Besides, signs of dyspepsia are often complained of by the sufferers. The symptoms are usually long-standing and ultimately the victims become neurasthenic.

TREATMENT. The condition in most cases can be prevented by suitable treatment. Prolonged rest combined with suitable diet and tonics go a long way to prevent the condition in parturient women. Constipation if any should always be corrected by proper purgatives. Graduated exercises should be taken by women to strengthen their abdominal and pelvic muscles, particularly after child birth. This helps to regain their normal postural tone and thus raise the intra-abdominal pressure. When the organs have dropped down low in the abdomen, some sort of support is required to hold them. A suitably fitted Curtis belt, serves the purpose well. Much comfort is then experienced by patients and most of the symptoms disappear. When the visceroptosis is due to weakness of the pelvic floor, exercise, local treatment by pessaries or even operation may be required to restore the tone of the muscles. In all these cases prolonged rest in bed constitutes the proper line of treatment. The normal routine should be gradually taken up by the patient only when symptoms subside. The diet should be of a mixed type including sufficient amount of proteins, fresh fruits, fats but not carbohydrate for symptoms of flatulent dyspepsia predominate in these cases. The meals should always be small but taken at frequent intervals so as to avoid over-loading of the stomach. The intake of fluids should be similarly restricted. Of the drugs, sedatives may be conveniently administered to neurasthenic subjects to calm their irritated nervous system and to promote sleep. If anæmia is present its treatment with iron, arsenic and other hæmatinic drugs help to restore the tone of the muscles and improve the general health of the patient. Massage,

both general and abdominal is highly beneficial in these cases. Electric treatment with sinusoidal current is helpful in restoring the tone of muscles. A change of climate is of immense value in improving the general condition of the neurasthenic subject. If medical treatment fails to relieve the patient surgical operations to restore the organs to their respective positions should be adopted as a last resort.

VITAMINS. See*page 176 and Appendix.

VOMITING AND NAUSEA. Vomiting or regurgitation of the stomach contents through the mouth is one of the emergencies sometimes required to be urgently attended to. The two symptoms of nausea and vomiting are common in many diseases where the latter is preceded by the former. Various causes may be grouped according to peripheral or central origin. Psychic impressions from unpleasant sights, odours or even thoughts, any profound emotion such as grief, anger or fear, count in a number of cases. Functional nervous disorders such as hysteria neurasthenia and psychasthenia are also held to be common factors in the causation of the symptom. Habit plays an important role in many cases. Diseases of the brain and its meninges, brain tumours, or cases of head injury are responsible in cases where it is of central origin. It also occurs in such diseases as dengue, malaria, cholera, scarlet fever, nephritis, migraine, and is a common symptom in sea-sickness, mountain-sickness and car-sickness. It is commonly met with in a variety of pathological processes in the abdomen such as appendicitis, intestinal obstruction, and diseases of the biliary apparatus and the urogenital organs. Irritation of the eyes, ears, nose, larynx, pharynx, œsophagus, stomach or the upper intestinal tract, is also a common ætiological factor. It is met with in pelvic diseases, disorders of menstruation and pregnancy in women. It is also seen after the toxic effects of anæsthesia, arsenic poisoning and uræmia. The prolonged intake of drugs such as digitalis, salicylates and morphine is also sometimes responsible for the condition. Vomiting in infancy is a common condition and the causes are middle ear disease, acute illness like pneumonia, cardiospasm, pyloric stenosis, over feeding, habit vomiting and worms. The actual act of vomiting is preceded by giddiness, salivation, rapid pulse and breathing.

TREATMENT. The treatment of all cases should aim at the investigation of the causal factors. Perfect mental and physical rest should be enjoined and the patient should be put to bed in a darkened room and excluded from noise, excitement, business cares and domestic worries. When sleep is induced nausea subsides in most cases. An ice bag to the head or sucking lumps of ice is often of distinct advantage. Many advocate the application of cold to the head and heat to the abdomen. Mustard poultices to the epigastrium have constituted a

favourite domestic remedy from time immemorial. During nausea there is usually more or less complete anorexia and as feeds by mouth are likely to aggravate the condition, parenteral routes are usually resorted to for the nourishment of the patient. The administration of saline and glucose combined with insulin is of particular benefit in these cases. A 5 per cent. glucose solution is an ideal feed during this time. Half to one fluid ounce of carbonated water or ginger ale every $\frac{1}{2}$ to 1 hour are useful drinks and are known to relieve the condition. As the condition improves a change of dietary may be instituted with the inclusion of strained soups, well cooked cereals and cereal broths or a suitable diet may be chosen according to the liking of the patient. In cases of protracted gastric vomiting washing out the stomach with $\frac{1}{2}$ per cent. sodium bicarbonate solution is sometimes very effective and this should always be tried when a toxin is suspected to be the cause of the condition. Tincture of iodine in 1 min. doses in a teaspoonful of water given every half an hour is sometimes useful. In cases of constipation and indigestion the bowels should be evacuated with suitable purgatives or preferably by an enema. The anti-emetic group of drugs include carminatives such as different forms of alcoholic beverages, spirit of peppermint and chloroform water, antacid, protectives including salts of bismuth and oxalate of cerium, sedatives, *e.g.*, bromides, chloral hydrate, morphine, barbiturates. The bromides are the best sedatives for all vomiting of central origin. They are said to depress the sensory centres and cut off the peripheral reflexes. Sodium bromide though containing a proportionately larger amount of bromine than the potassium salt is less active and is better tolerated by patients in heavy doses such as 15 to 20 gr. four times a day. Phenobarbital is extensively used for nausea, particularly in cases of pregnancy, in small doses about $\frac{1}{2}$ gr. three times a day. For local and peripheral action salts of bismuth, oxalate of cerium, cocaine and phenol are mostly used. The drugs are helpful in cases of irritation of the pharynx, oesophagus or stomach. Of the bismuth salts, bismuth subnitrate is usually given on an empty stomach in 30 gr. doses repeated every 2 hours till the condition improves. In nausea or vomiting of pregnancy, hysteria, epilepsy and migraine oxalate of cerium is used in doses of 3 gr. The local application of cocaine to the nasal mucous membrane has been recommended for the relief of nausea. The treatment of cardiospasm in infants consists in giving non-irritating diet and the occasional introduction of bougies through the cardiac orifice. In pyloric stenosis daily gastric lavage is of benefit and surgical treatment affords a radical cure. Over feeding in children should never be encouraged and feeds should be served at regular interval.

WARTS (Verruca). The treatment of warts is very important as every practitioner is expected to deal with such cases in daily life. Warts may occur in every part of the body. The cause is obscure though it has been suggested that a filterable virus is responsible. These growths are

usually sharply demarcated from the surrounding skin. The chief symptom is pain on pressure. Warts should be distinguished from corns or callosities.

TREATMENT. Should aim at complete removal of the growth; if any portion is left, regrowth will occur. Drugs are of little value for the purpose. Caustics such as trichloroacetic acid, nitric acid or pure carbolic acid have been used but are not suitable. Excision is likewise not desirable for uncontrollable bleeding may occur. The following are some of the agents that are commonly employed: (1) *Radium* application is the best method but it is not within the reach of every case. After such treatment, the wart becomes soft and uncrusted and then separates leaving a cavity which requires filling with antiseptics for some time. (2) *X-rays*. A full pastille dose should be administered using a 1 mm. aluminium filter. The surrounding skin must be protected. Pain disappears always after treatment. (3) *Carbon dioxide snow*. Warts may be frozen with snow. The stick is held against the growth for $\frac{1}{2}$ to 2 minutes. Preceding such treatment the wart may be softened by prolonged hot fomentation or by the application of a 25 per cent. salicylic acid plaster about 24 hours before. If treatment is successful, the wart is found adherent to the blister formed by the snow. This should be cut away and the cavity is filled with bismuth subgallate powder or packed with cyanide gauze. (4) *Electrolysis*. It is difficult to ascertain the exact time of destruction of the growth with electrolysis and it is not recommended. (5) *Curettage*. A general anæsthetic, if warts be multiple, or a local anæsthetic like novocaine, may be used if a few only are present during curettage. All traces of warty materials should be scraped away with a sharp curette (Volkman's spoon). Bleeding is controlled with the galvano-cautery. The part is then painted with iodine and a dressing applied. If the patient complains of much pain, a 5 per cent. stovaine ointment may be applied. (6) *Vaccines* made from the emulsion of tissues may be tried along with local treatment. Intramuscular injections of bismuth salicylate (2 gr. in 1 c.cm. of sterile olive oil) have been favourably reported, only two doses are required.

WEIL'S DISEASE. It is a form of epidemic jaundice with fever, vomiting and hæmorrhage described by Weil in 1886. In 1915 the causal organism was isolated and is known as *Spirochæta ictero-hæmorrhagica*. The disease is probably of world-wide distribution but is most common and severe in Japan. It occurs widely among rats. The infection is believed to enter man by contamination of food and drink or probably by direct passage of the organism through the skin. Bites by infected rats may also convey the disease.

Diagnosis. (1) Presence of sudden fever, prostration, herpes and jaundice; about the third day hæmorrhages (epistaxis and mæna) often occur in severe cases. Rash on the body is very common. The

urine contains albumin and bile. (2) Blood, (a) *Leptospira* is present up to the fifth day, but is too scanty to be detected. (b) The blood count shows leucocytosis and secondary anaemia. (c) The platelet count is low. (3) Guinea-pig inoculation. Intraperitoneal injection of 3 to 5 c.cm. of the patient's blood produces jaundice, collapse and death of the animals in 24 hours after an incubation period of 6 to 13 days. (4) Urine is scanty and contains albumin, bile and blood, and *leptospira* are present after the tenth day. Guinea-pigs may be inoculated with the infectious urine.

TREATMENT. (1) Rest and fluid diet, general and symptomatic treatment. (2) The Serum of convalescent patients may be tried, dose 30 c.cm. daily. Serum of immunised horses has been used in Japan with success. (3) Urotropine given intravenously daily for 3 days in doses of 5 c.cm. of a 40 per cent. solution. (4) Intravenous injections of normal saline with 5 per cent. glucose are given in severe cases. Rectal saline may also be given. (5) Calcium is given for hæmorrhage.

Prophylaxis. Rat extermination, avoidance of infected soils, disinfection of hands, avoidance of public baths, etc.

WHOOPIING COUGH (Pertussis). It is an acute specific infectious malady characterized by catarrh of the respiratory tract, paroxysmal attacks of coughing followed by a long noisy inspiration (whoop) and signs of nervous disturbances. The disease is especially one of childhood, between the ages of 1 and 10 years. The period of incubation is from 3 to 14 days. According to Bordet and Gengou, the causal organism is a coccobacillus (*Hæmophilus pertussis*) which is present in the mucous membrane of the respiratory tract.

Diagnosis. (1) Clinically the onset is marked by a preliminary catarrh which lasts for 7 to 14 days. Towards the end of the period the cough assumes a paroxysmal character with occasional attacks of vomiting. Several paroxysms may occur in quick succession. Each paroxysm consists of a rapid succession of short coughs with open mouth and protruded tongue which are continued until the chest is emptied of air; relief is obtained by relaxation of the laryngeal spasm and the occurrence of the *whoop* (very diagnostic). As a result of coughing, large quantities of bloodstained stringy mucus are expectorated. (2) The presence of sublingual ulcers may be of assistance. (3) Leucocytosis is considerable in the early stage and the presence of lymphocytosis is of confirmatory evidence. (4) Bacteriological diagnosis by culturing the expectoration in Bordet-Gengou medium.

TREATMENT. (1) *Isolation* should be enforced, but free ventilation and fresh air are necessary. The diet should be light and when vomiting is present food should be given in small quantities at intervals. (2) *Drugs.* During the catarrhal stages a simple expectorant mixture is useful to control paroxysms. Belladonna in fairly large

doses (10 to 20 min. of the tincture) is the most effective drug; other sedative drugs are bromide, antipyrine, chloral hydrate. Benzyl benzoate has been recommended in doses of 5 to 40 min. of a 20 per cent. alcoholic solution 3 to 4 times a day; intramuscular injections of 1 to 2 c.cm. of ether are said to reduce the number of paroxysms, but the method is painful. (3) *Vaccines* prepared from Bordet-Gengou bacillus or associated with other organisms, have been used both as prophylactic and curative, but the effect is uncertain. (4) *Radiotherapy* is said to mitigate the severity of infection.

Prophylaxis. (1) The patient should be isolated for about 5 weeks from the commencement of the whoop provided the paroxysmal cough has ceased for a fortnight. (2) Disinfection of room and clothing. (3) Convalescent serum and vaccine may be used prophylactically.

YAWS (*Framboesia*). Yaws is a specific infective granuloma caused by a spirochæte, *Treponema pertenue*. It is not a venereal or congenital disease though the course resembles syphilis. The causal organisms *T. pertenue* gain access to the body through insect bites, cuts, abrasions, etc. Varieties of yaws are (1) Crab yaws: affects the sole of the foot. (2) Gangosa: granuloma ulcerating in the palate. (3) Goundou: a nodular swelling on the nose. (4) Juxta-articular nodules may form tumours near the knees or elbows.

Diagnosis. The primary lesion occurs extragenitally which is not always demonstrable. The secondary stage consists of development of papules which may coalesce into larger masses. Later the scales fall off, the characteristic raspberry-like granuloma forms, from which the name framboesia is derived. Yellowish fluid is exuded which dries, and forms a heaped-up yellow crust resembling syphilitic rupia. The spirochætes are generally found in abundance in the thickened epidermis. The Wassermann test is positive in practically all cases. It is distinguished from syphilis by the facts that the primary lesion is never venereal, the central nervous system is never attacked, the disease is not hereditary and it fails to yield to mercury treatment. *Laboratory diagnosis.* Clean serum that exudes after scraping the margin of the lesion with the blunt edge of a scalpel is examined for treponema either by dark ground illumination or made into a thin film and stained by Tribondeau's modification of Fontana's stain.

Treatment. For an adult 0.5 to 0.6 gm. of salvarsan intravenously or sulpharsenol intramuscularly. The lesions heal after 2 to 3 injections but it is advisable to give 6 injections at weekly intervals. Locally the sores should be dressed with mild antiseptics.

Prophylaxis. Isolate the patient and protect the open ulcers. (See page 655)

YELLOW FEVER. See page 990.

APPENDIX I

Appendix I contains upto date informations regarding certain subjects published since these sections were printed in the book. It is composed of abstracts from articles in journals and other works and should be read along with the subject matter dealt with on the pages indicated.

MALARIA

Atebrin in Labour Forces. The new synthetic drugs plasmoquine and atebrin have simplified the treatment and greatly reduced the relapse rate in malaria. Some of those who continue to use quinine admit that with atebrin there is a lower relapse rate, but they express their preference for moderate doses of quinine given for several periods of a few days each, their main object being not to cure the malarial infection at once, but to produce an increased resistance to the disease by allowing the sufferer to pass through a few mild attacks. Incidentally, this must produce a number of reservoirs for the spread of further malarial infection.

ROUTINE OF ATEBRIN TREATMENT (p. 605). The method followed in using atebrin is :—As soon as the patient enters hospital he is given a purgative—usually, for an adult, calomel 3 gr. followed by mist. alba, 2 or 3 oz. after a few hours. His blood is taken and the type of parasite determined. A dose of stock diaphoretic mixture three times a day until fever subsides helps to promote sweating and lessen distress. After the blood has been examined and a purgative and diaphoretic mixture given, the administration of atebrin is commenced. In proportion to age, children require bigger doses than adults. Each tablet of atebrin contains 0.1 gm. ($1\frac{1}{2}$ gr.); the dosage followed in ordinary cases is :—

Infants, up to $\frac{1}{2}$ a tablet daily.

Children of 1 to 3 years, from $\frac{1}{2}$ to 1 tablet daily.

Children of 3 to 5 years, up to $1\frac{1}{2}$ tablets daily.

Children of 6 to 10 years, $1\frac{1}{2}$ to $2\frac{1}{2}$ tablets daily.

Children of over 10 years, and adults, 3 tablets daily.

The temperature will usually fall to normal within 2 or 3 days.

If the temperature does not rise again above 99°F. after 48 hours, the atebrin treatment is continued for 5 days only. If the temperature stands above 99°F. at any time during the third or fourth day atebrin is continued for 6 or 7 days. Atebrin is not given for longer than 7 days in one course. When the malaria is subtertian in type a course of plasmoquine is administered after the atebrin treatment is completed :

plasmoquine has also been given in relapsing cases of benign tertian, but not in primary cases. The dosage of plasmoquine used for an average adult is 0.01 gm. tablet three times a day for 5 days—for a child of 10, half of a 0.01 gm. tablet three times a day for 5 days, and for a child of 6, one-third of a 0.01 gm. tablet three times a day for 5 days. Children under 6 years are not given plasmoquine without special orders. As regards atebirin for injection purposes, the earlier preparations were too insoluble. This difficulty has now been overcome by the production of a very soluble salt, known as atebirin musonate. It is a dimethanesulphonate of atebirin supplied as a yellow powder in sealed ampoules, containing 0.125 gm. each, corresponding to the single dose of 0.1 gm. of the atebirin bihydrochloride tablet for oral use. Each powder is dissolved in exactly 3 c.cm. of water before injection. The contents of one ampoule is the maximum single dose that should be given intravenously, but three times this amount, comprising one day's treatment, may be given intramuscularly at one time. The indications for the injection of atebirin musonate are the presence of high or persistent fever, severe vomiting, the advent of cerebral symptoms. In addition, it may be valuable for the rapid treatment of supervised cases in the course of a great epidemic. In Ceylon it has recently been tried in this way, 0.375 gm. (*i.e.*, the contents of three ampoules) being dissolved in 9 c.cm. of water and injected into the buttock daily in one dose on two successive days only. Blaze and Simeon claim that as a rule the fever and parasites disappear entirely after these two injections. The relapse rate, after such a short course, will probably be high. Atebrin is usually well tolerated by young and old, by infants, pregnant women, nursing mothers and persons in whom other diseases are complicated by malaria. Vomiting is rarer than with quinine; most patients prefer atebirin and many experience a sense of well-being and increased appetite during treatment.

Results. Under the treatment outlined the temperature is usually normal on the second or third day and seldom rises again above 99°F. In a proportion of cases the temperature is higher, and the parasites are more numerous on the second day than on the first day, owing to the provocative effect of atebirin on the parasites. All parasites usually disappear by the third day; and, except for crescents, none are found in any patient on discharge from hospital. As an exception, the temperature of one man with a subtertian infection remained above 99°F. for 216 hours though four injections of quinine bihydrochloride 10 gr., and four injections of atebirin 1½ gr. were given intramuscularly, and atebirin and quinine were used consecutively in treatment—each for 5 days. The average time spent in hospital when plasmoquine was not administered after atebirin was 7½ days; many patients were discharged in 5 days. When plasmoquine was given separately after atebirin the patient was sometimes in hospital for 10

or 11 days, though part of this after-treatment was occasionally given in the lines.

PLASMOQUINE AS AN ADJUNCT TO ATEBRIN TREATMENT. Atebrin treatment by the eradication of schizonts prevents the formation of later generations of gametocytes. The earlier broods of gametocytes will die out in a few weeks. Whether plasmoquine should be given to kill the latter, depends therefore on the risk of infection being conveyed to others in any particular estate. In this several factors are involved; the number of persons with gametocytes in their blood; the number of malaria-carrying anophelines present (most important), the number of bites received from infected mosquitoes; the intensity of the infection conveyed; the effectiveness of the antimalarial work. A change in the level of the surface water, an influx of unhealthy new labourers or the clearing of new area may necessitate the adoption of measures not previously needed. The League of Nations Malaria Commission's Report (pp. 236-237) suggests that the percentage of malarial cases containing gametocytes in their blood may at times be as low as 1 per cent. though in children it may be 17 per cent. or more. But Green, in a series of 1,000 sub-tertian cases found that over half carried crescents in the proportion of 1 or more per 200 leucocytes and were therefore potentially infective to *Anopheles maculatus*. If these high rates are common the argument for giving plasmoquine is strengthened. Green found also that gametocytes seldom appeared before the 6th day in new infections and took on an average nearly 8 days to disappear under treatment with plasmoquine compound—the limits being 4 to 13 days. It may be assumed therefore that the treatment with plasmoquine simplex should not be started before the 6th day in primary attacks, and that with an adult a dosage of from 0.02 gm. to 0.03 gm. daily should be continued for from 5 to 7 days.

USE OF ATEBRIN FOR PROPHYLAXIS (page 607). The recent Report of the League of Nations Malaria Commission stresses the fact that quinine, even when given in the fever-free and parasite-free period just before a relapse, exhibits a lack of therapeutic action. Also, a considerable proportion of persons with enlarged spleens, chiefly of the fibrotic type, harbour no parasites at all, and some of them have acquired an immunity. The routine use of quinine for enlarged spleens has now been abandoned: atebrin treatment has been substituted for selected cases only—especially for new locally-engaged labourers who have either a recent history of malaria, parasites in their blood, or a temperature. No treatment is given to those with fibrotic spleens nor to any who have already received a course of atebrin for malaria, and who show no relapse, symptoms on examination. Acting on these lines a prophylactic course of atebrin was given, to about half of 962 persons found with enlarged spleens at special examinations in 1933, and to a similar proportion in 1934. Those who appeared ill were put in hospital, but the majority remained at work and received a 5 day's course of three tablets

daily given in one dose after they had come in from the field; no ill effect were observed. Wallace, working in Kedah, finds atebirin is the most effective drug for mass treatment at the beginning of the malarious season. In 1933, on one of his estates where malaria was seriously affecting the labour, no cases occurred within a month after a 5 day's mass course of atebirin and the malaria rate remained low for the two succeeding months. On another malarious division where the parasite rate was 18 per cent. amongst adults and 23 per cent. amongst children, a 5 days' course of atebirin and plasmoquine reduced the parasite rate to nil. After this 0.02 gm. plasmoquine was given three times weekly for 3 months, at the end of which the parasite rate was: adults 3.5 per cent., children 5 per cent. These doses of plasmoquine will inhibit the sexual forms and thus prevent infection of others.

COST OF ATEBRIN TREATMENT. Green states that atebirin is the cheapest drug for treating malaria if labourers are not subject to frequent reinfection, because it is superior to quinine both for destroying benign tertian and quartan gametocytes and for preventing relapses. It has no effect on sub-tertian gametocytes, for the destruction of which plasmoquine must be given. In two large comparative series of cases from the same estate, Green found that the percentage of days spent under treatment per unit of population, including a preliminary mass treatment, was atebirin 7 per cent., quinine 27 per cent. With atebirin the relapse rate was much lower, the working efficiency was maintained at a high level, and far fewer working days were lost. During the past 3 years in Malacca, the cost of a 5 days' course (15 tablets) has varied between 72 and 89 Straits cents (1s. 8d. to 2s. 1d.). Allowing a 15 per cent. relapse rate for which 12 cents may be added, the maximum cost per head is just over \$ 1 Straits (2s. 4d.). During the same period the price of quinine sulphate has varied from \$ 14.50 to \$ 17 Straits, and of quinine bihydrochloride from \$ 19 to \$ 24 Straits per pound. Taking into account the much higher relapse rates with quinine, not less than 1 oz. is needed for an average complete treatment on estates. The additional cost of 0.15 gm. of plasmoquine given in a 5 days' course is 43 Straits cents (1s.); which course is advisable, at any rate in subtertian infections whether atebirin or quinine has been used. While the total drug treatment with atebirin actually costs less than with quinine in properly supervised cases, there is a still greater saving effected by the low relapse rate lessened absence from work, and the greater efficiency following atebirin; the shortness and simplicity of administration is a further point in its favour. Atebrin is the best drug available for the controlled treatment of all types of malaria in Malaya, where effective oral administration is preferable to injection. (*Trans. Roy. Soc. Trop. Med. & Hyg.* 1935, Vol. 29, No. 3).

Toxicity of Atebrin (see page 608). Owing to the very slow excretion or destruction of atebirin in the body it seems unnecessary

to exceed the dose of 0.1 gm. for an adult for intravenous injection. The margin of safety is probably not great, and intravenous injection should be resorted to only in emergency. The injections should be made very slowly and timed to take several minutes for completion. The total injected over a period of twenty-four hours should not exceed 0.3 gm.

Untoward effects of atebtrin appear to include: gasping or accelerated respiration, circulatory failure, collapse, vomiting, possibly rise of temperature, psychoses, loss of appetite and of weight, abdominal pain, headache, diarrhoea, yellowed sclera, rather persistent yellowing of the skin. Recently various writers have drawn attention to symptoms varying from mental excitability and psychoses up to temporary insanity, after the use of the drug. Disordered mental conditions are well-recognised sequelæ of the treatment of malaria with atebtrin and numerous such cases have been seen during the recent epidemic of malaria in Ceylon. The onset of symptoms generally occurs towards the end of, or immediately after the usual course of 15 atebtrin tablets. Kingsbury (1934) published a record of seven cases of psychical neurosis in malarial patients treated with atebtrin in the Malay States. In the majority of cases the mental disturbance appeared after the usual dosage of atebtrin 0.1 gm. thrice daily for 5 to 7 days, but was generally of short duration. In a more recent publication Udalgama (1935) reports another series of seven cases of mental disturbance in a total of 644 cases after treatment with the standard course of atebtrin (two intramuscular injection of atebtrin musonate, each equal to 0.3 gm. of atebtrin). In five cases mental symptoms developed after the maximum therapeutic dosage in a child aged 8, it followed after two doses of 0.16 gm., and in the other after a single dose of 0.2 gm. Hay and others (1935) used the drug both parenterally and by the oral route in smaller doses and found that mental excitability after atebtrin is rare and when it occurs is easily controlled by sedatives.

The mode in which cerebral symptoms are brought about by atebtrin is not yet understood. It should be remembered that cerebral excitation and more serious forms of psychosis may arise as complications of severe malarial infection itself or they may be due to the action of atebtrin on the central nervous system. There seems, however, to exist some ætiological connection between the mental disturbances and the administration of atebtrin in malarial patients. It is quite possible that following the administration of large effective dose of atebtrin, a sudden liberation of toxins may occur in the tissues as a result of direct lethal action of the drug on the parasites, with consequent production of cerebral symptoms. In addition, a non-toxic dose may sometimes produce toxic affects in certain individuals whose tissues have been damaged by a malarial infection. Whatever may be the exact way in which this is brought about there are certain factors such as age, sex, race, individual resistance, which play a great part in the causation of

symptoms. It has been observed that with oral administration these symptoms are rare; with a moderate parenteral dose (0.15 gm.) they are still comparatively rare and are easily controlled with sedatives, but with larger doses (0.3 gm.) they more frequently occur and tend to be more serious and prolonged. Experience has shown that if the dosage of atabrin is increased above the optimum, the chances of untoward symptoms occurring are increased. A five-day course of atabrin with 0.3 gm. of the drug in divided doses daily as is now used, seems to be a dosage with a considerable margin of safety.

In view of the very slow excretion or destruction of the drug in the body, it has been suggested that a course of treatment with it should not be repeated within a period of, say, eight weeks, and that the drug should be taken only under supervision of a physician.

Totaquina (p. 549). Totaquina is a mixture of cinchona alkaloids prepared according to the formula of the Malaria Commission of the League of Nations. There are two types—Type I and Type II. The report of the Health Committee of the League of Nations (1934) deals with the results of trials with these two varieties on the lines suggested by the sub-committee and with supplies of totaquina provided by them, in a number of malarious countries. Totaquina is not intended to replace quinine, but it is hoped that the use of mixtures of the alkaloids will enable the treatment to be extended among the masses, as these mixtures are likely to be less expensive than pure quinine.

The results of the trials in the different countries have been analysed critically by Fletcher at Kuala Lumpur. Parasite-counting methods were employed in evaluating the treatment with totaquina and at the same time a control series of patients was treated with quinine. The records of the cases analysed, clearly show that totaquina acts like quinine as a potent remedy in all forms of malaria. But the opinion expressed is that a field trial of this kind is not a carefully controlled experiment and when it comes to deciding whether totaquina is a little better than quinine or not quite so good, one is on less sure ground in the absence of adequate controls treated with quinine. The observations made at the different centres were not sufficiently precise and unanimous to warrant a final decision on the relative merits of the different samples of totaquina. As regards toxicity, sufficient evidence was not forthcoming to show that totaquina is more toxic than quinine in the doses given. The findings of the Health Committee after examining this report is that totaquina seems able to fulfil the purpose for which it was intended since its efficacy is equal to or only slightly less than that of quinine.

Hicks and Diwan Chand (1935) performed experiments in India with two types of totaquina. The trial was carried out on the lines suggested by the Health Committee. More than 250 patients were treated and if the untreated control group is excluded, there was an

average of 40 patients in each group and no group contained less than 31, so that in point of numbers it may be considered an important series. The quinine and both types of totaquina for these experiments were supplied by the Madras Government Cinchona Department. The composition of the two types are given below :—

		Type I per cent.	Type II per cent
Quinine	...	32	19
Quinidine	.	1	4
Cinchonine	..	11	20
Cinchonidine	.	30	26
Amorphous alkaloid	...	15	19

The tablets of totaquina each contained 0.25 gm. of the alkaloids. A dose consisted of one or more whole tablets together with one tablet cut down to a size estimated to complete the correct total dose. The conclusions of these workers are that under experimental conditions there was no distinct difference in efficacy between quinine and the two types of totaquina in clearing the blood of parasites either in benign or malignant tertian malaria.

Russell and his co-workers, have on a small scale, carried out an examination of the problem of the treatment of malaria in the Philippines, from the economic, the botanical, the chemical and the medical points of view. From clinical trials reported in this paper the conclusion that can be drawn is that given in the doses in which quinine is usually employed, totaquina is an efficient anti-malarial drug. The final conclusions at which these writers arrive are given in detail because it is thought the problem of treatment of malaria in India is very similar :

"It is not improbable that if every case of malaria occurring in one year in the Philippines could be given a 250 gr. treatment there would be needed at least 30,000 kilo. more specific febrifuge than is now imported.

A 250 gr. treatment with quinine sulphate in the provinces costs from 2.50 to 5 pesos (1.25 to 2.50 dollars United States currency). The greater the need, the higher the price. Quinine dihydrochloride retails for from two to four times as much as the sulphate. These retail prices are far more than the average farmer in the provinces can pay. Quinine and the synthetic drugs, plasmochin and atabrin, may therefore be called a rich man's remedies. There is no probability that much more quinine can be paid for than is now imported.

The Bureau of Forestry has demonstrated that cinchona will grow in the Philippines and will give as good a yield of alkaloids as that

grown elsewhere. From our studies we conclude that the standardised total alkaloid extract of cinchona, recommended by the Health Organization of the League of Nations and called 'totaquina' can be prepared locally from Philippine cinchona easily and inexpensively.

We conclude from some clinical tests that this Philippine totaquina is probably about equal to quinine sulphate in its therapeutic value against malaria.

We conclude that, allowing a fair profit to the grower of cinchona, the manufacturer of totaquina and to the retailer, this Philippine totaquina could be sold to the people at not more than 35 centavos (0.175 dollar) per 250 gr. treatment.

Contrasting 35 centavos with the present retail price of from 2.50 to 5 pesos for a 250 gr. treatment with quinine sulphate or atabrin, we conclude that the local production of totaquina would materially aid in combating malaria in the Philippines.

We also conclude that the growing of cinchona and the manufacture of totaquina might have considerable economic importance to the Islands, being capable of becoming sizeable new industries."

The foremost consideration is now to inaugurate a policy of cinchona cultivation that will eventually place a cheap and at the same time efficient mixture of alkaloids in the hands of malaria-stricken masses of India. (*Ind. Med. Gaz.*, 1935, Vol. 70, p. 567. *Record of the Malaria Survey of India*, March, 1935).

Review of Report of the Malaria Committee of the League of Nations.

TREATMENT OF PRIMARY ATTACKS (p. 617). In selecting the best treatment for an attack of malaria the Commission say that "Quinine has no appreciable effect when given during the incubation period, and it has little effect when given on the first or even the second day of the 'initial fever'. It is much more effective after the patient has had several paroxysms of fever than at an earlier stage, and its effect is greatest when fever and parasites are beginning to decline as a result of the natural defensive mechanism which normal human beings possess" (p. 209). This and other statements found in the report lead one to believe that the Commission advocates that the patient should be left untreated for some days during the primary attack. Such a procedure may be all right under experimental conditions found in mental hospitals but would not be possible under ordinary hospital conditions in malarious countries. Even in induced malarial practices in hospitals where there is insufficient attention to the blood condition, the fatalities due to this strain of benign tertian malaria are not less than 10 to 14 per cent. (p. 217). Such a procedure therefore is likely to be very dangerous in general practice where there is no indication of the virulence of the infecting strain, nor can it be determined with certainty that a mixed infection is present or not.

Sinton and Mulligan (1933) have fully gone into this question and state: "James (1931) reports that the therapeutic action of quinine in benign tertian malaria is considerably enhanced, if the patient be allowed to develop a certain degree of tolerance to the infection before treatment is commenced. He, however, remarks that "it would be unjustifiable at present to withhold quinine from a case of malignant tertian malaria later than the first discovery of parasites in the blood. It appears to us that, in view of the not uncommon occurrence of unsuspected mixed infections in malarial patients in the tropics, one is seldom or never justified in allowing any malarial infection to remain untreated in the hope of obtaining this degree of acquired immunity. It was found by Antic (1925) that in experimental mixed infections with *P. vivax* and *P. falciparum*, the former parasite could be detected at a very early stage of the infection, but that the latter quickly predominated. The more conspicuous morphology of *P. vivax*, and its presence in the peripheral blood during the whole of its schizogony cycle, make it much more easily detectable than the small rings of *P. falciparum* which are usually present in the circulating blood for a much shorter period of each cycle. The latter parasite might, therefore, be overlooked during the first few paroxysms of an acute attack. The difficulty which is sometimes experienced in detecting *P. falciparum* in some early acute cases, has been noted by many workers, even when there has been no mixed infection to obscure the issue. If the patient remains untreated, in the hope that the more benign parasite may produce some tolerance to aid the effect of treatment, the unsuspected infection with *P. falciparum* may quickly predominate. Daily blood examinations are usually impossible under the conditions of general practice in the tropics. If treatment be withheld on the assumption that the primary diagnosis of *P. vivax* is correct, the rapid development of *P. falciparum* may remain undetected until therapeutic measures are too late to save the life of the patient, or at least to avert a pernicious attack."

"While believing that some degree of acquired tolerance probably augments the action of quinine, we do not think that patients can be left, as a routine measure, untreated so that such tolerance will develop. At least it does not seem a wise procedure in areas where *P. falciparum* is common. The shortage of hospital accommodation and expert medical supervision in many tropical areas also precludes this method as a routine step, however desirable it may be under the more carefully controlled conditions of therapeutic malaria."

"The work summarised by Mulligan and Sinton (1933) also suggests very strongly that any immunity, thus acquired, may only be effective against the same strain of parasite, and will have no very marked effect if the patient be reinfected with another strain. Now that several of the new synthetic drugs have been found to have a marked curative

action in chronic infections with *P. vivax*, the necessity for leaving malarial patients untreated in his fever seems to have disappeared to a very large extent."

It will thus be seen that delaying the treatment is not a measure which can be justifiably recommended for use in the majority of hospitals in the tropics nor for practising physicians of any country.

TREATMENT TO PREVENT RELAPSES. The Commission have endeavoured to indicate the principles by which the physician should be guided in selecting a system for preventing relapses (p. 233). It says:—"The frequency and severity of relapses are dependent chiefly on the amount of defensive power which the infected person possesses naturally or acquires as a result of previous attacks. A scientific method of preventing relapses should be based on this knowledge or should take this knowledge into account by allowing an infected person to acquire as much defensive power as possible. Persons who are treated with large doses of quinine or other specific drug at the first onset of fever in their primary attack and in each relapse get no opportunity of acquiring defensive power to prevent relapses. Persons who are so treated usually relapse every month for a very long period. During the primary attack, it may not be safe to abstain for a day or two from giving a specific drug, but it is quite safe to do so in the first and any subsequent relapse."

"In a scientific system for the prevention of relapses, no attempt is made to give 'treatment for the prevention of relapses' during the primary attack. One waits until the first recrudescence and then uses the specific remedies in such a way that they will assist, rather than hinder the development of the patient's natural defensive forces. By repeating this plan with the same watchfulness during the second recrudescence (using the specific drug at a later period and more sparingly than in the first recrudescence) and again, if necessary, during the third recrudescence, it happens, in most cases, that the patient becomes fortified or premunised against the disease to the extent that he not only ceases to suffer from relapses but fails to have an attack when he is 'reinfected'. In the Commission's view, an endeavour to follow that plan should be made for the prevention of relapses of benign tertian and quartan fever. But they consider that, for preventing relapses of malignant tertian fever, it is justifiable to endeavour to sterilise all the parasites by specific drug therapy during the first recrudescence" . . . "The Commission believes that, when it is not justifiable or practicable to prescribe a system for the prevention of relapses, which is based on the above principles, the best practice is to adopt a system of 'clinical prophylaxis' consisting of the administration of a small dose of quinine (0.4 gm.) daily throughout the period of residence in the malarious country and for several months after leaving" (p. 233).

That some degree of acquired immunity is of importance in controlling the clinical manifestations of a malarial attack is probably correct. This acquired immunity probably also assists in the radical cure of the disease specially when helped by the effects of appropriate specific therapy. In certain infections, however, in spite of opportunity for developing high degree of tolerance and specific therapy of a certain nature relapses may continue to occur for long periods. The failure in producing a radical cure is not due so much to a low degree of immunity as to a special resistance of the parasite to the destructive action of the specific drug used. In such cases the obvious thing should be to change the specific drug rather than allow the patient to continue relapsing for months in the hope of obtaining a higher degree of resistance, and so a tolerance which may be broken down at any time by adverse conditions.

It is stated that "the patient becomes fortified or premunised against the disease to the extent that he not only ceases to suffer from relapses but fails to have an attack when he is reinfected." In this connection the work of Sinton and others has shown that in human simian and avian malaria, an immunity such as has been ascribed to one strain of a species of plasmodium, may have little or no effect in preventing acute attacks when the host is reinfected by either heterologous strains or species of parasite. A patient would therefore have the acquired immunity to all the local strains of the parasites, a process which probably takes some years during which he would be in a continuous state of ill-health. It would appear, therefore, that an attempt to develop the premunition is not advisable for patients whose period of residence in a malarious country is short, or who are living under conditions in which the chances of reinfection can be avoided.

DELAYED TREATMENT DURING RECRUDESCENCE OF RELAPSES. The Commission considered that there is little danger to the patient's life on the occurrence of a recrudescence or a relapse of a primary infection. It is suggested that the patient should be allowed to have several febrile paroxysms, and that the amount and duration of specific treatment should be small so that the natural process of premunition may not be interfered with. It is well known that a considerable percentage of malarial infections are radically cured by the treatment given in the primary attack. In induced malaria the reappearance of fever and parasites is undoubtedly a recrudescence or relapse but this is not so under natural conditions in malarious places. In very malarious localities a patient who gets a malarial attack sometimes after the termination of treatment for the primary attack may be a fresh infection with a heterologous strain or species of parasite and not necessarily a relapse. Such an infection may give severe clinical manifestations. If such a case be treated by the method suggested by the Commission, for a recrudescence or relapse or a primary infection, the small dosage

and the delayed administration of the specific drug may allow such serious developments in the infection that it may be too late to save the patient's life, when proper treatment is instituted.

SEPARATE TREATMENT FOR ACUTE ATTACKS AND FOR RELAPSES. The Commission considers that "It is seldom or never in the best interests of patients to endeavour to combine a plan of treatment designed for the prevention of relapses with a plan having for its object the rapid clinical cure of an acute attack (p. 214). The two problems (cure of primary attack and prevention of relapses) are so entirely different that, in the opinion of the Commission, it is incorrect to endeavour to accomplish them both at the same time" (p. 215). Such a dissociation of the two treatments may be possible and advisable under conditions of therapeutic malaria, but in the tropics and in most malarious countries this would not be possible. The clinical effects of atebirin and quinine are apparently very similar, and there would not seem to be much advantage in administering them at the same time, to produce greater effect in the production of a radical cure. Some authorities consider plasmochin to be of very great importance in preventing relapses of benign tertian malaria when combined with quinine, so that they could be combined in the treatment for a radical cure of this infection.

CLINICAL PROPHYLAXIS. "Clinical prophylaxis is correctly defined as being a procedure for curing slight clinical attacks of malarial fevers—it is a curative, not a prophylactic measure" (p. 204). "The Commission is of opinion that quinine is effective for this purpose and that it is the best drug to use. The correct plan is to take a daily dose of 0.4 gm. (6 gr.)." Although it is quite likely that beneficial results with regard to morbidity and mortality may be obtained in malarious areas by this plan, such a plan cannot be put into practice among the undisciplined and uncontrolled population. Even if it was, the expense of the drug and the cost of distribution would make it prohibitive. Sinton obtained good results in lowering malarial morbidity and inefficiency among troops in India by this measure but the plan is wasteful and expensive.

One of the reasons given by the Commission for its advocacy of this method of clinical prophylaxis is that "it does not entirely eradicate the infection, the defensive mechanism of the body is continuously at work and becomes increasingly powerful as time goes on ('acclimatisation without risk')" (p. 235). If the defensive mechanism of the body is stimulated by the parasites, it may be argued that a much more powerful stimulus would be given if they were destroyed only when they were sufficiently numerous to produce fever (*i.e.*, when fever is imminent) rather than being continually kept at a very low level. If the benefits of clinical prophylaxis after a single infection are thought to depend mainly upon an increased defensive action of the

body, its benefits would, theoretically only be applicable to one strain of one species of parasite only, for the defensive action against a single strain should have little or no effect upon superinfection with a heterologous strain of plasmodium. According to the Commission, clinical prophylaxis should have no action in the prevention of superinfections, because it says that "quinine, even in curative doses, has no true causal prophylactic action."

Clinical prophylaxis may however be of greatest practical value under those conditions where it can be properly carried out. Such a system of treatment may be recommended when large bodies of people are sent into areas in which they have little or no immunity against the local strains of parasites, and it is desired that as few persons as possible must develop clinical manifestations of malaria during their stay in the area. The good effects of this method appear to depend on the fact that the number of parasites in the patient's body, as the result of infection and reinfection are kept below the limit of producing paroxysms. It is really an early clinical curative treatment. This method may help the individual to develop a considerable degree of immunity to reinfection or superinfection with local strains or species of malaria. The cost of such a daily dosage with the specific drug would be prohibitive.

General Principles of the Therapeutics of Malaria, with Special Reference to the Masses in India. The Commission in their report have dealt with modern therapeutics of malaria from "the point of view of persons who are in a position to obtain medical advice and efficient care rather than from that of the mass of the population of malarious countries" (p. 277). The vast majority of the millions of malarious sick in India however, are not in a position to obtain such advice and care, and it is probable that the same holds good for many other malarious countries. For the application of such therapy, infected populations may be divided into two main groups, in which, as judged in the light of our present knowledge, the object of treatment is distinctly different. These groups are—(a) those individuals in whom the risk of reinfection is relatively slight or absent, because of environmental factors, or of antimalarial measures of various kinds. In individuals situated under these conditions, one should aim at the production of a radical cure of the infection at the earliest opportunity, and by such methods as have been discussed above, or by such new methods as may be considered suitable.

If such persons are not liable to reinfection at frequent intervals, there appears to be no object in allowing them to acquire, by prolonged latent infection, an immunity which would be of value only against the infecting strain. The chances are that they may be infected on the next occasion by a heterologous strain or species, against the clinical effects of which their hard-won immunity may have little protective power. Under such conditions the patient will have suffered.

to little advantage, the long series of relapses and recrudescences advocated by the Commission.

In the production of radical cures in such individuals, wherever possible the treatment for clinical cure and that for radical cure should be combined. In this way the period of morbidity and inefficiency would be cut down to the minimum.

Sinton considers that both from the point of view of economy and because of their marked action on malarial infections, quinine or some of the other cinchona alkaloids should form the basis of all such "standard treatment." The newer drugs have in some cases advantages which the cinchona alkaloids do not possess, but they have also disadvantages not shared by those alkaloids. Such new drugs can only be considered as adjuvants to the action of the cinchona alkaloids, more especially because of their relatively high cost, which places them beyond the reach of the majority of patients. Therefore where possible, the adjuvant action of these and other drugs should be taken advantage of, in treatments which aim at a rapid clinical cure. Certain drugs can with advantage be used in combination with the cinchona alkaloids, while others may be substituted for them in those infections which for any reason have proved refractory to the radically curative effects of quinine, alone, or in combination with certain adjuvants.

Individuals who are liable to reinfection or super-infections within a very short time after the termination of treatment. There is much evidence to support the view that when, by natural or therapeutic means, an individual is radically cured of an infection with one strain of parasite, irrespective of its species, he rapidly loses most of any acquired immunity or premunity which he has developed to this strain as the result of his infection. The evidence available suggests very strongly that to maintain any high degree of such tolerance to the clinical effects of infection, it is necessary that the individual should continue to harbour the parasites of this strain, *i.e.*, that his defensive mechanism should be continually stimulated either by the parasites of a latent infection of the strain, or by continued re-inoculation with the same strain.

In view of these facts it would seem that the production of a radical cure under conditions where reinfections are frequent, is contra-indicated. Such cures of the infection would, theoretically at least, leave the patient more liable to severe clinical attacks, if the intervals between the reinfections with the same strain of parasite were greater than the duration of his immunity after radical cure.

In so far as Indian conditions are concerned, Sinton (1935) says:—
 "Most of the uncontrolled rural population of India have (a) no wish

to continue treatment after the fever and clinical manifestations of malaria have disappeared and (b) have not the financial means to pay for the cost of a treatment which might produce a permanent cure of the infection that is troubling them at the time. Even if they could be cured, the chances of reinfection at a comparatively early date are great in many places. Under such conditions of liability to reinfection, the attempt to produce a permanent cure seems futile and indeed may have unfortunate effects. As pointed out in our monkey experiments and as noted in malarial investigations in Europe, the patient who survives an attack may develop an immunity to the strain of parasite which infects him, and this immunity may act as a considerable protection against another infection with the same strain. Such latent infections under ordinary conditions do not produce very severe clinical effects, and such as are produced are usually easily controlled by a little treatment. As we have not solved the problem of the prevention of reinfection among the rural population, *i.e.*, the destruction of the infected insect host, or means for preventing the transmission of the disease by it, attempts to produce a permanent cure of the infection appears to be a waste of money in most cases."

"Under these conditions, in my opinion and in our present state of knowledge, the objects to be aimed at are (a) to make available suitable treatment which every sufferer can obtain, either free or within his financial means and (b) to ensure that such treatment can be obtained by the patient with ease in whatever place he may be. The result of such provision would be that a sufferer from a malarial attack would have treatment available, and thus (i) diminish the risk of a fatal result, (ii) diminish the intensity and duration of the attack, and (iii) curtail the period of physical disability."

Such a system of clinical cure among populations liable to reinfection, should not interfere radically with the development of their "tolerance" to the clinical manifestations with infections of the local strains, nor in the presence of continual reinfection should it interfere seriously with any immunity already acquired.

This power of developing tolerance appears to be present to a different degree in different races. As has been proved by experiments with induced malaria, the degree of individual susceptibility to the clinical effects of malarial infection in previously uninfected persons, may vary very considerably. It would also appear from field observations, in various parts of the world that certain races may possess a considerable degree of so-called "natural immunity" to malarial disease, as compared with other races. It is possible that through very many centuries of exposure to intensive, untreated malaria, persons with a greater susceptibility to the disease would be more liable to death in childhood, and would be weeded out. So the race would be continued by survivors (the adults) having a more marked degree of tolerance

or power to develop such tolerance rapidly. (*From Col. Stinton's writings*).

NON-SPECIFIC COLITIS

Non-specific colitis usually refers to the condition which is characterised by diarrhoea with blood and mucus in the stools, but is unassociated with dysenteric or other recognised infections. No specific cause has yet been found. It is probable that a variety of causes may be responsible for this condition.

The outstanding change in the bowel is an inflammation of the mucous and submucous coats, strictly limited to the large intestine, especially the descending colon. The changes in the mucosa follow the usual sequence of acute inflammation, ulceration, fibrosis, and local proliferation leading to polyposis. The normal function of fluid absorption by the colon is interfered with, which in later stages may give rise to incurable diarrhoea. The clinical course of the disease is very variable and is characterised by periods of remission.

TREATMENT. Various therapeutic trials have been made in the past and the observations on their results are noted below.

1. *Treatment by irrigation of the colon.* It is based on the view that the condition is caused by an infection which lies in the mucous surface within reach of the irrigating solution. It is a common practice to order lavage with disinfectant solutions. Sometimes appendicostomy or caecostomy is carried out to facilitate a thorough washing out. These irrigation methods have often proved unsuccessful and in certain cases have aggravated the condition. The tissues of the colon are highly sensitive to trauma in colitis, treatment by colon lavage therefore often does harm and surgical procedures are contra-indicated in acute colitis.

2. *Treatment with sera and vaccines.* The use of anti-dysenteric serum and of Bergen's specific streptococcus serum and vaccine have been much employed. Hern (1931) found that about 50 per cent. of the cases appeared to benefit by the treatment. The results are probably due to a non-specific protein reaction. Bergen's streptococcal serum and vaccine do not produce a specific curative reaction and the effect is uncertain.

3. *Treatment by diet.* The association of defective diets with intestinal disease is well known in tropical countries. Deficient diet is a very important predisposing factor in such conditions. Particular attention is directed to the vitamin B complex by some experimental work by McCarrison in 1921, and recent experiments by Wills which have shown that a deficiency of this vitamin may cause colitis. Hare used vitamin A and B products in large doses in the treatment of acute and chronic cases without satisfactory results. Ill-balanced diet cannot always be regarded as the cause, as the condition can occur in persons having adequate dietary.

Though diet deficiencies and colitis cannot be placed in the relation of cause and effect, it is important to regulate diet in the treatment of the patient. During the first acute attack a limited diet with fluids and soft solids, such as are chiefly absorbed from the small intestine, is given. Milk alone is generally not acceptable, and a large bulk of fluid increases the diarrhoea. Later, with improvement of the condition, the diet is increased but food is still given in small amounts at short intervals. Chronic patients should not be starved. They as a rule improve with generous and well-balanced diet. The diet should contain plenty of protein, *viz.*, meat, fish, eggs, milk and cheese; plenty of butter, fat, fruits and green vegetables. Carbohydrates are to be taken in moderation. In addition, special vitamin preparations are ordered for these chronic cases, *viz.*, marmite or bemax for vitamin B complex and halibut-liver oil or cod-liver oil for A and D vitamins. Liver therapy is usually of no value unless there is marked macrocytic type of anaemia.

Anaemia with a low colour index is a fairly common complication of colitis. Iron in large doses given in chronic colitis with hypochromic anaemia is of striking benefit.

Spasms of colicky pain frequently occur in colitis. Injections of atropine are useful in relieving the acute condition, atropine by mouth is given to chronic or convalescent cases. Although atropine relieves the colic it does not lessen the diarrhoea of the acute attack. There is really no satisfactory means of controlling diarrhoea and it is doubtful whether kaolin and bismuth have any beneficial effect.

Constipation is another result, which is often of spastic type. Both aperients and enemata often fail to give relief and are likely to increase the irritability of the muscle, while antispasmodic drugs relax the bowel and may permit the passage of normal stools. Liquid paraffin is very useful in such cases. (*Pro. Roy. Soc. Med.*, Nov., 1935).

ARTERIOSCLEROSIS

Arterial lesions which resemble those of human arteriosclerosis can be produced in rabbits by the administration of diets containing considerable quantities of cholesterol. It is concluded that the presence of considerable quantities of cholesterol in the diet with a resulting elevation of the level of cholesterol and other lipoids in the blood is essential to the development of the typical arterial lesions in rabbits. It is shown, however, that hypercholesteremia alone cannot be regarded as the cause of the lesions in the arteries. There are preliminary local alterations in the walls of the arteries which precede the precipitation of lipoids. Evidence is advanced to show that these preliminary changes are due to some form of injury to the arteries attendant on the experimental procedure of cholesterol feeding. It is concluded that the occurrence of local changes in the arterial walls, due in all probability to injury of some kind, is the primary event in the development of the lesions of

experimental cholesterol arteriosclerosis, an event which is followed subsequently by the precipitation of lipoids in the injured areas. A comparison is drawn between the lesions of experimental cholesterol arteriosclerosis and those of human arteriosclerosis. It is demonstrated that the two diseases are not identical, and that there are a number of important differences between them. Hypercholesteremia is not found with any regularity in association with human arteriosclerosis. It seems highly probable that arteriosclerosis in man can and usually does develop without deviation of the cholesterol content of the blood beyond the normal limits of variation (*Archives of Pathology*, 1935, Vol. 20, p. 293).

YAWS AND SYPHILIS

Acute yaws (p. 655) is comparatively easy to manage by treatment, though what the final results of the treatment will be cannot yet be determined. The primary lesions of yaws and of syphilis differ decidedly in their histological features. The secondary lesions of acute florid yaws differ decidedly in their gross appearance from most secondary eruptions of syphilis, though syphilis rarely causes lesions like those of yaws, and yaws is said sometimes to cause eruptions like those of syphilis. Histologically, typical lesions of yaws are characterised by the presence of spirochaetes, chiefly among the epithelial cells, by marked proliferation of the epithelium downward, by the large number of leukocytes that penetrate the epidermis and by the slight amount of involvement of blood vessels. Thus, the papules of yaws differ from most syphilitic lesions, but occasionally condyloma and some of the cutaneous lesions of syphilis may give similar pictures. Late ulcers of yaws and those of syphilis are so much alike that a diagnosis between them is frequently impossible. It has sometimes been noted that in certain tropical regions similar conditions were likely to be called syphilis in the city and yaws in the country. As to involvement of bone, it must be admitted that roentgenograms show that the bones are often affected in yaws and that the pictures are often like those seen in cases of syphilis. Both clinical and experimental work indicate that an attack of yaws confers considerable immunity against a second infection. Also, clinical observations and laboratory experiments suggest that a certain amount of cross immunity between yaws and syphilis may be produced, but the statements are somewhat conflicting. Opinions on the relationship of yaws to syphilis differ widely. Yaws has been called syphilis of the tropics and stone-age syphilis; syphilis and yaws have been called brother and sister as well as twins. Castellani regarded them as wholly distinct infections, like tuberculosis and leprosy. Apparently no one has recorded having actually witnessed the transformation of yaws to syphilis or of syphilis to yaws in man. The evidence that is available gives the impression that the spirochaete of either yaws or syphilis has

undergone a functional but not a morphological mutation in some human host, giving rise to the other infection, and that the resemblances between the two infections indicate that the new infection has evolved from the older one in comparatively recent times. (*Archives of Pathology*, 1935. Vol. 20, p. 626).

STAPHYLOCOCCAL INFECTION OF JEJUNUM AND ILEUM

Staphylococcal infections of the small intestine occur which give rise to septicæmia and prove fatal within approximately thirty-six hours from the onset of symptoms. The early symptoms are like those of staphylococcal food poisoning, and consist of nausea, vomiting, diarrhoea and prostration. Later, with septicæmia and circulatory failure, coma and various other neurological signs appear.

The autopsy shows widespread lesions of unusual character in the jejunum and upper portion of the ileum. The intestinal contents are blood stained, and include long casts of the mucosa which are composed of necrotic fragments of intestinal villi, fibrinopurulent exudate, and staphylococci in large numbers. The microscopical sections show diffuse superficial necrosis and acute inflammation of the mucosa of the jejunum and portion of the ileum affected, associated with numerous staphylococci in the inflamed tissues. Thrombi in small vessels are found in a number of organs, and are most numerous in the jejunum, ileum and liver. There are focal necroses in the liver, spleen and bone-marrow, and small hæmorrhages, not associated with thrombi in blood vessels, are scattered in the brain and meninges. (*Bull. John Hopkins Hosp.* 1935, Vol. 57, p. 289).

WEIL'S DISEASE

Weil's disease seems to be one of those conditions fated to play an ever larger part in medicine and public health. It has been shown that: (1) the Weil strain of *Leptospira* is the same the world over; (2) at least 10 per cent. of wild rats in the United States harbour and excrete virulent organisms; (3) occupational exposure exists (most of the 12 reported cases occurred in persons working at certain trades); (4) spirochetes have been found to thrive in water in many places and (5) sporadic cases of Weil's disease (clinically and pathologically identical with the classic European variety) continue to be reported at intervals. (*Archives of Pathology*, 1935, Vol. 20, p. 475).

FEVERS OF THE TYPHUS GROUP IN INDIA (p. 375)

Boyd has analysed one hundred and ten cases of fever of the typhus group according to their serological reactions with *B. proteus* XX, X2 and X19, and according to their clinical characters. A definite XX group is described corresponding closely to Malayan "scrub" typhus. It is suggested that there may be two other types of typhus found in

India, one having as the main antigen of its virus an unknown strain of proteus, and resembling in this and in other features the Rocky Mountain fever, the second having X19 as the main antigen of its virus and resembling endemic typhus. But it is possible that these two types may in reality be but one.

In other countries (Japan and Malaya) the vector of the fever in which XK is the main antigen of the virus is known to be a mite. This is obviously a possibility in the Indian XK cases, but so far there is no evidence of any kind in support of this hypothesis. From a comparison of the clinical details of the cases, there appears little doubt that some of the cases correspond to what have figured from time to time in the literature of the disease as "Indian Tick Typhus." Whether or not the tick is the vector, or the only vector of this disease remains an open question. There exists at present no definite scientific proof on this point. The absence of any history or evidence of tick bite in the present series of closely questioned and closely examined cases is a finding which cannot lightly be disregarded; in only one is there any suggestion of tick bite, where a papule with a necrotic centre was observed; no ticks were seen; there was no associated adenitis. It is of interest to note that a definite history of tick-bite is a most inconstant feature in most cases which have been reported in the literature. Until the differential diagnosis of these fevers is more clearly established, the diagnosis "Indian Tick Typhus" should be shelved. There is at present no scientific justification for applying it to any one of the types of the disease which have been described. (*Jour. Royal Army Med. Corps.*, 1935, Vol. 65).

DIABETES MELLITUS (p. 1043)

A summary of the more important and original conclusions arrived at by the Diabetes Clinic of the Ministry of Pensions is as follows:— (1) Several cases of diabetes were found to supervene on certain specific pancreatic lesions, particularly acute pancreatitis many years previously. (2) The connection of diabetes mellitus with functional nervous diseases hyperthyroidism and consequent hyperadrenalinæmia, having been considered, the conclusion is offered that nervous shock and prolonged mental stress and strain are frequent causes of diabetes, particularly amongst war pensioners. (3) The small incidence of a family history and of obese subjects in the series is explained by the dietetic habits and type of life enforced upon most of the patients during the War period. (4) The relationship of renal glycosuria to diabetes mellitus is that renal glycosuria frequently represents a residual condition after a mild case of diabetes has been cured. The absence of any senile cases of renal glycosuria is explained on the assumption that the renal threshold rises as arterio-sclerotic changes set in with advancing years, and that the condition frequently undergoes a spontaneous cure. There is no evidence in these patients that any case of renal glycosuria

afterwards developed diabetes. (5) Three conditions are considered: (a) Diabetes mellitus, (b) "para-diabetes" or hyperglycaemic glycosuria, (c) renal glycosuria. To distinguish between these the use of a three-day blood-sugar tolerance test is advised. This is really a pancreatic exercise tolerance test. (6) The former very low carbohydrate high fat diets, the legacy of the pre-insulin period, are condemned as unsatisfactory. It is shown that carbohydrate and fat can be interchanged in a diet without greatly affecting the insulin requirements, although there are some individual variations.

Diets containing a high carbohydrate allowance with restricted fats are shown to be the most satisfactory for general use. The restriction of fats may not be agreeable to the patient, but the discomfort is not so great as the extreme restriction of carbohydrate. In practice it was found that the old diets were not kept to by the patients and apart from the distaste were expensive. The present diets are more satisfactory and kept to more readily. (7) In cases which show fasting hyperglycaemia on insulin treatment the giving of a small part of the morning dose of insulin at waking is shown to result in all cases in satisfactory blood-sugar control. (8) In many cases receiving insulin treatment the renal threshold tends to fall as an improvement in tolerance occurs. (9) As regards insulin treatment every case of true diabetes, however mild, should be given insulin, at least for a short course of treatment. They consider that it may improve the tolerance, and possibly may effect a cure. The patient's general condition is improved; in other words it acts as an excellent tonic. It also prepares the patient to deal with an intercurrent infection should it arise. In the case of a febrile condition such as pneumonia, or a septic condition insulin is well tolerated and should be given in increased quantities. It is necessary to give carbohydrate, possibly as glucose, at the same time. In cases of tuberculosis the prognosis is improved by the high carbohydrate diet with large doses of insulin.

The method of instituting treatment advised is that the patient, having been placed on the appropriate diet selected for final use, insulin is administered in two daily doses, increasing the dose at intervals of three days, until the blood sugars, taken several times throughout the day, are within normal limits. To arrive at the appropriate diet the calories sufficient for the patient's needs must be calculated, and is considered best that the subject should be maintained slightly under rather than above the normal weight. In emaciated cases high carbohydrate diets are to be given at first. High fat diets with restriction of carbohydrates tend to ketosis and death from diabetic coma.

Most mild or moderate cases can be well controlled by two insulin doses, generally given twenty minutes before breakfast and the principal evening meal. In more severe cases where there is difficulty arising from a high fasting value of the blood-sugar, the divided morning insulin dose has resulted in great success. It is shown that

in nearly every case perfect control of the blood-sugar was obtained with a smaller insulin dose. (*Jour. Trop. Med. and Hyg.* 1935, Vol. 38).

CHORIOMENINGITIS

Acute Lymphocytic Choriomeningitis

There is evidence to show that some if not all such cases represent a disease entity due to a filtrable virus described by Dickens and Armstrong. The clinical picture of the disease is that of an infection of the upper respiratory tract, followed by meningeal symptoms which are ushered in by sudden onset with headache, nausea or vomiting, rise in temperature to 100°F., stiff neck, and usually a positive Kernig sign. There is no evidence of nerve involvement and, other than noted above, the neurological examination is negative. The disease runs a benign course for about 10 days to 2 weeks. The temperature declines by lysis and recovery is complete without residuals of any kind. Four patients who have been followed for more than 3 years remained entirely well.

The cerebrospinal fluid is under slightly increased pressure and is clear or at the most slightly hazy. The cellular response is almost entirely lymphocytic—rarely do we find as many as 10 per cent. polymorphonuclear leucocytes in the fluid. The number of cells may range anywhere from 50 to 2,000, according to the severity of the attack. The chemistry of the cerebrospinal fluid is important in that the sugar, chlorides, and urea content will be found within normal range. The Kahn or Wassermann is negative and the colloidal gold curve will be in the meningitic zone and of low colour change. No organism or clot can be demonstrated. Drainage of a few cubic centimetres of cerebrospinal fluid will usually relieve the headache and nausea, and quieten the patient. The white blood cell count may show a slight increase up to 9,000 or 11,000 with a fairly normal differential percentage. The fact that the cerebrospinal fluid shows no tendency to clot and that the sugar and especially the chlorides remain within normal limits are most important diagnostic points definitely against tuberculous meningitis, with which the disease is at first often confused. The fact that no muscle weakness, or definite neurological signs are found helps to rule out encephalitis (of all types) and acute anterior poliomyelitis.

The virus of Armstrong produces a symptom-complex in monkeys similar to the above. The blood serum of patients recovered from the disease protects animals from the virus of Armstrong (National Institute of Health strain). This disease occurs sporadically in man, and has been transferred experimentally to animals. Traub has isolated a virus from white mice and Rivers and Scott have isolated a virus from human patients which are serologically identical with the National Institute of Health strain of the Armstrong virus. (*United States Naval Medical Bulletin*, 1935, Vol. 38).

BACTERIAL FLORA OF THE NORMAL BODY (p. 760)

The bacteria are able to live in the body or its cavities for long periods of time without causing demonstrable harm and must therefore be considered normal inhabitants of the body. It is customary for the secretions from the mouth, the vagina, and the urinary bladder, to contain a few pus cells, or at least cells which under other circumstances would be called pus cells. Likewise, it is evident that there are almost constantly signs of inflammation in the mouth and in other body cavities. So long, however, as there are no symptoms which would ordinarily be noticed, we are accustomed to call a given organ normal. Cultures made under anaerobic conditions yield one flora, while those grown in air show another. The time of the year, the geographical location, the food habits, the hygienic habits, and various other individual differences of the host play their parts in determining the flora to be observed. In describing the various organisms which are found in normal bodies it is necessary to distinguish between those that are practically always found, those that are frequently found, and those that are occasionally present. In the first group is *Staphylococcus albus*, which is always found in the skin of the human being. Likewise, *Escherichia coli* seems to be a normal inhabitant of the bowel of every human being wherever he may be found. *Streptococcus viridans* is said always to be found in the nasopharynx, and *Lactobacillus vaginatis* is almost always found in the human vagina, provided meddling douching has not altered the normal habitat. In the second group are those organisms which are so frequently present that they elicit no surprise when they are found. Of these there are a great number, but we are, of course, mostly interested in those which are capable of acting as pathogens—staphylococcus, pneumococcus, streptococcus, and a number of others which need not be mentioned in detail.

In the last group we place those organisms which are occasionally present. Typhoid 'carriers' may be perfectly well and yet carry virulent typhoid germs. Likewise, there are those who harbour the meningococcus, the gonococcus, the organisms of syphilis, the diphtheria bacillus, the germs of tetanus, of gas gangrene, and probably a great many others, yet give no outward signs of disease.

FLORA OF THE NORMAL ALIMENTARY TRACT. *Mouth and pharynx.* Many bacteria live in the mouth and throat. Moisture and food are abundant. Contrary to the usual belief, saliva has but slight bactericidal effect. Dogs and animals lick their wounds and commonly experience rapid healing, but this is more likely due to the fact that the wound is kept clean by this method than to the theory that the saliva inhibits the bacterial growth. There is usually some degree of catarrhal inflammation of the mucous membrane of the mouth, but wounds of the mouth usually heal rapidly. This is largely due to the unusually rich blood supply. It is impossible to sterilize the mouth cavity, and any

attempt to do so is certain to do more harm to the mucous membrane than to the germs. If the mucous membrane is injured the body's protection against germs is weakened and bacterial invasion is more likely to take place. The organisms found in the mouth are of many kinds :—*Staphylococcus albus* is often there; and occasionally *Staphylococcus aureus* can be found. *Streptococcus viridans* is nearly always present; *Streptococcus hemolyticus* and *non-hemolyticus* may be present without causing disease, and are, indeed, fairly common. *Pneumococcus* is present in a large percentage of mouths, especially during the winter and spring months. The pneumococci found usually belong to Type IV, which is the least pathogenic. The other types are rarely found in normal mouths except when the person is in contact with a case of pneumonia of the same type. *Gaffkya tetragena* is rather common. Of the genus *Neisseria* several species are rather commonly found, particularly *Neisseria catarrhalis*, which has been accused of causing a catarrhal inflammation of the mucous membrane of the nose, throat, and sinuses. It is probably of slight importance, but cannot be classed as being entirely harmless. Other Gram negative diplococci are found and make it hard to be sure, when the presence of meningococcus is reported, that the organism of Weichselbaum is really present. The true meningococcus is not infrequently found in the throats of normal individuals. *Corynebacterium diphtheriae* and *C. pseudodiphtheriae* may be present in the normal throat. The fusiform bacillus and the spirillum of Vincent are present in a large percentage of mouths. Some authorities are finding them in nearly all mouths, but this seems an exaggeration. Several species of *Treponema* are sometimes found and may be mistaken for *Treponema pallidum* in a dark field examination. *Proteus vulgaris*, *Aerobacter aerogenes*, *Klebsiella pneumoniae*, and a number of other Gram-negative bacilli are often found. Chain-forming Gram-positive bacilli are common; also a great many large saprophytes, yeast cells, and occasionally *Leptothrix* and *Streptothrix*. Sarcinae are common.

Oesophagus. The flora of the oesophagus is essentially the same as that of the mouth and the pharynx.

Stomach. The acid of the gastric juice usually kills all bacterial growth. As a result, food commonly leaves the stomach in a sterile condition. Undigested food, of course, contains many bacteria, and some may pass into the duodenum in the centre of compact masses of food. One of the most important functions of the gastric juice is that of disinfection of the food. With normal gastric digestion there is much less danger of dysentery, typhoid fever, cholera, food infection, and related conditions. Persons with weak gastric digestions will suffer from fermentation of the food in the stomach, causing discomfort, foul eructations, and indigestion. Many people cannot drink sweet milk because of the large amount of buffer substance in the milk, which neutralizes the gastric juice, allowing the bacteria in the milk to ferment

the lactose with gas. Most of these people can, however, drink butter-milk, because in this case the lactic acid reinforces the gastric juice and the lactose having already been fermented cannot produce gas. Patients with cancer of the stomach commonly have a very low acidity. The Oppler-Boas bacillus is often found in such gastric juice and has been supposed to be the cause of the cancer. This is not the case, since the Oppler-Boas bacillus is one of the non-pathogenic *Lacto-bacillus* species and simply lives in the stomach as a saprophyte. It is largely responsible for the organic acid commonly found in the gastric contents of persons with carcinoma of the stomach.

Intestine. The contents of the normal duodenum are usually nearly sterile, but the bacteria rapidly increase as the lower levels are reached. It is commonly stated that about one-third of the faeces are composed of the bodies of dead and living bacteria. The commonest organism is *Escherichia coli* (or possibly *Esch. communior*). There has been much discussion as to whether we should regard this organism as a friend, an enemy, or a harmless, saprophyte. The noted pathologist Adami traced a great deal of trouble to the colon bacilli. He thought that the portal circulation took them up in large numbers, that the liver had the important task of destroying them, and that a chronic state of intoxication resulted. The Russian bacteriologist, Metchnikoff, believed that they were the cause of old age and attempted to supplant them with *Lactobacillus bulgaricus*. The whole theory of lactic acid therapy is based upon the assumption that the usual flora of the bowel is harmful. Other authorities regard the colon bacilli as being of some benefit. They point out that they may aid in the digestion of certain products, though this seems rather far fetched for the reason that the things that they will digest (sugars) are easily broken down by the intestinal juices. They say that colon bacilli tend to inhibit the growth of worse germs and this is quite plausible. Others think they are a harmless organism, except in a few cases when they get into other organs or may cause a colitis in debilitated individuals. The bacterial flora of the bowel varies with age and diet. At the time of birth the bowel contents are sterile. From the first to the third day, however, there is a period of "adventitious bacterial infection," and after this time the bowel will be heavily contaminated for the remainder of life. The flora of the breast-fed baby is usually characterised by the presence of *Lactobacillus bifidus* in large numbers. The stools of such a child are inoffensive in odour. Other organisms present are *Aerobacter aerogenes*, *Streptococcus lacticus*, *Escherichia coli*, *Escherichia communior*, *Lactobacillus acidophilus*, etc., several of which are anaerobic and proteolytic. In adult life there is a relative increase in the number of the members of the coli group, and a corresponding decrease in the sour milk type of organism. The colon comes to harbour a great number of the organisms belonging to the genus *Clostridium*. *Clostridium welchii* is often found in the normal

colon, and may, as in cases of pernicious anæmia, ascend to much higher levels. It has, indeed, been accused of being the cause of this disease. The more likely explanation is that it is allowed to ascend in the bowel for the reason that the bowel does not have a normal function because of the atrophy of mucosa so characteristically seen in this disease. The presence of the Welch bacillus is, then, probably a result rather than a cause of the condition. This organism can cause a marked diarrhoea with much gas formation. *Bacillus mesentericus* is a common inhabitant. In many respects it resembles *Bacillus subtilis* and produces an active proteolytic ferment, making it important in the putrefactive processes taking place in the bowel. *Clostridium putrificum* (Beinstock) is considered to be a normal inhabitant of the faeces and is active in putrefaction. A great many other organisms of less importance are found regularly and still others occasionally in the perfectly normal intestine. With a special milk diet the faecal flora tends to change toward the acidophilic forms. Two factors determine the degree of such transformation : (1) The original presence of appreciable numbers of *Lactobacillus acidophilus* in the lower part of the digestive tract. (2) The stability of the flora that were already established when the special feeding was begun: A diet high in carbohydrate tends to simplify the flora in favour of the acidophilic organisms, while a meat diet tends to favour the colonic flora and to induce putrefaction. In other words, a carbohydrate diet tends to establish the fermentative organisms, while a high meat protein diet tends to cause the putrefactive organisms to flourish.

FLORA OF THE RESPIRATORY TRACT. *Nasal cavity.* It is one of the functions of the nasal cavity to remove dust and germs from the inspired air so that the lower levels of the tract may be protected from such contamination. As the air enters the nostril it first encounters the vibrissae, or hairs, which grow in the vestibule of the nasal cavity. These hairs are more or less moist and catch a great deal of dirt, as every one knows who has worked or lived in dusty places. As the air passes on into the nose it comes in contact with the moist surfaces of the mucous membranes and a large part of the dust remaining is left in the slimy covering of those membranes. The arrangement of the folds of mucous membrane over the turbinates is such that the air is swirled about so that every particle of dust is likely to come into contact with a moist surface. Once the germs find themselves caught in the mucous secretion they may be blown out of the nose, may drain into the throat to be swallowed and destroyed in the stomach, or they may be expectorated. There is likewise some method, by no means understood, by which they are destroyed by the mucous membrane itself. Doubtless phagocytosis plays an important role in this respect, though there are apparently other means at the disposal of the membrane.

As might be expected, a great variety of organisms are found in the nose. Probably the most common ones of interest to physicians are *Staphylococcus albus*, *Neisseria catarrhalis*, *Streptococcus viridans*, and certain diphtheroids. A variety of cocci and rather frequently members of the colon group and the Friedlander group are commonly found. The fact that these organisms are found in noses that are normal indicates that while the nasal secretions may not be definitely germicidal, they are by no means favourable for growth and development in such a way as to cause disease. It is likely that the increased susceptibility to cold which is rather characteristic of civilized man is due to the fact that he mostly lives indoors, where the air is likely to be dry, dusty, and overheated, thereby producing excessive dryness of the membranes of the nasal cavity and reducing resistance to bacterial invasion. Increased opportunity for contacts with other persons suffering from colds is also a big factor. Hypertrophy of the adenoid tissue of the throat and nasopharynx is doubtless a response to the excessive load thrown upon the lymphatics by reason of the inability of the mucous membrane to perform its full function when excessively dry and heavily contaminated by dust and germs.

Accessory sinuses. The strictly normal sinus is probably always or nearly always sterile. Cultures made upon fresh human cadavers dead of various causes and without sinus symptoms usually give no growth, or, in a few instances, non-virulent strains of *Staphylococcus albus*. When bacteria have been injected into the sinuses of normal dogs they have usually remained viable for only a few hours. The drainage from the sinuses is such that this result is to be expected, provided there is no source of continued reinfection. In recent years there has been much attention given to the apparent increase of sinusitis. It sometimes seems that, in certain regions at least, there are no really healthy sinuses. *Staphylococcus albus* and *aureus*, various Gram-negative diplococci, and streptococci are the more common offenders. In not a few of these cases the sinus seems to be normal sometimes for weeks or months at a time, but in all probability the organisms are still there in latent form.

Bronchial tree. The ciliated epithelium of the trachea, bronchi and the branches of the bronchial tree is constantly sweeping the mucus upward so that it may be expectorated or swallowed. In this way large quantities of dust are removed, as every one knows who has coughed up dark material after having been exposed to dust or coal smoke. As cultures are taken deeper and deeper in the bronchial tree the number of organisms obtained becomes less and less until it is found that the really healthy parenchyma of the lung is sterile or practically so. Sometimes after deep and labored breathing with the mouth open germs succeed in getting into the depths of the

lungs, but in quiet breathing this rarely happens except when there is a heavy infection of the upper respiratory tract or the germs are carried to the lungs by the blood stream.

FLORA OF THE GENITO-URINARY TRACT. *Urethra.* The short female urethra is frequently sterile but also often is contaminated with *Staphylococcus albus* and colonic organisms. The male urethra usually shows the presence of these two types of organisms and in addition often furnishes a habitat for non-pathogenic diphtheroids. *Mycobacterium smegmatis* is commonly found in the folds under the male foreskin and also in the creases between the various members of the external female genitalia. It bears a close resemblance to the tubercle bacillus and may easily be confused with it unless its presence is kept in mind. The deeper parts of the male genito-urinary system are sterile when free from disease. Occasionally organisms are found in the urinary bladder when there seems to be no evidence of infection, but it is doubtful if they can be regarded as being normal or harmless inhabitants.

Vulva and vagina. On the vulva, as might be expected streptococci, staphylococci, *Escherichia coli*, *Corynebacterium pseudodiphtheriae*, and many saprophytes are to be found. During the later weeks of pregnancy streptococci and staphylococci are found in the vaginas of 40 to 75 per cent. of healthy women. Such being the case, it is easy to see that it is not necessary to suppose that puerperal fever can take place only when the germ is carried to the parturient woman. We should remember, however that the germs which are commonly present in the vagina of a particular woman are far less dangerous to her than those which are brought from another case to a woman who has had comparatively little contact with these germs. In other words, the woman is more or less immune to the germs which she carries herself.

The classic studies of Doderlein upon the bacterial flora of the vaginal secretions are important. He distinguishes two forms of vaginal secretion: (1) Normal, which is white (like curdled milk), acid, contains no mucus, is small in amount, and (2) pathologic, which is thick, yellowish or greenish mucus, sometimes foamy, usually alkaline, but not necessarily so, and contains numerous pathogenic and non-pathogenic micro-organisms. The normal vaginal secretion usually contains only *Lactobacillus vaginalis* (Doderlein's bacillus) a harmless organism. The *Lactobacillus vaginalis* produces large amounts of lactic acid which rather effectively prevents the growth of the other organisms. This germ must be regarded as the normal inhabitant of the vagina, and its presence is undoubtedly beneficial. Because of the fact that this germ causes odours which are objectionable for æsthetic reasons, antiseptic alkaline douches have been much used. In this case the æsthetic ideal and the hygienic ideal are opposed. The removal of Doderlein's bacillus and the neutralization of the acid secretions favours

the development of bacterial flora which are capable of causing irritation and infection. There is of course, comparatively little danger of this except in the few weeks preceding obstetrical delivery. At such times douches are definitely contraindicated.

It is not unlikely that the reason for the great number of cases of puerperal fever in women delivered under the most careful attempts at asepsis is due to the fact that many women who have habitually used douches have not had the normal experience with germs which is necessary for the development of an immunity to them. Such women are in much danger if an exogenous germ is introduced.

Uterus. While the vulva and the vagina are usually contaminated rather considerably, the uterus is normally sterile except for the lower third of the cervix. There is a mucus plug that closes the mouth of the womb and prevents bacteria from entering. Under certain conditions bacteria live in the contents of the uterus in the later months of pregnancy, but do not reach the child (the germ of syphilis can pass from the mother to the child, as can filtrable viruses—and possibly other germs, very rarely). The greatest care must be taken when an instrument or the hand is to be introduced into the gravid, the non-gravid, or the parturient uterus.

When there has been a considerable laceration of the cervix as a result of childbirth, bacteria invade further into the uterus. Under certain circumstances organisms can enter the uterus and cause endometritis, but the uterus is no longer a normal organ in that case. The gonococcus can traverse the cavity of the womb and cause serious infection in the fallopian tubes and in the peritoneal cavity, but rarely causes much trouble in the uterus itself.

FLORA OF THE NORMAL TISSUES. It has often been supposed that the tissues themselves are commonly sterile except when definitely infected. This is by no means true. It is easy to show by anaerobic cultures that the muscles, the liver, and probably other organs harbour members of the Clostridium group when apparently perfectly healthy. Lymph nodes frequently show the presence of living organisms which, in all probability, they are in the act of destroying. The liver has been shown to receive considerable numbers of organisms which have passed through the intestinal wall into the portal vein and thence to the liver. It is doubtless an important function of the cells lining the sinusoids of the liver to pick up these organisms and destroy them before they go further. Diphtheroid organisms can be isolated from a number of organs of the body. They have been found a number of times in pathogenic lesions which are probably non-infectious and have erroneously been supposed to be the cause of Hodgkin's disease, sarcomata, and various granulomatous conditions; when, as a matter of fact, they were probably merely harmless parasites which had nothing to do with the disease in question.

SYMBIOSIS—MAN AND BACTERIA. It is commonly assumed that the host and the parasitic bacterium are each trying to kill the other. Each is merely trying to preserve itself against the other and in case either should cease attacking the other a condition which is essentially symbiosis is likely to be set up. As soon as the acute ravages of gonorrhoea are overcome, the body is rather content to allow the organism to lie latent in the tissues. Many organisms which cause disease—or indeed, most of them—may thus lie latent for weeks, months or years, causing little or no harm but able to seize an opportunity further to invade the tissues or to spread even to other individuals. This is an important immunological fact that has too often been overlooked. Inasmuch as we rarely make bacteriological examinations on persons except when they are in the grip of a definite infection, this principle has often been missed or inadequately appreciated. We are constantly living in symbiosis with many kinds of bacteria and billions of individuals of the various species. Indeed clinical healing in a large percentage of cases is merely an armed truce which upon slight provocation may become active warfare. A large percentage of lesions—abscesses, tubercles, gummata, etc.—are merely localizations of the conflict when the resources of the body have been more or less successful in interning the organism and compelling it to restrict its activity, though it is by no means dead.

At the same time that the patient is becoming immune to the attack of the germ, the germ is also in many instances becoming immune to the attack of the body. This "reciprocal immunity" enables each to live in the presence of the other, or in other words, to establish a condition of symbiosis. An example of this is seen when children are immunized against diphtheria by being given toxoid. The immunity produced is an antitoxic immunity directed against the toxin rather than against the germ itself. In such case the individual is protected against the clinical form of the disease but not against the carrier condition. There is reason to believe that the number of carriers will increase if immunization continues to be practiced, though clinical diphtheria may become quite rare.

This principle may be the explanation of the apparent fact that many diseases seem to be decreasing in virulence though they still produce much morbidity. Inasmuch as man has never been able, by artificial means, to bring about the total extinction of any biological species the attempts to do so in the case of various disease germs may be quite impracticable. It is not unlikely that we might be more successful if we should seek rather to gain a truce and accept the principle of "live and let live". The physician must give consideration to the general biology of symbiosis in his study of the forces by which his patient achieves victory, accepts balance, or submits to defeat and death as a result of bacterial invasion. (*Text-book of Bacteriology*—T. B. Rice).

BACTERIOLOGY OF URINE

Suggestions to the bacteriologist and clinician in deciding what to look for in a given specimen of urine.

MYCOBACTERIUM TUBERCULOSIS. Tuberculosis of the kidneys and bladder is not particularly rare. When it is at all possible specimens to be examined should always be collected through a catheter for the reason that they may otherwise be contaminated by the smegma bacillus which is nearly always present on the external genitalia. This organism is acid fast and very similar to the tubercle bacillus in many respects. If tuberculosis of the kidney is suspected the ureters should be catheterized through a cystoscope and the urine from the two kidneys kept separate. Direct microscopic examination of the urine will rarely be successful. The urine should be sedimented in the centrifuge, the clear urine poured off, and salt solution poured on, shaken and again sedimented; the sediment is then injected into the peritoneum of a guinea pig. In case the smegma bacillus is present, guinea-pig inoculation will rule it out since it is not pathogenic.

STAPHYLOCOCCUS. It is often the cause of cystitis and may be easily found if present in the urine. A smear of the sediment will reveal numerous pus cells and the organisms themselves. Culture on ordinary culture media will easily establish the identity of the organism.

STREPTOCOCCUS PYOGENES. It may be present in the urine, usually coming from the kidney or the kidney pelvis, but occasionally coming from the bladder itself. Catheters in the ureters will decide the source of the infection. Streptococci in the sediment will call for enriched culture media and more careful methods of culture. If autogenous vaccines are to be made from the streptococci great care must be exercised in the giving of them as they are likely to cause a focal irritation of the kidney with swelling and suppression of the urine. Very small doses should be given until one is sure that the patient is not excessively sensitive.

ESCHERICHIA COLI. It is rather frequently found in the urine of cases of cystitis. Much care should be taken in the use of a catheter in patients with large prostates and residual urine that this organism is not introduced. Infection of the bladder of debilitated patients with this organism may be a serious matter. The colon bacillus is, of course, easily cultured and identified. Patients with spinal cord injuries are very liable to cystitis of catheter origin.

EBERTHLLA TYPHI. The urine of typhoid fever patients carries the germ in a large percentage of cases. For this reason the urine should not be infected with the feces. The fact that the germ is in the urine may occasionally be used for diagnostic purposes but rarely so. Urine "carriers" are very dangerous.

PROTEUS VULGARIS. This organism is rather easily separated from the last two by the fact that it rapidly liquefies gelatin medium. Otherwise it is much like the colon bacillus for all practical purposes.

NEISSERIA GONORRHOEA. The gonococcus is occasionally found in the urine but the fact is of no practical significance. The organism has merely been washed out of the urethra in the act of urination and its presence does not mean that the bladder is involved in the specific inflammatory process.

Several other organisms have been occasionally found in the urine, as *Borrelia recurrentis* (relapsing fever) and the organism of Weils disease (epidemic jaundice), etc., but these are, of course, very rare and need not be considered in a manual of this sort.

COLLECTION OF SAMPLES

SPUTUM. If sputum is to be cultured it must be received into a sterile container and without disinfectant of any sort. It is usually well to rinse the mouth and throat with a cleansing—but not disinfectant—gargle and mouth wash. Boiled or sterile water or salt solution is good for this purpose. Effort should be made to get the sputum from the part affected—lungs, throat, posterior nasopharynx, etc,—with the least possible contamination from the saliva of the mouth. The sputum should be taken at once to the laboratory and kept in a cool place.

If the sputum is to be examined for acid-fast organisms but is not to be cultured or injected into an animal, it should be taken in a 5 per cent. phenol solution in equal volume with the sputum. Morning sputum is more likely to have the germs.

THROAT SWABS. For suspected diphtheria use no gargle of any sort. Depress the tongue and inspect the throat carefully. The physician should be careful to avoid causing the patient to cough or sneeze into his face. It may be well to wear a mask. The tongue depressor used should be perfectly clean and the swab should be carefully taken and planted on the culture medium. Other swabs are taken in much the same manner from the throat and planted upon appropriate media. In suspected meningococcus cases or carriers the culture is taken from the nasopharynx through a glass tube to avoid contamination with other secretions. The swab is then immediately planted upon special warmed medium in a plate poured but a few minutes before. It is usually better to have the suspected 'carrier' come to the laboratory than for the bacteriologist himself to go to the bedside of the patient.

Direct smears. When stained smears rather than cultures are to be made, the material should be evenly and thinly spread upon a clean glass slide that has been properly labelled. The film should be allowed to dry thoroughly in air. A number of germs will remain infectious when the film is spread upon a slide and dried in the air.

Smears for gonococcus should be taken in such a manner as to ensure that the germ may be found (after massage of the prostate in chronic cases in the male) and that contaminating germs may be

avoided (taken from the cleaned cervix through a vaginal speculum in the chronic case in the female). At least two smears should be taken.

EXUDATES AND TRANSUDATES. These can usually be handled in much the same manner as pus or other liquids and hardly require detailed instructions.

SPINAL FLUID. Obviously the most rigid asepsis should be practised in entering the spinal canal. It is therefore easy to collect the fluid under ideal conditions from a bacteriological standpoint. When the meningococcus is sought by direct stain the stain should be made as promptly as possible. When the fluid is to be cultured it will often happen that incubation at body temperature will greatly increase the chances of culture. A clear spinal fluid suspected of containing the tubercle bacillus should be allowed to stand for several hours in the ice box and both the fluid and sediment studied. Fluids containing other organisms should be handled as would other fluids for bacteriological study.

BLOOD CULTURES. Very important is the thorough cleansing of the skin before inserting the needle. Unless scrupulous surgical technic is used there is a great danger of contamination with the staphylococci which are so commonly present on and in the skin. When a staphylococcus septicaemia is suspected extreme care will need to be taken else one cannot decide whether the organism was in the blood or on the skin. If *Staphylococcus albus* is found it is usually a contamination.

BLOOD FOR SEROLOGICAL TESTS. It need not be drawn with such care as indicated here, except that such measures as will protect the patient from infection must be observed.

TISSUES REMOVED BY BIOPSY. The area should be very carefully washed but antiseptics must be used sparingly or not at all. Rigorous asepsis must be used and the tissue received into a sterile Petri dish or wide-mouthed tube.

PUS. The manner of the collection of pus will vary according to the quantity of the same and the lesion from which it comes. If a large abscess is aspirated it is usually easiest to inject the pus directly from the syringe into a sterile culture tube with a cotton stopper. If the pus is to be sent some distance a sterile tube can be drawn out making an ampoule. The pus is injected below the constriction which is then sealed with the flame. A smaller amount of pus may well be collected in a 'Pasteur pipette'. After the capillary end is properly sealed in a flame the tube can be packed in a case and handled quite conveniently without fear of breakage or contamination. Pus from ulcers of various sorts is commonly taken on a swab and then transported in a sterile tube with a cotton stopper. An objection to this manner of taking a sample is that the pus may dry out. This is not commonly a serious matter unless considerable time must elapse.

FÆCES. It would seem too much to demand that fæces be received and handled only in sterile vessels, but it is essential at least that the

container be scrupulously clean, else there is danger that the organisms from other cases may be carried over into the specimen. A clean white enamel pail of one or two quarts capacity is probably the best container. It should have a tight lid in order that the escape of odours may be avoided. The plant should be made as soon after collection as possible and it is best to keep the material in the icebox until the examination is made. Faeces examinations are most commonly made for the typhoid and dysentery bacilli; also the stools of infants with various diarrhoeas or of adults following food infection. Examination for acid-fast bacilli is likely to be very misleading.

It is frequently best to take the material for faecal examination on a swab taken directly from the bowel through a proctoscope or sigmoidoscope. This is particularly true in ulcerative conditions—colitis, dysentery, etc.

URINE. The bacteriologist should refuse (except under very unusual conditions) to examine a urine bacteriologically unless it has been drawn through a sterile catheter into a sterile bottle with a suitable stopper. Highly significant in urine examinations are the staphylococci, the *Esch. coli*, and the tubercle bacilli. The first two of these may be introduced into the urine during the act of normal passage, and the smegma bacillus normally found about the genitalia is very likely to be confused with the tubercle bacillus. Clinicians will say that the bacteriologist should distinguish between *Mycosmegmatis* and *Mycotuberculosis*, but this is far harder to do than to insert a catheter and is much more likely to result in error. If information is desired concerning the urine from a particular kidney, ureteral catheterization should be done when practicable.

If a contaminated urine is sent to the bacteriologist and he finds organisms which did not really come from the urine the report is almost sure to be very misleading and may cause serious error. For this reason aseptic care must be taken in preparing the genitalia and inserting the sterile catheter. Never send a specimen of urine to the bacteriology laboratory unless it has been drawn through a sterile catheter into a sterile bottle with a sterile cotton stopper. In taking the specimen to the laboratory do not wet the stopper.

BACILLUS ACIDOPHILUS

The implantation of this organism in the intestine has given some remarkable results in the experience of many clinicians. The organism must be given in milk and at least 1,000 c.cm. of milk is given daily, containing 200,000,000 organisms to each c.cm. This amount of milk must be given for at least a month or six weeks. The stools should be studied and plated to see that the flora has changed before the treatment can be stopped. Under no circumstances should the tablets put up by manufacturers be used. The organism grows well in lactose

and a good preparation for treatment is for the patient to eat a good quantity of lactose daily for a week.

C. C. Bass gives the following instructions for the preparation of the milk:

Carc of stock culture. The stock culture should be kept up by frequent transplanting (preferably every day) to autoclaved milk in regular culture tubes. Relatively large amounts of inoculum must be transferred. Small pipettes drawn from glass tubing of proper size plugged with cotton before sterilizing and fitted with a rubber bulb just before using are convenient for this purpose. The outside of the pipette can be sterilized just before using by passing through a flame.

Preparation of inoculum for routine production of acidophilus milk. Bottles of skimmed milk, plugged with cotton, are sterilized in this autoclave for fifteen minutes at 15 pounds pressure. A bottle should contain as much milk as will be required to inoculate all the milk to be inoculated on a given day.

"The first bottle of inoculum is prepared by inoculating one of these bottles of milk from the stock pure culture and incubating for 24 hours or longer, until coagulation takes place. This should be broken up by shaking before using. Subsequently, the bottle of inoculum for the next day may be inoculated by pouring some of the day's inoculum into another bottle of autoclaved milk, etc.

"Preparing milk to be used in routine production of acidophilus milk: Round tincture bottles with cork stoppers having a capacity of 20 ounces ('English quarts') are most convenient for making 500 c.c. quantities. This allows extra space for shaking. They should be dry sterilized.

"Milk (skimmed or whole) should be brought to boiling temperature for a few minutes in a double boiler and poured while hot into the bottles, about 500 c.c. to the bottle. After cooling down to about 37°C. they should be inoculated.

"Inoculation: Pour 10 to 15 c.c. of inoculum into each bottle, replace the stopper, shake and put in the incubator at 37°C. for about 24 hours. Remove, shake thoroughly and place in the ice box. This is 'acidophilus milk' and is ready for use. If kept cold, it is good for at least two or three days.

Administration. Information available at present indicates that taking 1,000 c.c. or more of acidophilus milk daily results in almost complete transformation of the intestinal flora, in most individuals at least, within a period of from one to two weeks. Much smaller quantities are far less effective. Less than 500 c.c. daily probably has little transforming effect. Ideally a portion of the daily quantity should be drunk along with each meal. Unfortunately, the acidophilus flora give way to the usual mixed flora within a week or two after the acidophilus milk is discontinued." (*Methods of Treatment*. Clendenning. 1935).

DEATH OF OVUM AND PREGNANCY TEST

The value of the biologic tests for pregnancy (p. 1454) in determining intrauterine viability is not yet established. In an attempt to solve this question Bishop has summarised the results given by the test in a series of cases in which the date of foetal death could be determined clinically with some degree of certainty. The Friedman test was employed in the eleven cases of the series. In two instances the test was still positive six weeks after the death of the foetus. With these exceptions the test tended to become negative between ten and twenty-four days after intra-uterine death has taken place. The Aschheim-Zondek test, according to other reports, tends to remain positive even longer. The reason for this apparently lies in the greater sensitivity of infantile mice to pregnancy urine than that of adult rabbits. Evidence exists that the Aschheim-Zondek and Friedman tests depend primarily on the presence or absence of functional chorionic tissue rather than on the life or death of the ovum. Since, however, the main function of the placenta is to provide a means of nourishing the living embryo, it might be expected to become inactive on the death of that embryo. Practically, however, it is clear that there is no direct relation between the death of the ovum and the disappearance of gonadotropic substance from the urine. Furthermore, the time after death of the ovum at which the placenta ceases to elaborate the gonadotropic hormone seems to vary considerably in individual cases and to be determined by no mechanism so far understood. (*Jour. Amer. Med. Assoc.* 1935. Vol. 105, p. 1609).

WEIL-FELIX REACTION

The Weil-Felix reaction (p. 977) is included among the heterophile phenomena because there is now little doubt that it is brought about by a specific antigen-antibody reaction. Although the agglutination of strains of *B. proteus* X by the serum of most human beings suffering from typhus fever has been accepted as a fact since 1916, the basis of this specificity has been questionable. Until recently, most bacteriologists refused to accept the theory advanced by the original authors, who expressed their belief in the specificity of the reaction, since the agglutinins for the proteus X bacillus appeared only as the result of an antigenic stimulus, presumably supplied by the virus of typhus, but the weight of evidence to-day impels acceptance of the original view. The agglutination of *B. proteus* X occurs practically only in typhus and typhus-like fevers and not in other febrile conditions. In almost all diseases now known to have a rickettsial aetiology, agglutinins are produced for one or another serologic variety of *Bacillus proteus* OX. (*Archives of Pathology*, 1935, Vol. 49, p. 878).

X-RAYS IN DIAGNOSIS (p. 136)

It is recognized and established that X-rays are of supreme value in diagnosis not only for detection of disease but as a routine examination for the positive diagnosis of health. Every qualified practitioner should understand the extent to which they can be used in diagnosis and should be able to give an opinion on an X-ray examination. When the clinical and X-ray evidence agree the liability of error is very small but when they fail to agree both should be revised in the fuller knowledge of the facts which each has revealed.

Examination of Bones. Bones are liable to injury, inflammation, nutritional disorders, congenital defects and new growth.

INJURY. All injuries to bones should be X-rayed. The injury may be fracture, dislocation, rupture of ligaments tearing away flakes of bone, or merely bruising of the tissues. X-ray films give the fullest information and indicate the line of treatment and prognosis. In all injuries true antero-posterior and lateral views should be taken. Whenever a bone is fractured and displaced the X-ray should be available for immediate use after reduction and until a satisfactory position is obtained; thereafter the part should be X-rayed at intervals during the process of healing.

INFLAMMATIONS. Inflammations of bone produce pathological changes and these changes in structure are shown on the X-ray film. The progress of suppurative osteomyelitis, the line of demarcation of the disease stops short of destroying the shaft, the formation of the involucrum and separation of sequestra—all can be followed in accurate detail by X-ray examination. Of the chronic specific infections of bone, tuberculosis is commonest; early diagnosis is essential and the X-ray alone confirms the diagnosis and shows the extent to which the disease has spread.

DISORDERS OF NUTRITION AND CONGENITAL ANOMALIES. X-ray examination of the growing ends of bones reveals the changes peculiar to these diseases in the delicate growing bones of children, and—with the clinical evidence—establishes the diagnosis.

NEW GROWTHS. X-rays afford the only means of diagnosis in the early stages of new growth of bones—primary sarcoma and secondary carcinoma or hypernephroma. There is growing evidence that the X-ray appearances are more conclusive than even the microscopic section.

Injuries of the Skull. The value of radiography as applied to the skull is well recognised. Each patient must be studied as a separate entity and modification of the usual methods may have to be adopted to meet the vagaries of the patient's condition or complaint whether due to age or illness. Stereoscopic X-ray pictures should be a matter of routine, as many mistakes can be made from single 'flat' films that would not occur if stereoscopic films were taken. A radiograph of the skull

presents at first sight a confusing collection of linear and other shadows due to sutures, vessel grooves, depressions for Pacchionian bodies, Wormian bones and other structures. The variation of these shadows within normal limits is considerable. So is also the thickness of the skull bones. These points must be fully appreciated and considered when examining a skiagram for evidence of injury or disease.

Congenital deformities such as anencephaly and hydrocephalus can be observed in radiographs taken during the latter months of pregnancy and such knowledge may be invaluable. Later deformities such as microcephaly and oxycephaly produce well-marked appearances. In cases of meningocele the extent of the defect in the cranial bones can be observed. Hydrocephalus gives perhaps the most striking picture with the widened sutures and the dappled appearance of the thinned skull bones. The disease may affect the whole of the bones of the skull, face and jaw, and also be visible in the upper part of the spine in some of the radiographs.

INJURIES. Injuries to the skull may result in various forms of fracture. In cases of depressed fracture, these may be best demonstrated by an additional tangent view over the injured area when the extent and depth of the depressed portion of the bone will be seen. Fractures of the base may at times be difficult to demonstrate and X-ray pictures taken in several planes may be necessary before the injury is detected. Fractures of the malar bone frequently involves the maxillary antrum causing hæmorrhage into the cavity, which produces an opacity in the shadow of that sinus. Fractures of the lower jaw are usually easy to show in two or three planes. In cases where sepsis develops from a fracture or following the extraction of a septic tooth, widespread osteomyelitis sometimes occurs and spreads rapidly through the jaw producing in the radiograph a typical worm-eaten appearance of the bone with multiple sequestra of various sizes. The subsequent healing process can be followed by periodic re-examination. Foreign bodies of various nature are of course met with in different parts of the skull and nose and, provided they are sufficiently opaque radiologically, no special difficulty should occur in their localization.

NEW GROWTHS. Primary neoplasms in the cranial bones are uncommon, the ivory exostosis or osteoma being that most frequently met with. They show as a dense homogenous shadow of irregular pattern but smooth outline and varying in extent. Osteo-sarcomas are rare and produce a less homogeneous shadow and their progress is much more rapid. Tumours of the pituitary produce, as a rule, a deformity of the normal outline of the sella turcica, usually showing as an expansion in one or more directions. The posterior clinoid processes are frequently displaced and may eventually disappear and the floor of the fossa may be seen bulging down into the sphenoidal sinus. Neoplasms of the brain rarely show in an X-ray picture without accessory methods as they

rarely contain any salts opaque to X-rays. There are a number of regions in the cranial cavity where calcified deposits are not infrequently seen and must be recognized as normal occurrences. The commonest is in the pineal gland, but in case of cerebral tumour it may be seen to be displaced in some direction and so aid in the localization of the tumour. Other regions where calcifications occur are the choroid plexus, falx cerebri, various blood vessels especially the internal carotid and parts of the dura mater. Calcification in a haematoma may occur and calcified tuberculomas, single or multiple, show as irregularly shaped shadows in sundry areas of the brain. Another form of the deposition of lime salts seen is that of the calcified haemangiomas where areas of dilated and tortuous vessels show well-marked calcification in their walls and the appearance resembles a group of worm-like deposits. Other rarer calcified deposits are seen in the cysts of *Cysticercus cellulosae* which have recently been shown to occur in the brain.

NASAL SINUSES. As a routine examination four or five views are sufficient, provided they are carried out with the necessary care. The erect posture is essential for some positions but others are more comfortably and satisfactorily obtained in the horizontal plane. The final diagnosis of the condition of a sinus must be based on the combined information obtained from all the positions. The one most commonly under observation is the maxillary antrum and practically all the pathological conditions to which it is subject can be demonstrated radiographically. A radiographic examination is the only method at present available by which a general and accurate idea of the size and condition of the sinus can be obtained. Among the common antral conditions met with are polypi which may be seen as 'cherry-like' shadows projecting from one of the walls or more commonly the floor. They vary in size and may almost fill the sinus cavity. Thickening of the lining mucosa shows as a band-like shadow round the wall of the antrum resulting in a diminution of the air space. When fluid is present, if it fills the whole cavity a homogeneous opacity is the result, but if less than full a fluid level may be demonstrated and can be shown to remain horizontal, when the head is tilted. The frontal sinuses show more anatomical variation than any of the others and range from complete absence on one or both sides to a sinus which covers a large portion of the cranial surface, there is also a corresponding variation in depth, this ranging from nothing up to one and half inches or more. Large frontal sinuses are sometimes found in cases of acromegaly. The common conditions discovered by radiographic examination are infection resulting in thickened mucosa or pus which may on occasions be seen as a fluid level. As already mentioned, chronic infection may terminate in osteomyelitis. The ethmoidal cells make an interesting technical study and they can be viewed from many angles. It is uncommon to find evidence of infection of these cells in the absence of infection of neighbouring sinuses, with

correct positioning their lesions can generally be demonstrated satisfactorily. The sphenoidal sinuses may show marked asymmetry both as regards their length and their width. They are easy to demonstrate and can be well shown in three planes. The mastoids present their own problems. The development of the process and the cells themselves vary greatly in individuals, and in the lateral view the anterior extent of the cells may be superimposed over the shadow of the sphenoidal sinus. The size of the cells also differs considerably, some being large and clear and others quite minute, and in some cases the region appears almost non-cellular. Asymmetry of the two sides is common, and in consequence great care must be taken in diagnosis. The introduction of lipiodol into various sinuses may give a clear demonstration of polypi and other lesions in their cavities. During the course of a sinus investigation several other points of information are often available, such as the shape and position of the nasal septum; the size of the turbinate bones and the resulting nasal airway; the presence of unsuspected adenoids may be shown as an encroaching shadow into that of the naso-pharynx. Considerable information regarding the teeth can be obtained such as gross apical infection and the presence of unerupted teeth. The detection of impacted wisdom teeth has sometimes solved an obscure case of neuralgia, headache or some vague group of symptoms.

Chest Diseases. The radiological examination is an essential part of the investigation of chest disease. It is of particular value when history and symptoms suggest the presence of disease and the physical signs are lacking. This is especially true in the case of early pulmonary tuberculosis. The interpretation of the skiagrams, however, requires skill and experience and the practitioner should familiarize himself with the appearances seen in normal cases before attempting to interpret the abnormal.

NORMAL APPEARANCES. If a good film taken in the anterior position is studied, the following structures can be made out:—(1) the soft parts of the chest wall (breasts, pectoral muscles); (2) the bony framework of the chest consisting of the ribs, dorsal spine, and shoulder girdle; (3) diaphragm; (4) the heart and great vessels; (5) the lungs represented by the bronchovascular shadows and the clear spaces between them; and (6) the right horizontal septum.

Soft parts. The shadow thrown by the pectorales major and minor encroaches slightly on the lung fields laterally opposite the second, third, fourth, and fifth ribs.

Diaphragm. The right dome in full inspiration is usually situated at the level of the tenth rib, and the left dome slightly lower. The lung on each side extends downwards below this level, and is therefore partly concealed.

Heart and mediastinum. The trachea is visible above owing to its air content, and normally lies slightly to the left of the mid-line. Below

this the heart and great vessels throw a dense opacity which conceals part of the lung on one side. The right border of this central shadow is formed above by the superior vena cava and below by the right auricle with a distinct notch between the two. At the right cardio-phrenic angle a small triangular shadow is formed by the inferior vena cava. The left border shows a prominence above called the aortic knob or knuckle, and below this there is a lesser prominence caused by the conus of the pulmonary artery. The remainder of this border is formed by the left ventricle. At the left cardio-phrenic angle a triangular shadow is usually seen especially in fat subjects, due to the reflection of the pericardium on to the diaphragm.

Lungs. The lungs on each side, where not obscured by the structures mentioned above, are represented in the film by a fine network of spidery shadows which extends outwards from the lung root or hilum to the periphery. At the lung root these shadows are condensed into an irregular somewhat 'fan-shaped' opacity.

Lung septa. The main or oblique septum is not visible in the anterior view, but the right horizontal septum is projected as a fine transverse line which cuts across the anterior parts of the third and fourth ribs.

CHANGES IN DISEASE. *Pleurisy, pleural effusion, and empyema:* When a simple dry pleurisy with a friction rub is present there may be no changes on X-ray examination beyond restriction of movement of the affected side on screen examination, and sometimes even this is not seen. More often, however, there is some thickening of the pleura, which is evident at the margin of the lung field especially in the costo-phrenic angle. If fluid is present, the shadow becomes accentuated and owing to the negative pressure in the pleural cavity, it extends upwards along the margin of the lung as a lateral opacity, broad below and narrower above. As the fluid accumulates, the shadow increases in size and the heart and mediastinum are displaced to the opposite side unless prevented by the presence of adhesions or fibrosis in the lung.

An exactly similar shadow can be seen in the early stages of empyema, but if the fluid becomes encysted a more circular shadow will be present. A lateral skiagram will be required to localize its position before exploratory puncture. When air is also present in the pleural cavity the negative pressure is reduced and a characteristic fluid level is seen in a skiagram taken with the patient erect. If the accumulation of fluid is large, the whole of the lung field may become opaque, and in such a case the presence of fluid can be diagnosed from the displacement of the heart and mediastinum away from the affected side. In massive fibrosis of the lung with pleural thickening a similar opacity is evident, but the heart and mediastinum are observed to be displaced to the affected side.

Pneumonia. The radiological signs of lobar pneumonia are characteristic and consist of a hazy opacity over the affected lobe which usually appears within the first twenty-four hours and lasts for some weeks from the commencement of the illness. X-ray examination is valuable during the acute stage to show the area of lung involved, and during convalescence in order to determine if normal resolution is occurring. It is almost essential where empyema is suspected. The X-ray appearances in bronchio-pneumonia consist of scattered areas of opacity which appear two or three days after the onset of the illness and which show a tendency to coalesce. In serious cases considerable areas of the lung may become opaque.

Bronchitis and emphysema. The X-ray changes noted are as follows :—(a) Increased clarity of the lung fields especially at the bases ; (b) flattening of the domes of the diaphragm ; (c) increase in the root shadows and basal lung markings from the presence of fibrosis ; and (d) degenerative changes in the bronchi (shown by a lipiodol examination).

Bronchiectasis. Patients suspected of this distressing malady require an X-ray examination which will include not only plain skiagrams of the lungs, but also films obtained after the introduction of lipiodol by the oral or cricothyroid route or by means of a nasal catheter passed into the trachea. In the preliminary films the presence of bronchiectasis may be suspected if a localized 'honeycomb' appearance is present in some part of the lung field. But the true nature and extent of the disease can only be shown after a careful lipiodol examination.

Pulmonary tuberculosis. In this disease the X-ray examination is one of the most important of the various methods of investigation, and it should never be omitted. The radiological appearances vary with the age of the patient and can be described under the headings of :—(a) tuberculosis in children ; and (b) adult type of disease.

Tuberculosis in children. Lesions due to active disease are comparatively rare in children. If the infection involves the mediastinal glands, the root shadows are seen to be enlarged and clouding will be present in the adjacent lung field. The glandular enlargement can be seen in skiagrams taken in the anterior position and also in a skiagram taken in the true lateral position. An interesting group of cases comprises those in which areas of opacity, sometimes corresponding to a whole lobe and resembling pneumonia in appearance, are seen. Skiagrams in other patients will reveal the presence of the adult type of disease.

Adult type of disease. In the stage of early infiltration a small area of clouding about the size of a shilling is visible in the lung field. The commonest site is just below the clavicle but it must be recognised that the disease may also be located in some other part of the lung field and that it may be concealed by the heart shadow unless an oblique view is obtained. These early changes are frequently not discovered by screen examination alone and require skiagrams of the best quality

for their detection. In a difficult case serial skiagrams may be required at intervals of fourteen days to establish the presence of a progressive lesion. In fibro-caseous disease the changes seen in the skiagram correspond closely to the signs of the disease observed clinically and to the pathology. Cavities appear as annular shadows which enclose an area of translucency, and fibrosis is shown by the presence of dense linear opacities.

Lung abscess. •X-ray examination is required in this condition to show the site of disease, which is revealed by the presence of clouding in some part of the lung field, and in order to localize accurately the area of lung involved before bronchoscopic or surgical treatment is undertaken. In the first stages of the disease, the typical appearance is a 'cotton wool' shadow in some part of the lung field. As the disease progresses a cavity may be formed and is then seen as a central translucent area with a fluid level. If resolution does not occur, the X-ray changes become more marked and the whole lung field may be obscured.

New growth. The presence of a bronchial carcinoma is revealed by an opacity, which is due partly to collapse of some part of the lung. Involvement of the mediastinal glands causes an enlarged hilum shadow which can be demonstrated in the anterior and lateral skiagrams. Serial films will reveal a slowly increasing opacity. When the growth starts in the mediastinum an irregular shadow can be seen spreading out into the lung field on each side. If the growth is located in the superior mediastinum close to the great vessels, the appearance at first is closely simulated by an aneurysm. The X-ray appearances of metastases consist either of multiple rounded opacities in the lung field rather like snowballs in appearance or of a coarse generalized mottling which must not be mistaken for the finer mottling of miliary tuberculosis.

Benign tumours form a circumscribed, rounded opacity which is a conspicuous feature in the skiagram.

Abdominal Diseases. From the radiological point of view the easiest diagnosis is gastric ulcer. The characteristic appearance is a niche or projection on the wall of the lesser curvature. The niche may vary in size from a pinhead to a cherry, but in the majority of cases is about the size of a pea. In addition to the niche there are various indirect signs of gastric ulcer, the chief of which are localized pain on pressure, localized spasm and gross disturbance of the rate of emptying of the stomach. In the early days of radiology considerable reliance was placed on the indirect signs because in many cases the niche could not be brought into view when situated deep on the posterior wall of the stomach. A modern method of examination of the gastric mucosa, generally known as 'dosed compression' has eliminated this difficulty. The technique of 'dosed compression' consists in introducing a small quantity of a watery solution of barium into the stomach, and under the screen slowly squeezing this mixture

over the gastric walls so as to outline the gastric rugae. In cases of ulcer, the rugae of the lesser curvature instead of taking their normal linear course converge to a point above the ulcer and diverge from a point below the ulcer. In addition to this finding the rugae of the greater curvature are generally seen to be raised and thickened, an appearance aptly described by Berg as an ulcer gastritis. Examination of the gastric mucosa alone gives no evidence of the tone, peristalsis or rate of emptying of the stomach and should therefore only supplement the ordinary barium meal examination in selected cases. The size of the niche is not an adequate guide to the true size of the ulcer and is not a reliable guide to prognosis. It was formerly thought that a large niche was in favour of the ulcer being malignant and irrespective of this factor, that a large niche was an indication for surgical rather than medical treatment. A careful screen examination of the gastric mucosa will generally show whether a niche is malignant or not, and every radiologist has seen craters as large as a florin disappear under adequate medical treatment.

The diagnosis of early carcinoma of the stomach is perhaps the most difficult problem for the radiologist. The earliest sign of a small area of malignant infiltration must be an interruption of peristalsis over the affected area. Advanced gastric carcinoma produces on a radiograph a characteristic appearance known as a filling defect; in other words there is a large area of the stomach which is not covered by barium. There are innumerable types of filling defects depending on whether the neoplasm is of the fungoid or scirrhous type. As a rule malignant filling defects have a ragged outline and there is complete absence of peristalsis over them. Malignant filling defects can be simulated by spasm, by adhesions and by rare lesions, such as adult pyloric hypertrophy and gastric syphilis. Syphilis of the stomach is seldom diagnosed by X-ray alone.

DUODENAL DISEASE. Duodenal ulcers are usually situated on the posterior wall and therefore cannot be shown in profile like gastric craters. They are most readily visible when there is associated spasm, and fortunately this is usually the case. The characteristic appearance is an indentation on the greater curvature of the cap, retraction of the lesser curvature and between the two a small dense fleck of barium. The fleck is tender on pressure and may be visible for some hours after the stomach and duodenum have completely emptied. This fleck is the only diagnostic sign of duodenal ulcer and every effort should be made to get an X-ray picture of it. If there is strong indirect evidence of ulcer, such as deformity of the cap and pain on pressure with reflex irritation of the stomach, the duodenum should be examined further by means of serial skiagraphs.

JEJUNAL ULCER. The X-ray diagnosis of jejunal ulcer as a sequel to gastro-jejunostomy has been considerably improved by the compression

technique and the demonstration of the mucosa at the site of the anastomosis. As in the normal stomach and duodenum, the diagnostic appearance is a persistent fleck with thickened rugae converging on it. When a jejunal ulcer is visualized by X-rays the meal should be carefully followed and if necessary an enema should be given shortly after the meal to determine whether such adhesions are present or not.

APPENDIX. X-ray examination of the appendix is reliable in 95 per cent. of cases. In about 80 per cent. of cases the appendix fills readily during an ordinary barium meal examination; of the remaining 20 per cent. 15 can be filled by following the barium meal with a saline aperient or by giving a barium enema, and the remaining 5 per cent. cannot be filled by any method. Failure to fill suggests, but is not diagnostic, of a morbid change. The radiological signs of an inflamed appendix are 'rosary bead' appearance due to fecoliths, kinks which cannot be straightened out, fixity of the tip of the appendix and pain on pressure.

LARGE INTESTINE. For the investigation of diseases of the large intestine both a barium meal and a barium enema are desirable. Mucous colic is perhaps too frequently diagnosed from X-ray appearances. Characteristic findings are stated to be:—(1) Rapid filling of the colon on barium meal examination, i.e., the meal reaches the iliac colon in 6 to 9 hours instead of the normal 16 to 24 hours; (2) Spasm of the distal half of the colon giving a ribbon appearance; (3) Complete evacuation of the meal in 24 hours or less; (4) A narrow lumen of the pelvic and descending colon with absence of haustration on enema examination; (5) Pain on pressure over the descending colon. Unfortunately all of these signs can be produced by the injudicious use of aperients and enemas, a prevalent addiction which renders the accurate X-ray diagnosis of mucous colitis very difficult.

Ulcerative colitis has such a typical picture that X-ray examination is only used to determine the extent of bowel involved and the progress of the disease under treatment. A barium enema, but not always a barium meal, gives characteristic appearances. The enema appearances are:—(1) Absence of haustration; (2) dilatation of the lumen with intermittent contractions giving a 'string of sausages' appearance; (3) non-homogeneous filling of the gut, the barium lying in flecks on the oedematous mucosa; (4) large flat flecks which are actual ulcer craters. The mucosa of the large intestine and the actual craters can be visualized by using the following technique. The patient is given a thin barium enema and makes an evacuation shortly after the injection. This evacuation expels one third to one half of the barium. Air is then gently pumped in with a Higginson's syringe and the residual liquid barium is evenly distributed over the intestinal mucosa. The introduction of the air is not a comfortable procedure and is seldom necessary in a case of ulcerative colitis. The method, however, is of great value for the detection of single ulcers (possibly malignant) and bleeding polyps of the lower bowel.

Diverticulosis and diverticulitis can give rise to the same clinical findings as carcinoma of the large intestine, and X-ray examination is the most useful method of making the differential diagnosis. The barium enema is more valuable than the barium meal. There are two diagnostic appearances:—(1) A saw-tooth edge of the affected area of the intestine. (2) The demonstration of the diverticula. Both are usually seen together, but sometimes the saw-tooth edge is seen alone.

Carcinoma of the large intestine. Generally speaking the X-ray appearances go hand in hand with the symptoms—the more severe the symptoms the more obvious are the X-ray appearances—but occasionally the radiologist discovers an entirely unsuspected intestinal neoplasm. The earliest signs of carcinoma of the large intestine are spasm or interference with peristalsis in the affected area. The characteristic sign of carcinoma is a filling defect which may or may not be associated with distension of the bowel proximal to the defect. The filling defect, like that seen in carcinoma of the stomach, is usually irregular in outline and may vary in extent from half an inch to a foot.

GALL BLADDER. The frequency of gall-bladder disease and the influence it exerts on other abdominal organs has been revealed by the introduction of cholecystography. This has been described in detail elsewhere. (*Practitioner*, July, 1935).

GROSS APPEARANCE OF INFECTED WOUNDS

It commonly happens that the physician or surgeon must decide by the gross appearance of a wound or ulcer what the infecting organism may most likely be.

STAPHYLOCOCCUS INFECTION. During the early stage of the typical staphylococcal infection the tissues are hard and indurated. Later this area will either go back to the normal condition or it will soften in the centre and a slough will form. This slough is composed of dissolved tissue, pus cells, and bacteria, and is surrounded by a zone of tissue and vascular response which is called 'pyogenic membrane.' The pus is usually thick in consistency and creamy yellow in colour, being the most common form of pus that is seen. Occasionally the pus may have a pale greenish colour or may show streaks of blood.

STREPTOCOCCUS INFECTION. Wound infections due to various strains of *Streptococcus pyogenes* are the constant dread of the surgeon. Staphylococcal pus was often described as being 'laudable pus,' while that now known to be due to the streptococcus was called 'pernicious pus.' This pus is thinner, may be lumpy or curdy; often streaked with blood, black, red, brown, or dirty colored.

ESCHERICHIA COLI INFECTION. These lesions are usually seen only in those who have been long in bed, are considerably debilitated, and of low resistance. The lesions are more commonly near the pelvic organs.

The tissues about the lesion are usually not very badly inflamed, the pus is greyish and rather slimy, and has an odour commonly described as 'fæcal' though this is not strictly correct. Nearly always *Staphylococcus albus*, and often *Staphylococcus aureus* are associated. The granulation tissue is indolent, grey and usually oedematous. The lesions are not often highly destructive, but may persist for a long time.

PSEUDOMONAS AERUGINOSA (BACILLUS PYOCYANEUS) INFECTION. These infections present a very striking appearance and are likely to be quite alarming to the patient and his family. The pus produced is of a bluish-green appearance and stains the dressings. Unless the patient is reassured he is likely to think that gangrene has taken place and that his case is hopeless. As a matter of fact the infection is rarely of any consequence and the patient may be reassured.

CLOSTRIDIUM TETANI INFECTION. It is a matter of common knowledge that a mere scratch may suffice to cause 'lockjaw'. More commonly, however, a wound that causes tetanus shows evidence of having had pus and a crust over it, or a foreign body in it. The diagnosis of tetanus is made, however, not from the wound but from the systemic symptoms, the history of a scratch or an injury being merely confirmatory. A piece of tissue removed at biopsy may be useful in making a diagnosis. When crushed or sectioned typical bacilli may be seen when a bacterial stain is used.

ANTHRAX INFECTION. (Malignant pustule). This dangerous infection resembles a boil at first but soon changes in appearance to a dark or black necrotic lesion with serosanguineous or seropurulent contents and is surrounded by an 'angry' red area. If it is promptly excised the patient will usually recover but if neglected the outcome is fatal as a rule.

CLOSTRIDIUM WELCHII INFECTION: (Gas gangrene). The part is commonly much swollen, and greatly discoloured. A 'bronzing' of the skin is characteristic. Crepitation of the tissues due to the presence of tiny bubbles of gas makes the diagnosis nearly certain. The exudate from the wound is commonly a brown fluid that contains many gas bubbles. A fætid putrefactive, or acid odour is common.

CLOSTRIDIUM HISTOLYTICUM INFECTION. This is a rare condition which produces very marked proteolysis of the tissues affected, without producing general symptoms of any consequence.

CORYNEBACTERIUM DIPHTHERIÆ WOUND INFECTION. This is a very serious condition, but fortunately is rare. When there are symptoms of marked intoxication as in diphtheria and the patient has a wound, close examination of the latter is indicated. Smears should be made, and there should be no delay in giving antitoxin if there is anything that resembles a diphtheritic membrane in the wound.

PASTURELLA TULARFENSIS INFECTION. A papule first appears, then an ulcer and an ugly black slough. Regional lymph glands swell, and systemic symptoms appear

HEMOPHILUS DUCREYII INFECTION. The soft chancre consists at first of a red papule which in two or three days becomes a vesicle surrounded by a zone of 'angry' hyperemia. In four or five days the lesion becomes a pustule and then the cuticle breaks through, forming an ulcer. This ulcer is rather characteristic in that it has a ragged, inflamed, and undermined margin, but shows little induration. It heals in about three weeks if everything goes well and it is given the proper care.

NEISSERIA GONORRHOEA INFECTION. Thick yellow pus, with underlying tissue very red.

BED-SORES. It is commonly said that these are simply pressure sores caused by the continuous local anæmia in the patient with a poor circulation and not enough fat to pad the skin and bones. The bacteriology of bed-sores has usually not been taken into consideration. Examination of a rather large number of these sores in recent years has revealed that all of these lesions contain at least the *Staphylococcus aureus* and *Escherichia coli*. *Staphylococcus albus*, *Pseudomonas aeruginosa* and a great many other contaminating and saprophytic bacteria are also commonly found, but the significant ones are undoubtedly *Staphylococcus aureus* and *Esch. coli*. These organisms doubtless account for the destructiveness of the lesions, for the purulent discharge and for the pungent faecal odour—a particularly disgusting and offensive odour. These lesions are probably caused, as is commonly stated, by the local anæmia and local trophic nerve disturbances, or irritation, but it is the action of bacteria that causes them to have the characteristics that are so commonly seen.

If the bacterial infection can be corrected these lesions will heal fairly promptly, provided, of course, that the condition that caused the sores has been removed. Bacteriophage active against cultures of *Staphylococcus aureus* and *Esch. coli* has been successful to a striking degree in cleaning these dirty, ugly sores, checking the offensive discharge and odour and in bringing about the development of healthy granulation tissue, and healing with the minimum of scar. Bacterial infection is not the sole cause of these sores, but it is always present after the sore has developed, and if corrected will greatly foster the healing process. Patients with diabetes, syphilis, arteriosclerosis, trophic nerve disturbances, and senile changes of marked grade have shown complete healing, usually in spite of the fact that their primary condition was unimproved or definitely worse. The treatment of decubitus ulcers is bacteriological as well as physical.

Site of focal infection. (1) The faucial tonsils, the peri-tonsillar tissues and supratonsillar fossae. In this may also be included the lymphoid tissue embraced in the pharyngeal tonsil and elsewhere in the nasopharyngeal space. The abundance of this tissue in the child probably explains the frequency of infections like acute rheumatic fever, diphtheria, tonsillitis, etc., in the earlier periods of life. The fact that chronic septic focal infection may lie latent in the tonsillar

tissue has not been generally recognised. That this focal infection may produce a chronic systemic disease is established by clinical experimentation. (2) Abscess of the gums and alveolar sockets, pyorrhoea alveolaris and septic types of gingivitis may also cause systemic disease of various types. (3) The various sinuses about the head—maxillary, ethmoidal, sphenoidal, and frontal—may also harbour focal infection and cause systemic disease. (4) Bronchiectatic and pulmonic cavities due to chronic disease may also produce chronic systemic infections. (5) Chronic ulcers of the gastro-intestinal tract, specially of the bowels. This source is probably rare and more problematic than that of any other systemic infection. (6) Chronic appendicitis. Chronic catarrhal appendicitis may produce not only the local discomforts including disturbance of the functions of the digestive organs, but may also be a focal source of systemic infection with the damage done chiefly to the cardiovascular apparatus. (7) Cholecystitis and cholangitis, with or without calculi, have been recognised as sources of systemic infection, the brunt of the damage apparently falling on the cardiovascular apparatus and kidney. (8) The urinary tract, including the pelvis of the kidney, the bladder, and more particularly the prostate gland. Pyelitis of whatever type, even when there is only moderate obstruction of the drainage of the kidney pelvis, may produce myositis, arthritis, neuritis, etc. (9) Genital tract. The prostate and seminal vesicles are a common source of infection of gonorrhoeal arthritis and probably of ordinary septic infections. The fallopian tubes and the uterus are less commonly a source of chronic systemic disease in all probability. It is said that the parametrium is a more common focal source of infection. (10) Local, septic, submucous and subcutaneous foci anywhere in the body may be a source of systemic disease.

Systemic results of focal infection. (1) Chronic arthritis is one of the most common results; (2) nephritis, both acute and chronic; (3) cardiovascular degenerations; (4) chronic neuritis and myalgia (myositis).

INTEGRATION OF THE ENDOCRINE SYSTEM

To state briefly the view of the integration of the endocrine system there is doubtless an autonomous activity of these glands according to the steady biochemical demand of the body, but their activity can be profoundly modified and extensively controlled by centres in the diencephalon which are largely concerned with emotional expression. These centres may operate directly through the sympathetic nervous system (indeed, the hypothalamus has been called the head ganglion of the sympathetic) or indirectly through the chemical activities of the anterior pituitary. The anterior pituitary forms two basic secretions probably of a protein character, one being stimulating the other inhibitory in effect. They correspond in fact to

Sharpey Schafer's original distinction between a hormone and a chalone. It is suggested that the former is produced by the eosinophile, the latter by the basophile cells. These basic secretions are capable of chemical modification according to the needs of the body, and are then ready to stimulate or restrain the secretion of simpler hormones by the other endocrine glands, including the post-pituitary. It may be as Zondek maintains, that the hormones circulate in an inactive form, only becoming activated when they reach their destination. This indeed might explain some of the observations on the alleged hormone-antihormone linkage. Certain it is that their destination is decided by some peculiar receptive capacity in the structure on which they act, catalytically or otherwise. What determines that receptive capacity, we do not know as yet. But we can say that the whole process appears to be a special case of the general law that nervous stimuli, whether passing from the diencephalon to the pituitary, or down neurons to pre and post-ganglionic endings, act through the intermediary of chemical substances locally produced. And there may be some further support for this view in the fact that, in one instance, the same substance, adrenalin, is the final product of either hormonal or nervous activity. (*Lancet*, 1935, p. 1160).

Endocrinology in Relationship to Interpretation and Understanding of Common Symptoms. Advances in the study of glands of internal secretion cannot be judged solely or chiefly by the extent to which they lead to successful organotherapy but more by the profound influence they have on the understanding and interpretation of common symptoms. Consideration of their relation to hypertension, obesity and disturbances in carbohydrate metabolism is of especial importance because of the frequency of such manifestations, because they are often encountered in the same individual and because in certain striking instances they are directly attributable to pathological changes in the hypophysis or the adrenals. Although participation of these and other glands of internal secretion must be suspected in many cases of high blood pressure, obesity and diabetes, caution is necessary lest the newer knowledge be applied prematurely and too extensively in surgical and radiological treatment. (*Jour. Amer. Med. Assoc.*, 1935, Vol. 105).

PYROGENIC (FEVER PRODUCING) SUBSTANCES IN DISTILLED WATER (p. 42)

The fact that certain bacteria can grow in distilled water is well known. The work of Seibert, and of Broun and Seibert (*Am. J. Physiology*, 71, pp. 621-629) has done much to explain the fact that intravenous solutions made from stale contaminated distilled water can cause dangerous reactions and may even cause serious injury even though it is sterile at the time the injection is made. It was found that about 50 per cent. of distilled waters from different laboratories produce fever

when injected intravenously into rabbits. The fever-producing substance is a bacterial product and can be removed by distillation.

The bacteria at fault can be divided into three groups (25 strains studies) :—

I. All strains studies which were not responsible for fever production are put into this group, which is in turn divided into two groups. (A) Red chromogenic bacilli, and (B) Chromogenic micrococci.

II. The strains which were responsible for mild fever seem to be related to Jordan's group XI, and are characterised by the fact that they are bacilli which do not liquefy gelatin, and do produce alkalinity in milk.

III. Strains responsible for severe fever and even death all seem to fall within the group X described by Jordan. They are somewhat similar to the coli group except that no gas is produced on sugar broth and no indol is formed. They produce acid in milk, but do not liquefy gelatine. They seem to belong to an unnamed tribe of Bacteriaceae belonging somewhere between *Erwineae* and *Bastercae*.

As to the chemical nature of the pyrogen, it is destroyed very slowly by heat alone, but readily by heat in the presence of acid or alkali. It can be concentrated under diminished pressure, and temperature under the boiling point, the amount of concentration being tested by the degree of rise in temperature in rabbits when it is injected.

Anaphylactic reactions were produced in rabbits sensitized by concentrated pyrogenic water, while non-sensitized rabbits did not respond similarly. Similar shock reactions were produced in rabbits by the first injection of aqueous Berkefeld filtrates of the two strains of bacteria isolated from pyrogenic waters.

This work does much to explain the very annoying chills which so often follow intravenous medication. Only distilled water which has been sterilised immediately after distillation and then stored in a germ proof container is safe for intravenous use. Such water may be prepared in any well-equipped laboratory or surgery or may be bought in ampoules. All connections should be thoroughly cleaned before being sterilized. Rubber tubing should be thoroughly brushed on the inside with a slender tube brush. It should then be rinsed thoroughly and boiled with the apparatus. There are doubtless other causes of 'chills' after intravenous medication, but certainly the most common one is the presence of a pyrogenic substance in the distilled water, a result of bacterial growth.

In making solutions for intravenous use, use only water that was sterilized and sealed immediately after having been distilled.

CLIMATE AS A DISEASE FACTOR

According to the meteorologists the temperature, moisture and movement of the air, the amount and quality of the light, the rainfall and barometric pressure form the chief items of a group of conditions

which, taken together, constitute the weather of a place at any given moment; the average weather of a place throughout the year constitutes its climate. It is, however, advantageous to use the word "climate" in the loose, popular way as indicating the general weather conditions of the locality at a given season rather than to attempt to summarise the average weather for the whole year.

CLIMATE AND HEALTH. Climatic conditions affect the health of human beings in several ways:—(a) *Directly*. The conditions of air temperature, moisture and movement taken together may be favourable to the vitality and energy of the body, they may act unfavourably by lowering resistance to disease, or they may actually cause diseases like heat-stroke or frost-bite. Light may act in a favourable or unfavourable manner; excess of light gives rise to solar dermatitis and night blindness; defect of light is one of the causes of rickets and osteomalacia. Light may increase vitality when it falls on the body in suitable amounts, whereas deficient exposure to light may be a cause of lowered vitality. (b) *Indirectly*. The crops of a place, and hence the food supply of the people, depend largely on climate. Insect life is much influenced by climate. Diseases which are conveyed by insects can only be transmitted when the climatic conditions are suitable for the existence of the insects, for the development of the disease parasites in their bodies, and for their ability to bite human beings. Bacteria which have to pass through the air on their way from person to person are also affected by the temperature, moisture, and movement of the air, so that climatic conditions may greatly influence the spread of 'droplet' infections, and even in some cases the spread of contact infections. Much attention has been devoted to the influence of climate in connection with the prevalence of diseases like malaria, plague, relapsing fever, small-pox, cholera, etc. There is doubt regarding the association between climate and cholera transmission, though the influence of air temperature and moisture on the spread of this disease is not understood. Rainfall for instance may favour transmission or cause its disappearance.

GENERAL EFFECTS OF TROPICAL CLIMATES ON THE HUMAN BODY. There is a most unfortunate impression that any sensation of cold ought to be avoided: the origin of this mistaken belief is that many fevers start with a feeling of chilliness, and so it is natural for people to think that chill has been the actual cause of these fevers whereas it has merely been a symptom of the onset. The dread of the slightest sensation of cold on the surface of the body is responsible for a vast amount of ill-health; it leads to the closing up of doors and windows, and so conduces to the spread of droplet infection; it also causes people to coddle themselves so that they lose the power of reacting to a fall in air temperature and therefore become liable to suffer ill effects from slight exposure to cold. The body ought to be capable of resisting changes of temperature; it cannot attain to full vigour unless

exposed to these changes within reasonable limits. In very hot weather, especially when the high air temperature is accompanied by excessive air moisture and lack of movement of the air, the body has to contend against a set of unfavourable conditions: the cooling effect of the air, combined with evaporation from the body surface, may be just sufficient to keep the temperature within normal limits, even when the muscles are relaxed and all the other tissues are inactive. In such conditions exercise is almost impossible, as bodily work is always accompanied by a great increase in heat production, the appetite is feeble, because assimilation of food causes increased heat production; the body has no opportunity of reacting to cold and hence loses the power of doing so. Persons exposed for long periods to these conditions tend to become enfeebled and lose their resistance to disease. Their mental energy is also sapped: they often become fatalistic and cease to make any effort to improve their climatic environment. In cold countries steps are taken to heat dwelling-houses, but in the tropics artificial cooling of houses is regarded by many as a preposterous suggestion, although it is much more necessary for the maintenance of health than artificial heating in cold climates.

SUNLIGHT AS A FACTOR IN CAUSING HEALTH AND DISEASE. The rays of the sun have very different properties according to their wave-length. These are shown in the following table.

Properties of the Sun's Rays

	Visibility.	Chief actions.	Diseases caused.
Heat rays.			
1. Infra-red.	Invisible.	{ Heating.	{ Heat exhaustion.
2. Red.	Visible.		
Luminous rays.			
3. Orange.	Visible.	Chiefly illuminating	{ Glare headache.
4. Yellow.			
5. Green.			
Chemical rays.			
6. Blue.	{ Visible.	{ Stimulating and anti-rachitic in moderate doses.	Solar dermatitis.
7. Indigo.			
8. Violet.			
9. Ultra-violet.	Invisible.	Irritant and destructive of tissues in excessive doses.	Pigmentation.

* TROPICAL SUN. In the tropics all the rays of the sun tend to be more powerful than in cool climates, but they have no mysterious dangerous properties, such as are often attributed to them. The prevailing idea that certain rays of the tropical sun can penetrate through

considerable thicknesses of cloth or other material is a myth. Any fabric which cuts out the visible rays will also cut out the ultra-violet rays. The strongest tropical sunlight, after passing through a thin white muslin cloth, acts less powerfully on the skin than the unscreened rays of the noon-day sun in England. The real harm done by the rays of the tropical sun consists in their powerful heating effect on the body, so that when a person is exposed to trying atmospheric conditions the direct heating action of the sun's rays adds greatly to his discomfort and also to the risk of heat-stroke. The wearing of a broad-brimmed pith helmet in bright sunlight is a highly rational procedure—it protects against heat and glare; but to wear a 'topi' in a well shaded verandah, or when the sun is near the horizon, is absurd. In the cool of the morning a reasonable exposure of the body to light is very useful, though excessive exposure to the ultra-violet and heat rays throughout the day is most injurious.

CLOTHING IN THE TROPICS. It would be much easier to devise suitable clothing in the tropics both for men and women if the decrees of fashion could be ignored. In existing conditions all that can be done is to rectify the more glaring defects. There are places in the tropics in which the most suitable 'clothing' would consist of a large umbrella; but idyllic simplicity of this kind is impracticable, so we have to fall back on the next best thing, which consists of white, loose clothing of light texture. A loose tennis shirt of thin white cotton kept open at the neck, a loose pair of white cotton 'shorts' supported by buttons fixed on the shirt, and a large well-ventilated pith helmet are most suitable for wear in the day time. Long trousers are necessary after sundown to protect the legs against mosquito bites. It is even more difficult to devise suitable clothing for ladies than for men, but with the passing of the dangerous short skirts, which left the legs exposed to mosquitoes, the day clothes of European women in the tropics are now more suitable on the whole than those ordinarily worn by men. When a coat is worn braces are more suitable than a belt; the clothing should not constrict any part of the body, especially the neck and waist. Special materials like 'Solaro' have no great advantage over ordinary fabrics; white has the valuable property of filtering out the heat-rays better than any other colour, and the ultra-violet rays which are allowed to pass through any ordinary cloth are so reduced in intensity that they are incapable of doing any harm. Pale blue comes next to white in its power to cut out heat-rays, then comes khaki, while black is least effective of all.

In malarious places a really important point is that the body should be protected as completely as possible against mosquito bites after sundown. Chill has to be guarded against when there are sudden changes in temperature: the abdomen is the part most liable to damage by chill. A light woollen shawl or blanket should be wrapped round the abdomen at night, even when the weather is so hot

that no other bed clothing is endurable. There is often a sudden fall in the temperature at night in the tropics; if the abdomen has not been protected a sharp attack of diarrhoea or a lighting up of an old dysentery may result. After exercise it is usual for people to put on heavy sweaters and flannel coats. This practice may be necessary for those who have not trained their bodies to react to changes of temperature, but for the healthy person who has not coddled himself a tepid bath and a change into light clothing is the best procedure. A Turkish bath and perspiration produced by heavy woollen clothes is both nasty and unhealthy. The sensation of coolness should be sought after rather than dreaded, provided that the abdomen and chest are protected and local chilling of one part of the body is avoided. The general rule for the tropics is "keep as cool as you can, as long as you can"; if you have kept cool and accustomed yourself to react to changes of temperature, there is little reason to dread the chills which are such bugbears all the world over. It is not suggested that chills should be ignored. Those who have kept themselves in hot house conditions for years may suffer from very serious illness if they are exposed to cold; they must expect to pay the penalty for having adopted wrong habits; the acquisition of these is the initial mistake. The importance of local chilling of the body in lighting up fibrositis, respiratory infections, etc., is well recognised, but war experience has shown that exposure to cold and wet can be endured by healthy persons with surprisingly little ill effects. The fashions in women's dress which involve exposure of the neck and chest to cold have not resulted in the expected crop of pneumonia and sore-throat.

HEAD WEAR. A good topi protects the head and a great part of the body from the heat-rays of the sun, and so helps to ward off heat-stroke. The local heating of the head and surface of the brain by the noon-day tropical sun may be very harmful in itself, apart altogether from the extra heating effect which is produced on the body as a whole. Corrie in Senegal has made some interesting observations on the air temperature inside various kinds of head-gear in noon-day tropical conditions. The records were:—(1) Pith helmet, with white cover and ventilation 35.6°C. (2) Straw hat, with white cloth cover (French Marine pattern) 37.5°C. (3) French non-commissioned officer's kepi, without cover, but with ventilating holes 39.0°C. (4) French sailor's cap, with white cover, 40.0°C. (5) French sailor's cap, without cover, 41.0°C.

A large thick pith topi with effective ventilation round the rim and in the top is the best form of head-gear. An umbrella is even better than a topi, as it protects a much larger area of the body from the heat rays of the sun.

HOUSING IN THE TROPICS. Where the prevailing climate is one of intense dry heat, insulated roofs and walls, lofty rooms provided with doors and windows which can be properly closed in the heat of the day are essential. Single-storied bungalows with low plinths are better

than two-storied houses as the earth under the house serves as a reservoir of 'coolness' for a considerable time after the onset of the hot weather. The house should be closed early in the morning and opened only when the outside temperature falls below that of the inside. Clerestory windows, high up in the walls, are useful in allowing the heated air to escape during the night; like the other windows, they must be closed during the heat of the day. Where the prevailing heat is moist and excessively high air temperatures do not occur, the insulation of the roof and walls is of less importance; the essential point is to construct the house so that plentiful through ventilation can be secured during the whole day and night. Air which is heated by contact with the roof or walls is so rapidly swept away by the through draught of air that it has no influence on the air temperature of the lower part of the room. No single type of house can be prescribed as suitable for all tropical countries; each place has its own special conditions which must be studied. In malarious places the houses must, of course, be mosquito-proof in an intelligent manner.

ARTIFICIAL COOLING OF HOUSES. In large industrial centres artificial systems of cooling are gradually being introduced into offices, hospitals, operating theatres, places of amusement, etc. The first plant of this kind in India was installed in the Calcutta School of Tropical Medicine. It has been in regular use since the opening of the school in 1920, and has proved very successful. The incoming air is cooled by being blown by a fan over the cold pipes of a refrigerating plant. In the cooling chamber the temperature of the air is lowered to such an extent that much moisture is precipitated. The air is then forced into the room where its temperature rises several degrees so that it becomes relatively dry. Air is constantly being drawn from the room by the same fan which forces the cool air into the room; some of this air is returned to the room after being cooled again, but provision is made for the introduction of an ample supply of fresh air through a gauze filter contained in the circuit. The net result is a regular supply of cool, fresh, dry air, free from dust and insects. No fans are needed, and books, delicate instruments, etc., keep in as good condition as in temperate climates. The cost of installation to cool a whole house would be prohibitive, but one or two rooms could be cooled by an inexpensive plant on the same lines. In the case of offices, hospitals, barracks, etc., a system of central cooling will probably be found practicable in the near future. Already several commercial concerns are specialising in 'air-conditioning' plants, but these are still too costly for general use. In places where dry heat prevails, a simple system based on the principle of the 'thermantidote' will suffice. A good electric exhaust fan like the 'Sirocco' is fitted into a hole in a door. To the outside of the door is fitted a frame slightly smaller than the door and about eighteen inches in depth. To the frame a *khus-khus* screen is attached in such a way that all the air

sucked into the room by the fan must pass over the screen, which is kept constantly moist by a drip from a cistern placed overhead in a shaded place. This system will not be effective when the outside air is damp, but in this case the heat will be less intense and ordinary fans will suffice. In many cases the flow of air created by the two fans of the installation will be enough if the flow of water over the *khus-khus* screen is cut off. In places which have a cold winter and hot summer both conditions can be provided for simply by using a coil of hot-water pipes instead of the *khus-khus* screen in cold weather. The cooling effect of evaporation of water has not been adequately exploited in dry, hot places. It is deserving of further study and experiment.

The Cooling of Railway Carriages. The air of railway carriages is often dangerously hot, especially in places where intense dry heat prevails. Blocks of ice do little to mitigate discomfort, as the air which is cooled by them falls to the floor and is rapidly swept away through the chinks under the doors. Rather better results can be obtained by keeping the carriage floor constantly wet. To cool a railway carriage exactly the same principle as has been suggested for cooling a room may be adopted. Carriages of the Pullman or refreshment car type are most suitable; in the front of the carriage can be fitted a *khus-khus* screen, kept moistened by a drip of water from a cistern. The movement of the train will provide ample air-flow through the screen if a small air-shoot is fitted.

Very effective cooling can be obtained by spreading a wet towel over the naked body and turning a fan in the direction of the bed on which the person is lying. After a few minutes the air under the towel becomes positively cold and there is risk of local chill if the towel comes in contact with the chest or abdomen. To obviate this a surgical cradle can be placed over the body and a large wet towel spread over this so as to shut in the cooled air on all sides. For invalids an arrangement of this kind may be absolutely necessary in extreme heat. (*Tropical Medicine*—Rogers & Megaw, 1935).

DIET IN THE TROPICS (p. 146)

Alcohol in the Tropics. Alcoholic excess is responsible for more disability and shortening of life among Europeans in the tropics than any of the great tropical diseases. In strictly limited quantities alcohol does no harm, it may even be useful in certain circumstances, yet the great majority of people who admit alcohol to their dietary in the tropics suffers to some extent sooner or later. The mischief done by alcoholic excess is well known and need not be emphasised; the evil that is wrought by 'moderate drinking' is far more important as it is not generally recognised. The real danger of alcohol consists in its tendency to give rise to habit formation, and unfortunately nobody knows

till he tries whether or not he is one of the people who will acquire the habit. Alcohol is usually taken, to begin with, because it is customary to do so and nobody likes to be considered a crank who refuses to adapt himself to the social customs of his fellow-men. Then the treating system which is almost universal induces most people to drink more than they really care for, and so they are compelled to experience the dangerous effects of the drug. They find themselves pleasantly exhilarated and soon they have to resort to alcohol to prevent the after depression which results from the use of the insidious drug. Worst of all, those who are 'under the weather' for any reason or who suffer from an inferiority complex find release from their disabilities in a large dose of whisky or brandy. They are really happy and contented only when under the influence of alcohol. Gradually increasing doses are needed to produce the desired feeling of well-being, and in extreme cases the result is a condition of chronic alcoholism. Even people who would be indignant if it were suggested that they drink to excess suffer very definite injury from their 'few pegs a day.' Every medical man should do his utmost to abolish the treating custom in the interests of the men for whose health he is responsible. He should also warn every young man of the dangers of alcohol, and best of all, should set an example by avoiding those dangers himself. It has been abundantly proved that alcohol is not necessary in the tropics, although there is no evidence that a small peg twice daily has any harmful effect in itself. The cocktail habit is specially pernicious: concentrated alcohol taken on an empty stomach is far more harmful to the stomach and liver than well-diluted whisky pegs. Some diseases are definitely associated with alcohol, such as alcoholic neuritis, delirium tremens and cirrhosis of the liver. In the cases of amoebic hepatitis, liver abscess, pneumonia, heat stroke and tropical neurasthenia, alcohol is of importance as a predisposing factor. Alcoholics take anaesthetics badly and run exceptional risks from surgical operations. Indigenous races of tropical countries should be discouraged from the use of alcohol in any circumstances; they are notoriously liable to become addicts to the drug.

Dietetic Errors of Indigenous Races. The chief defects consist in the excessive bulkiness and low nutritive value of the diets. People who live chiefly on rice often take 30 to 40 oz. daily; this, when cooked, forms a very bulky diet which causes distention of the stomach and is incompletely digested. McCay, who carried out important investigations into Indian diets, made the following observations:—(1) The absorption of proteins from cooked rice is actually diminished when excessive quantities are eaten, for example, 8½ gm. were absorbed when 19 oz. of rice were eaten daily, but only 6½ gm. when 30 oz. were consumed. The larger ration does not make up for the poor quality of proteins of the diet but rather the reverse, while the excess of carbohydrates upsets the balance of the

diet. (2) Certain vegetable sources of protein are unsatisfactory; from a diet of millets, dāl and vegetables containing 16 gm. of protein in all, only 9½ gm. were absorbed, whereas from a diet of wheat containing 16 gm. of protein as much as 13 gm. were absorbed. (3) Unsuitable methods of cooking and disorders of the alimentary system caused a reduction in the absorption of proteins. (4) Great variations in physique and fitness were found among the races using different diets. Europeans and Sikhs who absorbed over 0.25 gm. of protein per kg. of body-weight were far more robust than Bengalis who absorbed only 0.11 gm. per kg. The average Sikh diet approaches closely to good European standards: it consists of milk ¼ pint, wheat 24 oz., butter or ghee 2 oz., dāl 3 oz., vegetables 6 oz., and meat 4 oz. An unexpected finding was that the low protein absorption of the Bengalis was associated with increased prevalence of degenerative diseases of the kidneys. The reason for this is probably malnutrition of the kidney cells.

The nutritional defects of indigenous populations are easy to discover but difficult to rectify; they are closely associated with poor economic standards of life, which in turn are connected with social customs, especially early marriage and unrestricted procreation of children. So long as immature boys and girls marry and proceed to have large families before they are able to maintain them, there is no prospect of economic improvement; any increase in the production of food will quickly be neutralised by a corresponding increase in the population. The solution of the problem lies in a rational education directed towards showing the rising generation how to adapt themselves to their environment by later and more provident marriages or by limiting the number of children in some other way. The chief dietetic error which prevails among the richer members of the tropical communities consists in excessive consumption of carbohydrates, especially in the form of easily absorbable sugars. This fault, when combined with lack of exercise, leads to obesity and finally to diabetes.

Drug Addition. See page 1116.

Invalid Diet in the Tropics. A good supply of fresh milk must be provided in every hospital. Another important practical point is that invalid diets are often deficient in the anti-scorbutic vitamins; a standing order should be observed in all hospitals that every patient who is on an invalid diet must be given the juice of an orange daily or a corresponding dose of vitamin C in some other form. The prejudices of patients may give rise to a certain amount of difficulty. Many of them regard rice as the only suitable staple article of diet, so that a good deal of persuasion may be needed to induce them to take other food.* Many Indians regard milk as unsuitable for those who have a cough, because of a traditional belief that the milk becomes converted into phlegm. Many patients also object to milk because they find that it causes diarrhoea. The explanation of this prejudice is that milk is

usually regarded as a drink and is taken in addition to a full diet, with the result that the suitable quantities, either alone or as a substitute for other food, it does not cause diarrhoea in the tropics, any more than in cold countries. Milk in the tropics is often boiled for a long time; care must be taken to ensure that it is just brought to boiling point and then cooled. (*Tropical Medicine*—Rogers & Megaw, 1935).

REPORT OF EXPERT COMMITTEE ON NUTRITION

The first part of the report states that 2,400 calories net a day are adequate for an adult man or woman living an ordinary everyday life in a temperate climate and not engaged in manual work. This allowance is to be supplemented for various grades of muscular activity. For light work it is estimated that an additional 50 calories per hour of work is needed; for moderate work, 50 to 100 calories; for hard work, 100 to 200 calories, for very hard work, 200 calories or more. For pregnant women 2,400 calories are considered sufficient, and for nursing mothers 3,000. For infants energy requirements are assessed on the basis of 100 calories per kilo. of body weight for the first three months of life; 90 calories from three to six months; 80 to 90 calories for six to twelve months. Further, it is suggested that the activities of girls from the age of 7 upwards and of boys from 7 to 11 years should be looked on as equivalent to light work; and those of boys from 11 to 18 years as equivalent to moderate work. As a general recommendation it is suggested that the protein intake of adult should not fall below 1 gm. of protein per kilo. of body weight, and that a part of this should be from animal sources. Some animal protein is considered essential during growth, pregnancy, and lactation. In the second part of the report, on mineral and vitamin requirements, the committee states that the most important protective foods are milk and milk products, eggs, and glandular tissues; then come green leaf vegetables, fruit, fat fish, and meat. It is also pointed out that "the increasing habit of large sugar consumption tends to lessen the amount of protective foods in the diet and is to be regarded with concern." In an attempt to define the quantitative needs of protective foods for the pregnant and nursing woman, the committee stresses the difficulty of arranging such a diet as will provide calcium, phosphorus, iron and vitamins B₁, B₂, C, and D. In this respect milk and eggs are of great service; the former rich in calcium, phosphates, and vitamin B₂; the latter containing vitamins A, B₁, B₂ and D, and being rich in iron. The proteins of both are of high nutritive value. It is recommended that additional vitamin D, in the form of cod-liver oil, should be given to the growing child and to the mother. It is also suggested that potatoes should replace part of the sugar and milled cereals in the diet, for they are a source of vitamin C, and yield more iron, calcium, phosphorus, and the B vitamins. On general lines the committee is of opinion that, (i) variety in diet tends to safety, so long as there is a sufficiency of

'protective, foods; (ii) that lightly milled cereals and potatoes should partly replace white flour (excessive consumption of sugar is condemned); (iii) that more milk should be taken at all ages, and that the nutritive value of skimmed and separated milk should be more widely appreciated; (iv) that fresh fruit and vegetables should always be included in a normal mixed diet; (v) that extra vitamin D should be provided, 'wherever sunshine is not abundant' and that the other vitamins are adequately provided in a diet which contains optimum amounts of protective foods. (*Brit. Med. Jour.* 1935, p. 1215).

LOW VOLTAGE X-RAY THERAPY

During recent years one of the most interesting developments of radiation therapy has been the use of higher and higher voltages in X-ray treatment and at the same time a parallel development has taken place in the field of relatively low voltages of the order of 50 kV. The dosage may now be measured and accurately controlled in a way previously impossible, so that even the very high dosage rates now available present little danger or difficulty in the handling. It is chiefly the work of Chaoul which has led to the experimental investigations regards the use of X-ray tubes at small focal skin distances with considerable success. The X-rays are generated at a constant voltage of approximately 60 kV, with 4 mA tube current. The tube is so designed as to have the source of radiation at one end of an earthed metal tube, the rays emerging through the target of gold-plated nickel and the water-cooling jacket. These normally constitute the sole filters employed, in all equivalent to approximately 0.2 mm. nickel. The mean wave length is roughly 0.32 A. U. The field on the irradiated skin is limited by metal applicators slipped on to the end of the tube, these applicators also ensuring the focal skin distance desired. The latter is usually 5 cm. or 3 cm., while the applicator may be either circular or elongated according to the lesion to be treated. Applicators of special shapes and sizes can be easily constructed. The dosage rate in air at 5 cm. focal skin distance, 60 kV and 4 mA, is approximately 110 r/min., while with "back scatter" this normally increases to about 130 r/min. All doses are defined with back scatter. This dosage rate is approximately twenty-five times that obtained from a 1-gm. radium 'bomb' at the same focal skin distance.

The daily dose per field used by Chaoul is 400 r with back scatter. The total dose per field is not arbitrarily selected, but depends somewhat on the reaction of the lesion to treatment. Usually, by about the fourth day the skin immediately surrounding the lesion, and purposely included in the field, has developed a mild degree of erythema, while during the next few days a pigmentation often occurs. The extent of both erythema and pigmentation depends very markedly on the usual factors, such as region of the body, condition of the skin, vascularity of the subcutaneous stratum, coloration of the patient, etc.

The edge of the erythematous area is very sharply marked, corresponding to the rim of the applicator, and although measurement shows often a 40 per cent. difference between the dose received at the centre of the field and that at the edge, the skin reaction appears quite uniform over the whole area. Regression of the lesion is occasionally noticeable even by the third day.

The total dosage is usually 5,000 to 6,000 r per field spread over about fifteen days, but irradiation up to this limit is continued until the erythema is well developed. The resulting skin reaction appears similar in all respects to that following radium treatment, with the exception of a shorter period of development. After intense irradiation skin sloughing results, but epithelialization rapidly proceeds from the periphery to cover the area with a pale scar. The sharply localised action of the beam renders the patient free from constitutional after-effects, so that a number of areas may be treated at one session, limited only by such factors as time and convenience. Even as many as six separate fields require only about twenty minutes to complete, the 400 r per field being obtained in about three minutes.

INDICATIONS. The following types of cases readily (according to Chaoul) admit of treatment by such low voltage therapy. *Skin cancer*, such as rodent ulcer and epitheliomata. *Buccal cancer*. This comprises squamous epitheliomata of lips, floor of mouth, alveolus, tongue, cheek, palate and tonsil pharynx. *Mammary cancer*. *Cancer of the cervix*. *Deep-seated lesions*. (*Brit. Med. Jour.*, Oct. 26, 1935).

OXYGEN THERAPY

It would hardly be an exaggeration to say that the methods of oxygen administration generally used have been so ineffective as to reduce this form of therapy to little more than a pious gesture. Much wider use has been made of oxygen therapy in America. This is reflected in the commercial production of several varieties of oxygen tent apparatus, and of special aids for nasal catheter administration of oxygen; and in the provision of oxygen chambers in many large American hospitals.

Of these three effective and clinical applicable methods, the oxygen chamber would naturally be expected to be the most effective, when available. The initial and upkeep costs of such a chamber are high, and it can obviously be available only in a large hospital. The nasal catheter method has the advantage of cheapness and ready availability. It is reasonably efficient if the tip of the catheter be introduced as far as the oropharynx and an adequate flow of oxygen maintained. Barach and Baker *et al* have shown that a flow of 5 litres per minute will maintain an effective concentration of about 35 per cent., even with a raised respiration rate. The catheter should have several perforations near its tip and the oxygen must be passed through warm

water to avoid painful desiccation of the pharyngeal mucosa. Several combined-flow-meter and humidifier devices are commercially available in America. There is no doubt, that oxygen can be more efficiently administered by a properly designed tent than by the best nasal catheter device. Finality has by no means been attained in tent design, as a survey of the various designs available will show; and it is possible that with increasing experience, useful modifications will increase the clinical usefulness of these devices. At present, the chief difficulty is the fact that enclosure in the apparatus often seems to have an unfavourable psychological effect on the patient. In the experience of some hospitals this sensation is so intense that a patient can hardly be induced to remain in it. A minor, but real, addition to this difficulty in the past was the unpleasant smell of rubber which tends to emanate especially from a new tent, this may well be eliminated in the most modern tents. Finally the nursing of a patient in the tent is undoubtedly a difficult problem. Favourable results following the use of their tent in treatment of a variety of pulmonary and cardiac conditions have been reviewed by Argyll Campbell and Poulton in their recent book. The available data on Oxygen and Carbon Dioxide Therapy suggest that the tent has been of more value in broncho- than in lobar pneumonia. This finding is in accord with theoretical considerations based on the pathology of these two forms of pneumonia. In cardiac failure it appears that more improvement is observed in cases of failure due to arterio-sclerotic disease than in those due to rheumatic disease. In cases of congestive cardiac failure reacting favourably to prolonged oxygen therapy, relief of dyspnoea and diminution of anoxaemia are almost immediate, and a fall of venous pressure, accompanied by diuresis is observed. In England favourable results of treatment in Dr. Poulton's tent have been recorded in cases of bronchitis and emphysema with circulatory failure, cyanosis after pulmonary lobectomy, and broncho-pneumonia complicating whooping cough. In very young infants the psychological troubles do not of course arise, and it is of interest that some of the most favourable results in pneumonia have been observed in infants. After such serious thoracic operations as lobectomy or thoracoplasty, the patient has to be content not only with shock but also with a local injury to the respiratory bellows; and in these cases the use of the tent in the first few days after operation may well save life.

There has been a tendency to pay insufficient attention to the late results in oxygen therapy. If these are considered it becomes apparent that it is in such conditions as the immediate post-operative period in major thoracic surgery, and in the pneumonia of infants, that the treatment is likely to be most efficacious, judged by the criterion of permanent restoration to useful life. Temporary improvement undoubtedly follows in some cases of chronic disease, such as arterio-sclerotic heart failure and pulmonary fibrosis, but cannot be expected to be maintained on return to normal atmosphere. In London the tent may prove espe-

cially useful during fogs, not only providing a high concentration of oxygen but also acting as a local air-conditioning plant. In an investigation dealing with patients ill enough to require oxygen administration for relief of anoxæmia, it is well-nigh impossible to provide satisfactory controls. It is greatly to be hoped, therefore, that the combined experience of clinicians in the London teaching hospitals with the oxygen tents rendered available by the British Red Cross Society will provide a basis for a reasoned appraisement of the value of this method of treatment. (*Lancet*, 1935, Vol. 2, No. 24).

PREMEDICATION

Pre-Anæsthetic Drugs

Nervous and highly-strung patients, especially children, should receive some form of sedative drug treatment to ameliorate the psychic effect before operation. Premedicants greatly decrease the amount of general anæsthetic needed subsequently. Such drugs should be carefully selected. The old and common practice of administering morphine to patients as a preliminary to chloroform anæsthesia has been given up and lately a number of premedicant drugs have come into use.

DRUGS GIVEN BY THE MOUTH. (a) *Chloretone*. Chloretone in doses of 0.65 to 0.97 gm. (10 to 15 gr.) has largely been used as a routine measure before ether anæsthesia. The advantages are many, the patient is brought to the operation theatre asleep and the post-anæsthetic vomiting is very much reduced. (b) *The barbiturates* (sodium amytal and nembutal). These drugs should be given in large doses so as to ensure that the patient is asleep before the general anæsthetic is begun. The use of sodium amytal should be restricted to robust and virile patients and is given in divided doses; 3 gr. the night before operation, 3 gr. three hours before, and 6 gr. two hours before the operation. The drawbacks to the use of these drugs are a fall of blood pressure and very often a period of excitement which can be controlled by morphine, follows. Nembutal is considered to be a safer drug than sodium amytal, but its sedative effect is much less potent and its action is very variable. The drug is suitable for women and the less vigorous male patients. It should be given in 3 gr. doses half an hour before operation. The custom of combining morphine with the barbiturates is not sound and should be discarded. Pernoxon, sodium alurate, pernoston, and other barbiturates are not very popular.

DRUGS GIVEN INTRAVENOUSLY AND SUBCUTANEOUSLY. (a) *The barbiturates*. Undesirable effects such as the fall of blood pressure, idiosyncrasy, etc., have led the anæsthetists to give up the intravenous use of the barbiturates in favour of their oral administration. Sodium evipan has won the reputation of a potent drug, producing a degree of narcosis equivalent to the third stage of anæsthesia. The fall of blood pressure is however, sometimes marked.

(b) *Morphine and its derivatives.* The use of morphine is now becoming much less frequent as it is a respiratory depressant and increases the post-anæsthetic vomiting. For obvious reasons the combined administration of hyoscine and morphine should never be encouraged.

DRUGS ADMINISTERED PER RECTUM. Such administration of drugs is preferred because in nervous and frightened patients the absorption of premedicants from the stomach is inhibited. Paraldehyde and avertin are the best narcotics for use in this way.

Paraldehyde. It is given in doses up to 0.56 c.cm. per kilo. (1 dr. per stone) of body weight. One part of paraldehyde is shaken up with ten parts of water and injected one hour before operation. The time of narcosis varies in different patients and small hæmorrhages in the mucous coat of the stomach, indicated by coffee-ground vomit, have occasionally been met with.

Avertin. It is considered the most suitable premedicant in small doses and is given in proportion to the age, physical condition, and weight of the patient. The usual dose is from 0.05 to 0.1 c.cm. per kilo. body weight. The fall of blood pressure is negligible, the patient falls asleep within half an hour of the injection and very little general anæsthetic is necessary to maintain narcosis.

Even in the administration of gas and oxygen some form of premedication is essential. Where post-anæsthetic vomiting is not desirable the preliminary administration of a small dose of avertin followed by anaesthesia with nitrous oxide and oxygen is very satisfactory.

Though a very old remedy, atropine has been admitted to be one of the best premedicant drug as it can be used before general anæsthetic. It inhibits the action of the vagus and diminishes mucous secretion. It should be given hypodermically in doses of 1/200 to 1/150 gr. one hour before operation except in the case of children, when it is better to give tincture of belladonna by the mouth, to obviate the discomfort of the subcutaneous injection. High basal metabolic rate is a contraindication to its use. (*Brit. Med. Jour.*, 1935, p. 782).

DIGITALOIDS (p. 246)

The effect of digitalis when given by mouth is decreased as a result of its reaction with the acid gastric juice and the intestinal alkali. Absorption is inhibited owing to the surface activity and adsorption of the drug. The effects become progressively decreased in patients under the pathological conditions of circulatory failure. With oral administration, even when pure substances are used, the production of quantitatively predetermined effects becomes impossible. By the rectal route these sources of error, although diminished, are not entirely removed, and the local irritative effects produced by digitalis glucosides exclude intramuscular and subcutaneous injections in their therapy. The only suitable way of administering this valuable remedy quantitatively to

the heart is, therefore, by intravenous injection. The essential conditions for intravenous administration of a drug are solubility in water and the stability of the watery solution. Recent developments in the chemistry of digitalis have revealed close relationships between the different glucosides and this 'Digitalis monotonic', to use Straub's expression, explains to some extent the similarity of their pharmacological actions. All these glucosides can be split by hydrolysis into a sugar-free organic compound—the genin—and one or more carbohydrate molecules. The similarity in chemical constitution is confined, however, to genins. Greater difference occurs however in the structure of the sugars with which the genins are combined. The genins of the glucosides of *D. purpurea* (glucosides of the first order) are combined with 2 or 3 molecules of digitoxose—a methyl pentose which occurs only in plants and which can be broken down by the human organism only with difficulty. On the other hand sugars of the digitaloids (glucosides of the second order, such as strophanthin, adonis, scilla, etc.) are easily decomposed in the animal organism since they are for the most part pentoses and hexoses. The carbohydrate of K-strophanthin, for instance, is a disaccharide consisting of glucose and cymarose both of which are readily soluble in water. G-strophanthin or ouabain contains the methyl pentose rhamnose which is far less soluble in water.

Slowing of the pulse rate being chosen as the criterion of action, the effect of glucosides of the first order was found to occur more slowly and to last longer than that of the glucosides of the second order. In the case of the latter the action both appeared and disappeared rapidly and, in contrast with what is found with digitoxin, the action could be maintained by repeated injections without any toxic effects attributable to cumulation of the drug appearing. Cumulation therefore proved to be least with the digitaloids and the absence of this phenomenon is an essential condition for the successful development of the intravenous method in treatment with the glucosides.

The narrowed choice among the digitaloids now fell on that group in which not the diuretic action, as in the case of adonis and scilla, but the cardiac action preponderated. K-strophanthin serves the purpose since it proved to be less toxic and more easily soluble than G-strophanthin. The toxic range of concentration is more readily attained under these conditions with digitoxin than with strophanthin. Therapeutic doses of the glucoside increased the isolated heart's capacity for work and its period of survival, and inhibited the processes of fatigue; and on the other hand, that toxic doses, themselves leading to morphological changes in the muscle, decreased the capacity for work and accelerated the processes of fatigue. Experimental investigations have shown that the digitaloids and especially the strophanthins are fixed to the heart for so short a period that the therapeutic dose is eliminated within 24 hours. Amongst the strophanthins the crystalline

product from G-strophanthin is more toxic than the amorphous compound obtained from K-strophanthin.

The main effect of digitalis in heart failure is an increase in the stroke volume and a change in the distribution of blood, resulting from the increased circulation rate. The intravenous injection of the glucosides is followed by the fixation of about 10 per cent. of the dose by the heart.

The absence of appreciable effect on the healthy as also on the diseased heart when functionally compensated and its appearance after minute doses in decompensation, may perhaps be explained in part by the intramuscular development of a specific sensitivity to digitalis in this latter group. The amount of strophanthin fixed per gramme of heart muscle has been calculated by Clark (1 gm. adsorbs at most 0.0002 mg. of the drug. One-tenth of the lethal dose of the drug has a detectable effect upon the diseased heart exhibiting a high sensitivity to digitalis, the concentration in which digitalis acts is of the same order as that found in the case of the hormones. The question whether there arises a specific increase in sensitivity to digitalis when the heart fails is controversial. The measurement of body weight excludes the possibility of neglecting the extrarenal loss of water and indicates by direct means the day on which the removal of oedema fluid is complete and to the time when the minute volume of fluid has in all probability reached its optimum. This enables one to avoid overdosage and at the same time, by gradation of the dose within 0.1 gm., to control accurately the rate of fluid removal and so to delimit precisely the period allowed for complete elimination of the retained water; a realisation of therapeutic ideal of obtaining optimal effects from the smallest doses. (*Lancet*, 1935, Vol. 2, p. 1101).

PHYSIOLOGY OF HYPERPYREXIA PRODUCED BY ARTIFICIAL MEANS

Is fever produced by diathermy and physical means the same as fever occurring from infections? The answer is in the negative. From the strictly physiological standpoint, the great majority of evidence points towards the two being entirely different, with the exception of temperature or heat, which they both share in common. To be sure, there are some findings, for example, in the urine and sweat, which are similar, or possibly synonymous, and the clinical interpretation of conditions and results add further to this conception, but this discussion is concerned only with the physiology. Von Grafe deals a vital blow when he shows evidence that most of the metabolic changes can be duplicated with infection devoid of and divorced from fever. The Juaregg school in general is very staunch in its opinion that something in addition to heat is responsible for the results in treating central nervous system syphilis, since in many cases better results have

been obtained with malaria at temperatures of 102°F. than with typhoid and other methods at much higher levels. There is a marked increase in basal metabolism in artificial fever, and possibly much of the benefit comes solely through this source, since its application is nearly always in diseases which at that time are not running temperatures of their own accord. That bacteria and infectious agents are actually destroyed is evident, but still may be questioned. Possibly the increased metabolism and circulation alone, hastening absorption and elimination of their by-products can be just as important a factors. In the face of current clinical reports carrying with them so much evidence of therapeutic benefit, physiological lack of support should not be permitted to hamper or stop continued progress and use of the measure in general except in that it must involve safety to the patient.

The conclusions are:—(1) From the physiological point of view, hyperpyrexia produced by physical means is not synonymous with spontaneous fever produced by disease. (2) Hyperpyrexia induced by malaria, chemicals, foreign proteins, etc. is also different from that produced by physical means. (3) The role played by heat retention in combating disease might share a common denominator in all three types of fever. (4) The heart rate is subject to changes in skin temperature more definitely than to changes in body temperature. (*Med. Press and Circular*, 1935, Vol. 191).

NON-SPECIFIC PROTEIN THERAPY (p. 1418)

(1) *Milk*. Ordinary skimmed milk, either fresh or pasteurized, is boiled for from five to ten minutes and then cooled to body temperature. The first dose for adults is 5 c.cm. injected intramuscularly, usually into the gluteal muscles. The dose is increased 2 or 3 c.cm. with each injection until a maximum of from 10 to 15 c.cm. is reached. (2) *Diphtheria antitoxin*. As used for foreign protein therapy, diphtheria antitoxin is not given for its antitoxic property but because it is an available form of horse serum. The dose is not fixed but is usually from 2 to 4 c.cm. given intramuscularly. In doses of this size it will usually induce a temperature of from 100° to 101°F. (3) *Vaccines*. Ordinary stock and autogenous vaccines are given intramuscularly unless sharp thermal reactions are desired. When such is the case, typhoid vaccine is by far the most popular agent and is given intravenously. Intravenous injections of Gram positive bacteria such as the streptococcus, pneumococcus and staphylococcus are much less likely to cause febrile reactions than the Gram negative organisms such as the gonococcus and typhoid bacillus. The reason for this difference is not clear.

Reaction. The reaction to foreign protein injections varies from an almost imperceptible one to extreme shock associated with high fever, profound vasomotor disturbance and other constitutional pheno-

mena. The reaction depends on the substance injected, the dose employed and the method of administration. It also depends a great deal on the physical condition of the patient and the number of previous injections. Intramuscular injections of protein usually excite only focal reaction, that is, a temporary flare up of acute symptoms in some focus of infection; a constitutional reaction may be entirely absent. When foreign proteins are given intravenously, the reactions are sharper and make their appearance more promptly. In acute infections, such as typhoid or pneumonia, in which a temperature of 102° to 104°F. already exists, the temperature during a protein reaction may sometimes go to 106° or 107°F. For this reason the dose of protein or vaccine should be very carefully gauged in the treatment of febrile conditions. As a rule the dosage for a febrile patient should be about half that for afebrile individuals.

Mechanism of the reaction. The typical thermal reaction of protein fever can be divided roughly into three phases. Immediately after the intravenous injection there is a short prodromal period, which is characterized by first a stage of latency with no symptoms and later a stage of chill. Then the temperature begins to rise. The period from the onset of fever to the point of maximum temperature is referred to as the first or *negative* phase. The second or *positive* phase extends from the height of the fever to the return of normal temperature. The physiological changes that take place in the body during the protein reaction are: (1) Alteration in the basal metabolism. (2) Peripheral and splanchnic vasomotor changes, including alterations in blood pressure and in the calibre and permeability of the arterioles and capillaries. (3) Alterations in renal function, detectable in the output and in the acidity of the urine, excretion of phenolsulphonphthalein, and concentration of nitrogen, phosphate, urea, uric acid, allantoin and albumin. (4) Alterations in serum ferments, antiferments, antibodies and the Wassermann reaction. (5) Alterations in organic activity demonstrated by increased secretion of lymph, bile, saliva, breast milk and menstrual flow and by changes in the activity of the liver, gastro-intestinal tract and spleen. (6) Alterations in the volume, specific gravity, freezing point and viscosity of the blood. (7) Alterations in the cellular elements of the blood. (8) Alterations in the fragility of the blood platelets and in fibrinogen, thrombokinase, coagulation time and sedimentation rate. (9) Alterations in the chemical constituents of the blood demonstrated by changes in the carbon dioxide tension of the plasma, carbon dioxide combining power, total non-protein nitrogen of whole blood and of serum, sugar tolerance, albumin globulin ratio and concentration of urea, uric acid, sugar, fat, total serum protein and chlorides. Jobling and Peterson attached great importance to the mobilization of enzymes, particularly proteases and lipases, following the injection of proteins. Perhaps the most important function of the foreign protein reaction is the mobilization of immune bodies in the circulating blood.

Untoward reactions. Severe and even fatal reactions sometimes follow the intravenous injection of foreign protein. Such occurrences, however, usually take place in patients who are already seriously ill or who have been greatly overdosed with protein. There have been surprisingly few severe anaphylactic reactions. The complications attributed to foreign protein reactions have been delirium tremens, cardiac failure, vascular thromboses, acute nephritis, herpes labialis, rheumatic purpura, acute diarrhoea, and activation of old pulmonary tuberculosis.

Clinical Application of Protein Therapy. Typhoid. Typhoid was the first infectious disease to be treated by foreign protein therapy. Holler used small doses of a 10 per cent. solution of deuto-albumose, beginning with two treatments a day and later giving one treatment daily continuing the injections until the fever was broken.

Pneumonia. Pneumonia is a disease for which an efficacious serum therapy is available in more than 60 per cent. of the cases. There still remains 40 per cent. of pneumococcic pneumonias in which some other form of specific or non-specific treatment would be feasible. In an infection of such comparatively short duration as pneumonia the interpretation of the results of protein therapy would be difficult unless the injections were given very early in the disease.

Nervous diseases. Both relapsing fever and rat-bite fever have been used therapeutically in dementia paralytica. The results with relapsing fever as reported by Plaut and Steiner and more recently by Signorelli seem to be about as good as those obtained by others with malaria; this is still further evidence that it is the febrile reaction and not the agent which produced the fever which is the essential part of the treatment. In 1924 Grosz reported very favourably on the treatment of multiple sclerosis with foreign protein therapy. Such cases were treated with typhoid vaccine and with malaria.

Diseases of the skin. In dermatology, foreign protein therapy has been widely used, and with considerable success, in certain inflammatory conditions, such as furunculosis, carbuncle and other staphylococcic infection of the skin, and to a less extent in ringworm, lupus, pruritus and the like. Sometimes a persistent form of urticaria will yield promptly to boiled milk or to some form of bacterial vaccine. Especially good results have been claimed for colon bacillus vaccine in urticaria. O'Leary has found foreign protein most beneficial in the treatment of anthrax and erysipelas. Schmidt reports excellent results with milk therapy in erysipelas.

Diseases of the eye. Non-specific therapy in the form of boiled milk or typhoid vaccine has been employed extensively in iritis, uveitis, keratitis, conjunctivitis and other inflammatory conditions of the eye. There seems to be some disagreement as to the benefit to be derived from protein therapy in trachoma.

Gynaecology. In pelvic diseases the most important field of protein therapy has been in adnexal infections of an acute or subacute type. In such conditions the results of protein therapy have often been quite striking. The consensus of opinion is, however, that its chief function is in the relief of pain and extreme tenderness. There is considerable doubt as to just how often a tubal infection is 'cured' by protein therapy. For gonococcic infections however, fever therapy is now more successfully used, in the form of diathermy or the short wave than by typhoid or gonococcus vaccine.

Peptic ulcer. One would hardly expect protein therapy to have any value in the treatment of peptic ulcer. Prilbram, however, has reported a large series of ulcers treated by intravenous injections of a vegetable albumin (novoprotein) and states that the pain was much relieved in from 50 to 60 per cent. of the cases. He even goes so far as to assert that roentgen observations indicate healing of the ulcer. Treatments were given at intervals of from two to four days, the patient receiving a total of eight or ten injections.

Vascular disease. One of the newer fields for foreign protein therapy is that of vascular disease, particularly thrombo-angitis obliterans. In vascular disease, however, it is probably the vasodilatation rather than the fever, leucocytosis or mobilization of immune bodies that is responsible for the beneficial effect obtained. According to Wright, the desired physiologic effect of fever therapy in vascular disease is release of spasm of the partially occluded vessels with resulting increase in the local capillary circulation. This is followed by cessation of pain and healing of ulcerations, if they exist.

Contraindications. The more important contraindications to intravenous foreign protein therapy are: (1) Advanced arterial, renal or cardiac disease. Patients with cardiac decompensation should not have intravenous protein therapy. On the other hand, rheumatic endocarditis with good compensation is not a contraindication. (2) Allergic states or conditions of marked protein sensitivity, such as angioneurotic oedema, giant urticaria and the like. (3) States of extreme exhaustion following prolonged illness. (4) Pulmonary tuberculosis, active or quiescent. (5) Haemorrhagic conditions, such as hemophilia, bleeding ulcers, and the like. (6) Chronic alcoholism, for fear of delirium tremens. (7) Marked nervous sensibility as seen in hyperthyroidism and the like. (*Jour. Amer. Med. Assoc.*, 1935, Vol. 105, No. 23).

BIOLOGICAL PROBLEM IN CHEMOTHERAPY

The discovery of a technique by means of which trypanosomes may be kept alive *in vitro* for at least 24 hours has enabled certain chemotherapeutic problems to be reinvestigated. Trivalent arsenic and antimony compounds have in comparison with pentavalent compounds surprisingly high trypanocidal activity both *in vitro* and *in vivo*. This

suggests that the therapeutic action of the trivalent arsenicals and arspenamine compounds is dependent on the trypanocidal action of the unchanged drugs, while that of the pentavalent compounds is associated with some previous change, probably reduction, in the body of the host. Nevertheless pentavalent are preferred to trivalent compounds in the treatment of trypanosome infections. This is probably due to a number of factors. When trivalent arsenicals are injected into rabbits the serum is at once endowed with an enormous trypanocidal titre. This high titre does not, however, last long. When pentavalent compounds are injected the trypanocidal titre develops much more slowly. Trivalent arsenicals are also excreted more rapidly in the urine, while pentavalent compounds such as tryparsamide, though rapidly giving rise to a high trypanocidal titre in the urine, are much more slowly excreted. After an injection of tryparsamide into a rabbit, for instance, the trypanocidal titre of the urine only reaches zero after a day or more. A further difference between tri- and pentavalent arsenical compounds is that reduced tryparsamide and neoarsphenamine diffuse rapidly into and out of red blood corpuscles and are unchanged in the process. Tryparsamide also diffuses into red blood corpuscles but is to some extent reduced by the hæmoglobin into its highly trypanocidal trivalent form. Other tissues also probably play a part in this reduction.

The essential characteristic of drug resistance is found to be a change in the parasites whereby they do not fix the drug applied *in vitro* as do normal parasites. The development of a resistant strain is fundamentally a mutation, *i.e.*, a gradual change in all or certain individuals resulting from the stimulus of frequent exposures to suitable concentrations of drug. When once a strain of trypanosomes has become arsenic-resistant it retains the character indefinitely. It is not lost when passed by syringe nor by numerous cyclical transmissions through the natural intermediate host. The importance of this concept is seen in the fact that arsenic-resistant strains of trypanosomes are being obtained in considerable numbers from African natives, probably as a result of the wholesale atoxylyzation of patients which is now being carried out by itinerant medical missions. Although it is easy to produce strains of trypanosomes resistant to aromatic arsenicals and antimonials it is fortunately difficult to produce strains resistant to Bayer 205. Experiments are described to show the importance of the size, and spacing a number of doses of a drug in producing resistant strains. (*Trans. Roy. Soc. Trop. Med. & Hyg.* 1935, Vol. 28, No. 5).

SEX HORMONES IN PRACTICE

It is agreed that promiscuous administration of endocrine extracts is sometimes harmful and usually valueless; that they must be used only after careful exclusion of relevant organic lesions; and that the user needs a cautious understanding which can develop only from

knowledge of physiology. Admitting all this, it seems that more interest should be taken, here and now, in the rational treatment of the menstrual and reproductive disorders that incapacitate so many women.

Inadequate menstrual loss which may take the form of primary amenorrhoea in which a girl reaches adult life without having a menstrual period there are usually signs of gross ovarian deficiency, the most important of these being an under-developed uterus, perhaps no larger than a hazel-nut. Such an organ, infantile in structure, is incapable of normal function, and the first aim of treatment therefore is to promote its growth. Kaufmann has shown that this can sometimes be done by giving large doses of the ovarian hormone known as oestrin or folliculin (*e.g.*, 200,000 to 4,000,000 international units of crystalline oestrone). The next object is to induce growth of the kind of endometrium associated with normal menstrual bleeding. In an adult uterus this can almost always be done by giving the corpus luteum hormone, progesterin, in doses of 5 to 50 rabbit units. Assuming success in these two aims, the primary defect—ovarian deficiency—remains to be overcome; for the injection of ovarian extracts is merely substitutive treatment, and it is doubtful how far it can initiate spontaneous menstrual cycles. The fundamental object is to convert the infantile ovary into an adult ovary with normal function. In immature animals this can be done by injecting gonadotropic (gonad-stimulating) principles derived either directly from the pituitary gland or from urine excreted in pregnancy. It would therefore be reasonable in primary amenorrhoea to follow treatment of the uterus (with oestrin and progesterin) by administration of gonadotropic extracts; and there is in fact evidence that in a few cases this has led to the onset of cyclical menstruation. It has to be acknowledged that the extracts at present in use are seldom potent enough to produce any lasting effect on a seriously undeveloped ovary. But where the deficiency is of secondary amenorrhoea, treatment is more promising; and in oligomenorrhoea, so often associated with dysmenorrhoea or sterility the outlook is far more hopeful. The principles of treatment here are much the same, but some authorities such as Clauberg claim that oestrin by itself suffices for cure. He finds that in immature mice its injection may actually lead to the formation of corpora lutea, and since it is well established that oestrin has no direct action on the ovary this effect must, it seems, be due to stimulation of the pituitary. It has become evident that the ovary and anterior pituitary are complementary in action; too much oestrin depresses pituitary activity while too little makes it unusually apparent. Clauberg describes this as the '*pituitary release phenomenon*'; he believes that large doses of oestrin promote pituitary quiescence and that sudden cessation of them brings about abnormal pituitary activity sufficient to cause formation of corpora lutea in the ovary and consequent changes in the uterine endometrium leading to pregnancy. The dysmenorrhoea often associated with scantiness of

menstruation responds, it is said, to oestrin therapy in some 30 to 50 per cent. of cases.

There are two other important conditions in which treatment with ovarian hormones is especially satisfactory. First, oestrin is found useful—in less heroic doses, and even by mouth—at the menopause. Hot flushes sometimes yield readily to relatively small doses such as 500 to 3,000 international units of oestrone daily by mouth. Treatment induces a sense of well-being and may relieve associated disorders such as pruritus or kraurosis vulvae and acne rosacea. Secondly, progestin finds rational employment in cases where repeated abortion in early pregnancy has no apparent cause, and the proportion of successful results is too high to be fortuitous. (*Lancet.*, 1935, Vol. 2, p. 1467).

TRYPANOCIDAL ACTION OF NORMAL HUMAN SERUM

The normal serum of man will destroy the trypanosomes pathogenic for animals (*e.g.*, *T. brucei*, *T. equiperdum*, *T. equinum*, etc.) either in the test tube or in the body of rodents infected with these parasites. Human serum does not affect the trypanosomes pathogenic for man (*T. gambiense*, *T. rhodesiense* or *T. Cruzi*), the common trypanosome of rats (*T. Lewisi*) or a trypanosome of newts (*T. diemyctyli*). One of the human trypanosomes, *T. rhodesiense*, is distinctive in that it becomes susceptible to the action of human serum after it has been passed successively through mice. The serum of no other animals, excepting certain monkeys, manifests trypanocidal activity. The serum of some monkeys, however, *e.g.*, that of the baboon, destroys not only the trypanosomes pathogenic for the lower animals but, as well, those infective for man.

The trypanocidal substance of human serum is found in the globulin fraction of the serum. It is thermolabile, being destroyed wholly when the serum is heated at 64°C. for an hour, and being reduced rapidly when the serum is let stand at room temperature. The trypanocidal substance passes readily through Berkefeld filters and with diminished intensity through collodion ultrafilters. It is removed from serum by absorption with trypanosomes or bacteria (the typhoid bacillus; *Proteus*). The substance exhibits its activity independently of all the known components of alexin. The essential substance in the human serum which brings about the trypanocidal effect is antigenic, and a specific anti-trypanocidal antibody develops in rabbits repeatedly treated with an active serum.

The trypanocidal substance probably originates in the normally functioning healthy liver. It is found in the blood serum and in serous exudates. The cerebrospinal fluid and the urine are without trypanocidal power. The substance appears in infants at a very early age and may be present at birth. It is probably elaborated within the body of the young child, since it is found neither to pass the placenta nor to

occur in human milk. The trypanocidal power is enhanced in women late in the period of gestation and is maintained at a high level for some time after delivery.

It seems unlikely that the action of the trypanocidal substance is that of an opsonin or an agglutinin, and the property is manifested wholly without the intervention of alexin. Some investigators have felt it acts essentially as a chemotherapeutic substance. Susceptible strains of trypanosomes become resistant or fast to human serum after repeated exposure to the serum in a manner comparable to that in which they become resistant or fast to drugs.

Since human serum affects only those species of trypanosomes which are pathogenic for animals and which are non-infective for man, and is without effect on the trypanosomes which are infective for man, it is by some believed that the trypanocidal action of serum is responsible for man's immunity to the animal pathogens. It is known, however, that strains of animal trypanosomes which have been rendered serum-fast still are non-infective for man, and that strains of human trypanosomes (*T. rhodesiense*) which become susceptible to human serum after repeated passage through animals retain their infectivity for man. Furthermore, the serum-resistant parasite *T. Lewisi*, which is widespread among rats is apparently unable to infect man. The serum of patients with trypanosomiasis is as active in trypanocidal power as that of normal persons. It appears, therefore, that the immunity of man to the animal trypanosomes depends on factors other than the trypanocidal activity of the serum.

The trypanocidal activity of human serum is sharply reduced in diseases which cause extensive destruction of the parenchyma of the liver. The fact that both the trypanocidal and bactericidal substances are removed from the serum by absorption with either trypanosomes or bacteria points toward a close similarity between the trypanocidal and bactericidal powers. The trypanocidal activity, however, differs from the bactericidal property and resembles the virus-neutralizing function of human serum in being limited to the serum of man and a few closely related primates and in occurring without the presence of alexin. (*Archives of Pathology*, 1935, Vol. 20, p. 788).

APPENDIX II

Appendix II contains general informations likely to be useful to the general practitioners in the Tropics.

TABLE OF BACTERIA PATHOGENIC TO MAN

WITH SPECIAL REFERENCE TO THE TROPICS

Disease	Common Name	Modern Nomenclature
Acne	White staphylococcus Orange staphylococcus Acne bacillus	Staphylococcus albus Staphylococcus aureus Corynebacterium acne
Actinomycosis	Actinomycetes bovis	Actinomycetes bovis
Adenitis	Streptococcus pyogenes Streptococcus scarlatinae	Streptococcus pyogenes Streptococcus scarlatinae
Adenitis (tuberculous)	Tubercle bacillus	Mycobacterium tuberculosis

Summary of Life History and Distribution of Intestinal Nematodes Found in Man

Name of parasite and geographical distribution	Site of adult	Larvæ	REMARKS
Ascaris lumbricoides Cosmopolitan Enterobius vermicularis Cosmopolitan	Intestine of man Mature males and females in small intestine of man. Gravid females in rectum	Developed within the egg and are swallowed by man Developed within the egg and are swallowed by man	• Male dies after fertilizing female in small intestine
Strongyloides stercoralis Tropical and sub-tropical; very unequal	Lungs and mucosa of jejunum of man	Rhabditiform larvæ passed in feces may (a) develop into infective filariform larvæ, or (b) develop into free-living males and females which produce numbers of rhabditiform larvæ; these develop into infective filariform larvæ	Larvæ penetrate unbroken skin
Trichinella spiralis Cosmopolitan, but rare	Small intestine of man, also found in pig; usually a parasite of rats	Each gravid female deposits larvæ over a period of three weeks in the blood stream, these encyst in striated muscle and are infective to another host when eaten	Viviparous
Trichuris trichiura Cosmopolitan	Cæcum of man	Developed within the egg and are swallowed by man	—
Ancylostoma duodenale Necator americanus Tropical and sub-tropical; very unequal, and locally in temperate zones	Small intestine of man	Developed within the egg; escape and become infective in soil	Larvæ penetrate unbroken skin

(Parasitology, Blacklock and Southwell)

Summary of Life History and Distribution of the Filarioidea Found in Man

Name of parasite and geographical distribution	Site of adult	Larvæ	Host of larvæ
<i>Wuchereria bancrofti</i> Tropical and sub-tropical unequal	In lymph glands and spaces	In peripheral blood ; nocturnal ; sheathed	Various species of mosquitoes
<i>Loa loa</i> West Africa	Worms in connective tissue ; migratory	In peripheral blood ; diurnal ; sheathed	<i>Chrysops</i> spp.
<i>Distalomena peritans</i> Africa and South America	In mesentery	In peripheral blood ; non-periodic ; unsheathed	<i>Culicoides</i> spp.
<i>'Filaria' ozzardi</i> West Indies	In mesentery	In peripheral blood ; non-periodic ; unsheathed	Unknown
<i>Ochoterca volvulus</i> Africa ; Central and South America	In subcutaneous tumours usually	In subcutaneous tumours and skin ; non periodic ; unsheathed	<i>Simulium</i> spp.
<i>'Agamofilaria' streptocerca</i> West Africa	Adult unknown	In cutaneous tissue, non-periodic ; unsheathed	Unknown
<i>Dracunculus medinensis</i> Tropical America, Nile valley, Arabia, Persia, Turkestan, India, Ceylon, Fiji, Africa, and West Indies	Gravid female causes superficial ulcers on skin in frequent contact with water	In ulcers on the skin ; non-periodic ; unsheathed	<i>Cyclops</i>

(Parasitology, Blacklock and Southwell)

Pathogenic Protozoal Parasites of Man

Class	Species of parasite	Disease caused	Geographical distribution
Rhizopoda	<i>Endameeba histolytica</i>	Amœbiasis Amœbic dysentery	Tropics, sub-tropics and temperate zones
Mastigophora	1. <i>Trypanosoma gambiense</i>	Trypanosomiasis	Africa
	2. <i>Trypanosoma cruzi</i>	Trypanosomiasis	S. America
	3. <i>Leishmania</i> spp.	Leishmaniasis (a) Kala-azar (b) Infantile kala-azar (c) Tropical sore (d) Espundia	Assam, India Mediterranean Persia S. America
Sporozoa	1. <i>Plasmodium falciparum</i>	Malaria	Tropics, sub-tropics and temperate zones
	2. <i>Plasmodium vivax</i>		
	3. <i>Plasmodium malariae</i>		
	4. <i>Plasmodium ovale</i>		
Ciliata	<i>Balantidium coli</i>	Balantidial dysentery	Tropics, sub-tropics and temperate zones

<i>S. hæmatobium</i> }	Cercaria in water, free swimming	S and A.
<i>S. mansoni</i> }		
<i>S. japonicum</i> }	Cercaria in fresh-water fish	A (M).
<i>C. sinensis</i> }		
<i>H. heterophyes</i> }	Cercaria in fresh-water crabs and crayfish	A, (M).
<i>P. westermani</i>		

<i>P. hepatica</i>	...	Cercaria on blades of grass, encysted	...	A, f and w.
<i>F. buskii</i>	...	Cercaria on fresh-water plants, encysted	...	A, f and w.
<i>A. lumbricoides</i>	...	Eggs containing larvæ in soil and water contaminated with feces of man	...	A, f and w.
<i>E. vermicularis</i>	...	Eggs containing larvæ on skin around the anus	...	A, f and w.
<i>T. spiralis</i>	...	Encysted larvæ in muscle of pork	...	A, (M).
<i>T. trichiura</i>	...	Eggs containing larvæ in soil and water	...	A, f and w.
<i>S. stercoralis</i>	...			
<i>A. duodenale</i>	...			
<i>N. americanus</i>	...	Filariform larvæ in soil, in latrines and water	...	S, A, f and w.
<i>W. bancrofti</i>	...			
<i>L. loa</i>	...	Mosquitoes; full-grown larva in mouth parts	...	S.
<i>D. persians</i>	...	<i>Chrysops</i> ; full-grown larva in mouth parts	...	S.
<i>F. ozzardi</i>	...	<i>Culicoides</i> ; full-grown larva in mouth parts	...	S.
<i>O. volutus</i>	...	<i>Culicoides</i> ; full-grown larva in mouth parts	...	S.
<i>A. streptocerca</i>	...	<i>Simulium</i> ; full-grown larva in mouth parts	...	(?) S.
<i>D. medinensis</i>	...	(?) Larva in mouth parts of some insect	...	A, w.
	...	<i>Cyclops</i> ; full-grown larva in body	...	

A—infection of man by way of the alimentary canal, i.e., ingestion of contaminated water or food, especially raw vegetables.

f—in food.

S—infection of man by the skin or mucous membrane, the larva, or the virus penetrating directly or through lesions.

I—inoculative method by insect vector.

C—contaminative method by insect or tick vector.

w—in water.

(M)—meat, fish or edible crustacea.

(Parasitology, Blacklock and Southwell)

Arthropod Vectors of Diseases in India

Malaria-carriers (Anopheline). Out of 42 species with 10 varieties 7 are proved carriers.

(A) Proved malaria-transmitting species.

1. *Anopheles culicifacies*. Punjab South-west, Rajputana East, Sind, United Provinces East, United Provinces West, Waziristan, Assam, Baluchistan, Bengal, Berar, Bihar, Bombay Deccan, Burma (Lower and Upper), Central India (East and West), Central Provinces (East and West), Ceylon, Chotanagpur, Delhi Provinces, Gujrat, Hyderabad (North and South), Kashmir, Konkan, Madras Coast North, Madras Deccan, Madras South East, Malabar, Mysore State, Nepal, N. W. F. P., Orissa, Punjab (East and North).

2. *A. minimus*. Assam, Bengal, Bihar, Burma, (Upper and Lower), Chotanagpur, Konkan, Madras Coast (North), Madras (Deccan), Madras (South-east), Malabar, Mysore State, United Provinces West.

3. *A. fluviatilis (listoni)*. Assam, Baluchistan, Bengal, Berar, Bihar, Bombay Deccan, Burma Lower, Burma Upper, Central India East, Central India West, Central Provinces West, Ceylon, Chotanagpur, Delhi Province, Gujrat, Hyderabad North, Kashmir, Konkan, Madras Coast North, Madras, Deccan, Madras South East, Malabar, Mysore State, Nepal, N. W. F. P., Orissa, Punjab (East and North), Punjab (South-west), United Provinces (East and West), Waziristan.

4. *A. philippinensis*. Andamans, Assam, Bengal, Bihar, Burma (Upper and Lower), Chotanagpur, Konkan, Malabar, Mysore.

5. *A. stephensi*. Assam, Baluchistan, Bengal, Berar, Bihar, Bombay (Deccan), Burma (Lower and Upper), Central India (West), Central India (East), Central Provinces (East and West), Chotanagpur, Delhi Provinces, Gujrat, Hyderabad (North and South), Kashmir, Konkan, Madras Coast (North), Madras Deccan, Madras South-east, Malabar, Mysore State, N. W. F. P., Punjab (East and North), Punjab (South-west), Rajputana East, Sind, United Provinces (East and West), Waziristan.

6. *A. sundalcus (ludlowii)*. Bengal, Burma Lower.

7. *A. varuna*. Bengal, Burma Upper, Ceylon, Chotanagpur, Konkan, Madras Coast North, Madras South-east, Malabar, Orissa, United Provinces (East).

(B) Species found infected in nature in Indian areas.

A. annularis (fuliginosus), Assam, Bengal, Berar, Bihar, Bombay, Deccan, Burma Lower, Burma Upper, Central India (East and West), Central Provinces (East and West), Ceylon, Chotanagpur, Delhi Province, Gujrat, Hyderabad South, Kashmir, Konkan, Madras Coast North, Madras Deccan, Madras (South-east), Malabar, Mysore State, Nepal, N. W. F. P., Orissa, Punjab (East and North), Punjab (South-west), Rajputana East, Sind, United Provinces (East and West), Waziristan.

A. maculatus, *A. maculatus* var. *willmori*, *A. pulcherrimus*, *A. maculipalpis*, *A. pallidus*, *A. ramsayi*, *A. vagus*.

(C) Species that are important carriers in other countries but of too limited distribution to be important in India.

A. superpictus, *A. multicolor*.

Yellow fever carriers (Culicini). Five prospective carriers.

(A) Proved carrier.

Aedes (Stegomyia) aegypti. Cosmopolitan (more or less).

(B) Suspected carriers.

Aedes (stegomyia) vittatus. Widely spread from the North-west Frontier to Assam and Burma and through Peninsular India to Ceylon. At Pusa (N. Bihar), it occurs throughout the year, but is commonest in the rains.

Aedes (stegomyia) albopictus. A very common species throughout India, including Assam and Burma, also in the Andamans and Ceylon, occurs up to 5,000 to 6,000 ft. in the hills.

Aedes (stegomyia) scutellaris. In Indian region, Andamans.

Mansonia (mansonioides) uniformis. Common in most parts of India (including Assam, Burma, Peninsular India) and Ceylon; less common in the North-west, but specimens have been received from the United Provinces, Punjab, Sind and Bombay. Often abundant and a troublesome blood-sucker.

Dengue carrier

Aedes (stegomyia) aegypti.

Filaria (Wuchereria) bancrofti carriers**(A) Proved carrier.**

Culex (culex) fatigans. One of the most abundant of Indian culicini. Found in all parts of the Indian region, and is largely a domestic mosquito. It occurs up to 5,000 ft. or more in the hills. In parts of the country it is most probably concerned in the transmission of filariasis.

(B) Suspected carriers (species infected under laboratory conditions).

Anopheles hyrcanus var. *nigerrimus*, *A. barbitrostris*, *A. subpictus*, *A. sundaicus* (ludlowii), *A. stephensi*, *A. fuliginosus*, *A. pseudojamesti*, *A. varuna*, *A. pallidus*, *A. philippinensis*, *Culex vishnui*.

Microfilaria malayi carrier

Mansonia (mansonioides) annulifera. Bihar and Orissa, Bengal, Assam, Burma, East and South-west coast of Indian Peninsula and Ceylon, Fyzabad (U. P.) and Central Provinces, does not appear to occur west of a line drawn from the western boundary of Nepal to Bombay.

Papatacci fever carrier

Phlebotomus papatasi. Very widely distributed over the northern and western regions of India, and on the plains of the Punjab and N. W. F. P. the sandflies consist almost entirely of this species and *P. minutus*. It does not appear to be found east of Pusa in Bihar and Orissa or south of Poona in the Bombay Presidency. Although it is essentially a plain living species and appears to be absent from the Himalayas at heights over 2,000 ft. Yet it has been reported in the hotter and comparatively drier valleys of the Hindukush Mountains at heights of 4,500 ft. and at Quetta, Baluchistan (about 5,500 ft.) in which places the climates more nearly approximate that of the plains than the moister and cooler slopes of the Himalayas.

Its seasonal prevalence is that described for the 'sandflies' of the Punjab and N. W. F. P. Its period of maximum prevalence more or less coincides with that of 'papatacci fever.' It also occurs in environs Calcutta.

Leishmania donovani carrier (?) (Kala-azar)

Phlebotomus argentipes. Occurs commonly all along the east coast of India, from Bengal to Ceylon, from sea level up to 1,500 ft. Like Kala-azar its distribution seems to be bounded on the north and west by a line joining Bombay and Delhi. Successful transmission experiments have been carried out with animals by the bite of *P. argentipes*.

Leishmania tropica carrier (?) (Oriental sore)

Phlebotomus sergenti. Seems to occur under somewhat similar conditions of climate and altitude to those which are favourable to *P. papatasi* but is a much rarer species. Its distribution seems to be extraordinarily localised in the areas in which it occurs. Like Oriental sore it seems only to occur in the parts of India north and west of the line joining Bombay and Delhi. (1) The Punjab strain of *L. tropica* develops in *P. sergenti* in a manner indicating a definite host parasite relationship. (2) The flagellate forms of *L. tropica* which develop in *P. sergenti* are infective when inoculated intradermally into a susceptible animal. (3) The flagellate infection is infective as early as the 5th day after the initial feed of the fly.

House flies (Muscidae)

Probable carriers of *Bact. typhosum* and allied species, cholera vibrio and allied species, bacteria of summer diarrhoea, bacteria affecting eye, pathogenic protozoa.

Musca domestica. Cosmopolitan.

Musca corvina. Widely distributed.

Musca determinata. Widely distributed.

Other members of genus *Musca*. *M. vicina*, *M. nebula*, *M. sorbens*. Blue and Green bottles are also probable carriers.

Genus. *Pycnosoma*, *Thelychata* and *Pyrellia*.

Well-known species are *Calliphora erythrocephala* (hills); *Lucilia suprina* (serenissima); Green bottle—*Chrysomya megacephala* and *Chrysomya bezziana*.

Myiasis producing (Muscidae)

Pycnosoma flaviceps. Nostrils of human beings and camels.

Chrysomya bezziana. Myiasis of carious tooth.

Sarcophaga fuscicauda, *Aphiochæta scalaris* and *Sarcophaga hirtipes* and accidental myiasis carriers.

Blood sucking (Muscidae)

Important from veterinary point of view only.

Genus. *Stomoxys*, *Hæmatobia*, *Bdellolarynx*, *Lyperosia*, *Philæatomyia*. These with some species of *Tabanidae* carry the parasite which causes 'Surra' or Trypanosomiasis of cattle.

Plague carriers

Bacillus pestis carriers (Siphonaptera). Schedule of species of rat flea found in regions liable to plague infection.

PUNJAB. *Xenopsylla cheopis*, *X. astia*, *Ceratophyllus punjabensis*.

BOMBAY. *X. cheopis*, *X. braziliensis*, *X. astia*.

UNITED PROVINCES. *X. cheopis*, *X. astia*.

CENTRAL INDIA. *X. cheopis*, *X. braziliensis*, *X. astia*.

MADRAS. *X. cheopis*, *X. astia*, *X. braziliensis*, *C. nilgiriensis*, *Leptopsylla musculli*.

Asiatic Relapsing fever-carriers (Lice)

Pediculus humanus corporis (body louse) is the natural transmitter of spirochaete of relapsing fever to man.

Pediculus humanus capitis (head louse) also transmits the disease.

Tick-Typhus carriers (?) (Acarina).

List of species of Ticks collected from Tick-Typhus areas.

Boophilus australis. Chin Hills, Shillong, Muktesar (Nainital Dist.), Burma, Bengal, Bihar and Orissa, Central Provinces, Madras Presidency, South Bombay, Hazara Dist. (N. W. F. P.), Dalhousie (Gurdaspur Dist.), Dharampur and Kasauli (Simla Hills).

Hyalomma aegyptium. Punjab, Sindh, Rajputana, United Provinces, Bihar and Orissa, Central Provinces, Madras and Bombay Presidencies. Rare in Bengal and Ceylon, Seistan and Perso-Baluchistan Frontier.

H. aegyptium. sub sp. *isaaci* Sheriff. Nepal, Bihar and Orissa, United and Central Provinces, Punjab, Madras and Bombay Presidencies.

H. (hyalomina) hussaini Sheriff. Bihar and Orissa, Central Provinces, Madras and Bombay Presidencies.

H. (Hyalomina) hussaini, var. *brevipunctata*. Bengal, Bihar and Orissa, Central Provinces, Madras and Bombay Presidencies.

Rhipicephalus sanguineus. India, Burma, Ceylon. Cosmopolitan.

Hæmaphysalis bispinosa. Upper Burma, Lower Burma, Assam, Bengal, Bihar and Orissa, Central Provinces, Madras and Bombay Presidencies, Punjab, Andamans.

Miscellaneous maladies caused by insects and other Arthropods

VESICULAR DERMATITIS. *Lytta tenuicollis* (Coleoptra).

'SPIDER (?) LICK.' *Pacderus fuscipes* (Staphylinids).

'NAGA SORE' AND EPIDEMIC CONJUNCTIVITIS. *Siphonella funicola* (Osciuidæ).

INTESTINAL 'SCARABIASIS.' *Onthophagus bifasciatus*, *Caccobius mutens* (Coleoptra).

IRRITATION, DERMATITIS AND PIGMENTATION OF THE SKIN. *Pediculus humanus corporis* (Body louse).

IRRITATION. *Pediculus humanus capitis* (Head louse), *Phthirus pubis* (Pubic louse).

ITCH. *Sarcoptes scabiei* (Itch mite).

Guinea worm carriers (?) (Crustacea)

'Guinea worm' (*Dracunculus medenensis*). *Cyclops coronatus*, *C. bicuspidatus*, *C. quadricornis*.

Indian Scorpions

Distribution of Genera and Species

1. **BUTHEOLUS** Simon. Eastern Mediterranean area of Palearctic Region; shores of Red Sea; Sokotra; Western and North-Western India.

B. bicolor Pocock. Western Ghats: Khandala, Wai, Satara, Poona.

B. flavescens Pocock. Kathiawar: Kharagoda.

**B. melanurus* Kessler. Northern Baluchistan; Waziristan: Sewa; Punjab; Ahmednagar: Shevgaon.

B. pallidus Pocock. Sind: Kashmor Bund, Khelat Frontier.

2. **BUTHUS** Leach. Mediterranean area of Palearctic Region; Siropia Region down to Zambesi; China; India, but absent from Ceylon, Burma.

B. acute-carinatus Simon. Sind: Hyderabad; Waziristan: Miran-shah; Central India: Gwalior.

B. alticola Pocock. Chitral; North-West Frontier: Malakand, Peshawar; Punjab.

B. atrostriatus Pocock. Sind: Kashmir Bund.

B. australis Linn. Northern Baluchistan; Sind: Hyderabad, Kotri, Kashmir Bund, Khelat Frontier, Punjab: Maurypur, Laharpur

B. caucasicus Fischer. Northern Baluchistan.

B. doriae Thorell. Sind: Karachi, Khelat Frontier; Baluchistan: Ormara on the Mekran coast.

B. hendersoni Pocock. Bilaspur: Nandghat; Raipur: Drug; Cud-dapah; North Arcot, Chingleput: Madras; Salem: Yercaud in the She-varoy Hills; Trichinopoly; Tanjore.

B. macmahoni Pocock. Northern Baluchistan.

B. nigritrons Pocock. Northern Baluchistan.

B. pachyurus Pocock. Mandla; Nagpur: Nagpur, Kamptee; Nasik; Satara; Godavari: Tanuku.

B. rugiscutis Pocock. Western Ghats: Satara, Mahableshwar, Paichgani.

B. tamulus Fabr. Waziristan: Miranshah, Banks of Chasma River; Dehra Dun; Garhwal: Srinagar; Bareilly; Shikarpur: Khelat Frontier; Karachi: Jati, Kotri Sujawal; Hyderabad, Aligarh: Jalali; Shahjahan-pur: Katra; Sitapur: Laharpur; Gwalior; Jhansi; Moth; Banda: Bharatkup; Benares, Allahabad: Munjhanpur; Ghazipur; Shahabad: Sarinja; Patna; Gaya: Arwal: Santal Parganas: Amrapara; Mahi-Kantha: Ilol; Kathiawar: Kharagoda; Panch Mahals; West Khandesh: Sakri; Bhopal; Saugor, Jubbulpur: Satna, Narsinghpur; Bilaspur: Bilas-pur, Lormi; Calcutta; Puri: Kakatpur; Raipur: Drug; Balaghat; Nag-pur; Chanda: Ahiri, Allapilli, Sironcha; Yeotmal: Dhanoba; Akola: Boriadgaon; Amraoti, Nimar: Khandwa, Buldana; Nasik: Dindori, Niphad; Thana: Shahapur; Ahmednagar: Shevgaon; Bombay: Salsette, Poona: Khandala; Ratnagiri; Satara; Kolhapur; Belgaum: Gokak; Bija-pur: Badami, Bagalkot, Bagewadi, Bijapur, Bilgi, Guledgudd, Muddebihal, Talikoti; Secunderabad; Vizagapatam: Anakapalle, Chodavaram Nakkapalli; Godavari: Dowai-shwaram, Kothapet, Tanuku, Yeleshwaram; Kistna: Nuzvid; Guntur: Addanki, Kollur; Nellore; Kurnool; Ananta-pur: Uravakonda; Bellary: Kanakal; Dharwar; North Kanara: Karwar; Chitaldroog; Holalkere; Tumkur: Chiknayakanhalli, Pavagada; Kolar: Hosur, Sidlaghatta; North Arcot, Arni, Chetpat, Polur; Chingleput: Madras; Bangalore: Bangalore, Closepet, Chikkabanavara, Velahanka; Mysore: Attikan, Mysore, Nagamangala; Hassan: Saklasnur, Shukra-vankot; South Kanara: Katapadi; Coimbatore: Bhavani; Trichinopoly: Karur, Trichinopoly; Tanjore: Swamimalai, Tanjore, Tirupanandal; Madura.

3. *CHARMUS* Karsch. Ceylon.

C. lanens Karsch. Ceylon.

4. *HEMIBUTHUS* Pocock. India.

H. crassimanus Pocock. Western India: Panch Mahals.

5. *ISOMETRUS* Hempr. and Ehrenb. Oriental Region, from India as far east as Queensland.

I. acanthurus Pocock. Kolaba: Matheran.

I. assamensis Oates. Assam: Dhubri; Puri: Kakatpur.

I. battiens Karsch. Ceylon: Haldumullah, Peradeniya.

I. pachycentrus Pocock. South Kanara: Mangalore.

I. septentrionalis Linn. Karachi; Bombay; Thana: Salsette; Ceylon: Peradeniya, Trincomalee; Burma: Akyab, Rangoon; Andaman Islands.

- I. rigidulus* Pocock. Central India: Bhopal.
- I. thurstoni* Pocock. Bhopal; Kolhapur; Belgaum; Cuddapah; Salem; Yercaud in the Shevaroy Hills; Nilgiris: Coonoor; Malabar: Manjeri; Trichinopoly; Tinnevely.
- I. thwaitesi* Pocock. Ceylon.
- I. vittatus* Pocock. Madras.
6. **LYCHAS** C. Koch. Tropical Africa; India to Australia.
 - L. fene* Thorell. Burma: Shwegoo.
 - L. hendersoni* Pocock. Salem: Yercaud in the Shevaroy Hills.
 - L. laevifrons* Pocock. Calcutta.
 - L. mucronatus* Fabr. Upper and Lower Burma; Tenasserim.
 - L. nigristernis* Pocock. Dehra Dun.
 - L. rugosus* Pocock. Central Provinces: Raipur
 - L. scaber* Pocock. Secunderabad; Madras.
 - L. scutillus* C. Koch. Southern Tenasserim.
 - L. shoplandi* Oates. Lower Burma: Prome; Pegu: Entagaw; Palone, Rangoon.
 - L. tricarlinatus* Simon. Bhopal; Nagpur; Kamptec; Belgaum; North Kanara; South Kanara: Mangalore; Nilgiris; Travancore: Trivandrum; Tanjore; Salem: Yercaud in the Shevaroy Hills, South Arcot: Pondicherry; Chingleput; Madras; Nellore.
7. **PLESIOBUTHUS** Pocock. India.
 - P. paradoxus* Pocock. Northern Baluchistan.
8. **STENOCHIRUS** Karsch. Malabar Coast, hills of Ceylon.
 - S. politus* Pocock. Kanara.
 - S. sarasinorum* Karsch. Ceylon: Peradeniya.
9. **CHÆRILUS** Simon. Ceylon; Himalayas from Kashmir to Assam; Burma, Malacca, Sumatra, Java, Borneo and Celebes.
 - C. ceylonensis* Pocock. Ceylon: Trinomalee.
 - C. gemmifer* Pocock. Sylhet.
 - C. granosus* Pocock. Western Himalayas: Mussoree.
 - C. insignis* Pocock. Ladakh.
 - C. margaritatus* Pocock. Simla Hills: Kasauli.
 - C. pictus* Pocock. Sylhet.
 - C. tricostratus* Pocock. Assam: Sadiya.
10. **CHIROMACHETES** Pocock. Malabar Coast in Southern India.
 - C. fergusoni* Pocock. Travancore: Trivandrum.
11. **HEMISCORPIUS** Peters. Soko'ra, Baghdad and Baluchistan.
 - H. lepturus* Peters. Northern Baluchistan.
12. **HORMURUS** Thorell, India; Burma; the whole of the Indo- and Austro-Malayan area; Polynesia and Melanesia.
 - H. australasiae* Fabr. Burma—Akyab; Prome; Toungoo; Thagaya; Henzada; Myanaung; Pegu Hills; Amherst: Kawkareik, Moulmein; Tavoy; Mount Mooleyit in Tenasserim; Reef Island; Great Cocos Island; Andamans; Nicobar Islands.
 - H. nigripes* Pocock. Panch Mahals; Jubbulpore: Satna.
13. **IOMACHUS** Pocock. British and German East Africa; S. India.
 - I. laeviceps* Pocock. South Kanara: Mangalore; Nilgiris: Kotagiri; Salem: Yercaud in the Shevaroy Hills.
 - I. nitidus* Pocock. Nellore.
 - I. punctulatus* Pocock. Nilgiri Hills; Coimbatore

14. *PALAMNÆUS* Thorell. Oriental Region from Indian and Ceylon to Borneo and the Philippines.

P. barberi Pocock. Tinnevely.

P. bengalensis C. Koch. Dehra Dun; Sahaspur; Gwalior; Allahabad, Benares; Jubbulpore; Satna; Chota Nagpur; Bengal; Assam-Sibsagar.

P. cesar C. Koch. Ceylon.

P. fulvipes C. Koch. Ajmere; Banda; Bharatkup; Mähi-Kantha; Himatnagar, Ilol; Kathiawar: Kharagoda; Panch Mahals; Narsinghpur; Bhandara; Nawegaon; East Satpura Hills; East Khandesh: Chalisgaon, Talegaon; West Khandesh; Nasik: Chandor, Kalvan, Malegaon, Nandgaon, Nipbad, Yeola; Belgaum: Saundatti; Bijapur: Badami, Bagalkot, Bijapur, Bilgi, Guledgudd; Secunderabad; Kistna: Nurvid, Cuddalaph, Tamkur. Chiknayakanhalli; North Arcot: Chetput, Polur; Chingleput. Madras; Bangalore: Chikka-banavara; Mysore: Bilikere, Krishnarajasagara, Nagamangala; Travancore: Ellappatti.

P. gravimanus Pocock. Mysore: Attikan; Tanjore; Ceylon.

P. indus De Geer. Ceylon: Peradeniya.

P. latimanus Pocock. ?

P. lirus Pocock. Gwalior; Narsinghpur; Bhopal.

P. longimanus Herbst. Burma: Cinchona Plantation; Thaton: Mokpalani Quarries; Andamans: Port Blair.

P. oatesii Pocock. Hanthawaddy: Rangoon; Mergui.

P. phipsoni Pocock. Aligarh: Jalali; Nasik Ghats; Nasik: Dindori, Lena, Peint; Thana; Bombay; Kolaba: Matheran; Poona: Khandala, Kolhapur: Bhudhargarh, Panhala; Bijapur: Badami; Godavari: Tanuku, Mysore; Adikkan; Nilgiri Hills; Coimbatore: Billigirirangan Hills at 4,000 to 5,000 feet; Salem: Yercaud in the Shevaroy Hills.

P. scaber Thorell. Dharwar; North Kanara; South Kanara, Coorg; Malabar; Travancore: Trivandrum.

P. serratus Pocock. Ceylon.

P. swammerdami Simon. Dehra Dun; Saran: Siwan; Shahabad, Burdwan; Chota Nagpur; Sambalpur; Jubbulpore, Satna; Narsinghpur, Raipur; Nimar: Khandwa; Bijapur: Talikoti; Belgaum: Saundatti; Dharwar; Vizagapatam: Chodavaram, Godavari: Chintur, Dowlishwaram, Tanuku, Yelleshwaram; Kistna: Nuzvid; Anantapur: Hindupur; Shimoga: Davangere; North Arcot: Polur; Chingleput: Madras; Bangalore: Yelahanka; Mysore: Bilikere, Krishnarajasagara, Mysore, Nagamangala, Periyapatna; Nilgiris: Coonoor; Coimbatore: Bhavani; Trichinopoly; Tanjore; Ramnad; Ceylon: Chilan, Trincomalee.

P. wroughtoni Pocock. Kolhapur: Gadingal; Belgaum.

P. xanthopus Pocock. Bilaspur: Lormi; Chanda: Ahiri; Satara; Bijapur: Badami; Mysore: Bilikere.

15. *SCORPIOPS* Pters. The Deccan; Himalayas from the Punjab to Assam, thence through Burma to Southern Tenasserim.

S. anthracinus Simon. Tavoy.

S. asthenurus Pocock. Darjeeling: Kalimpong; Cachar: Haflong.

S. binghami Pocock. Pegu Hills; Central Tenasserim.

S. crassimanus Pocock. —?

S. hardwickii Gervais. Himalayas; Kashmir; Jaunsar 6,000 to 9,000 feet; Dehra Dun 2,000 feet; Kasauli; Nepal.

S. insculptus Pocock. Jaunsar 6,000 to 9,000 feet; Dehra Dun 2,000 feet.

Leptochirus Pocock. Assam; Sadiya; Garo Hills: Tura.

S. lindstræmii Thorell. North Chin Hills; Mount Mooleyit in Tenasserim.

S. longimanus Pocock. Assam: Sylhet, Dhubri, Sadiya; North Cachar Hills; Naga Hills.

S. montanus Karsch. Waziristan: Razmak, Mount Shuidar 8,000 feet; Kangra: Dharmasala; Jaunsar 6,000 to 9,000 feet; Simla: Kasauli; Dehra Dun 2,000 feet; Garhwal: Srinagar; Moradabad; Sitapur; Laharpur, Misrih; Kolaba: Matheran; Satara: Mahabaleshwar.

S. petersii Pocock. Jaunsar 6,000 to 9,000 feet; Simla; Dehra Dun 2,000 feet, Mussorée.

(*Indian Medical Research Memoirs* No. 24, June, 1932)

Distribution of Poisonous Snakes in the World

Serpents have great ability of adopting themselves to low temperatures and select favourable hibernating places during very cold weather. Practically in all parts of the world where reptile life is possible snakes will be found. In the northern hemisphere they are found as high as 50° latitude in Canada, and the European viper is found in Siberia. The United States is rich in serpent life and a great number of them are poisonous. In Europe snakes are scanty there being only about a dozen non-venomous and half a dozen venomous types. The latter are *Vipera berus*, *V. aspis*, *V. latastii*, *V. ammodytes*, and *V. orsini*.

The Viper is never found in Ireland although it is common in England and Scotland. Hawaii has no poisonous snakes. The poisonous snakes in Europe are of small size and their bites only cause local symptoms and are rarely fatal to man. The adder is the only poisonous snake found in Great Britain. It ranges from Wales to the Saghalien Island and from Caithness to the north of Spain, and has been met with at an elevation of 9,000 ft. It occurs also in the northern parts of Scandinavia and is the only venomous snake found beyond the Arctic Circle. The Asp is found all over southern Europe, and in large numbers in the Alpine regions.

Of the 10 varieties of cobras in the world (1) *Naja naja*, (2) *N. bungarus*, (3) *Hemil bungarus*, (4) *Boulengerina*, (5) *Elapechis*, (6) *Sepedon*, (7) *Aspidelaps*, (8) *Walterinnesia*, (9) *Hamorelaps*, (10) *Dendrasphis*, the last eight are found outside India. Varieties 1, 4, 5, 6, 8, 9, 10 occur in Africa, the most widely distributed being the Egyptian cobra and the Black-necked cobra. The Cape cobra (*N. flava*) is found in the Cape Province of South Africa. A particularly interesting variety is the Ringhal, or Spitting snake (*Spedon haemachates*) of South Africa which occurs nowhere else in the world. The most dreaded snake in Tropical and South Africa is the Mamba or Tree cobra. It occurs in two varieties: black and green (*Dendraspis angusticeps* and *D. viridis*). The green mamba grows to a length of 9 feet, and the black one to as much as 13 feet. The black mamba, which is the more fierce and aggressive of the two, is the largest venomous snake in Africa and next to

the King cobra (*Naja bungarus*) the world's largest poisonous serpent. The venom of the mamba is of a deadly character. In South Africa there are two dangerous back-fanged colubrids, the 'Boomslang' or Tree snake and the 'Schaapstekker' (*Dispholidus typus* and *Trimorphodius*). The poison of both is more virulent than that of any other snake in Africa, but their bite does not usually cause appreciable harm.

In Africa, poisonous snakes are abundant throughout the tropical and subtropical zones, but fatal accidents here are less than in India owing to the sparse population. The *Atheris*, a tree-snake closely allied to the Echis or Saw-scaled viper is found further south in Africa where vegetation is luxuriant. Other varieties of *Atheris* found here are *A. chlorechis*; *A. squamiger* and *A. ceratophorus*. South Africa has very dangerous representatives of the viperine sub-family. One of these is the Puff adder (*Causus defillipi*) which is also found in Central and East Africa. It reaches a length of 5 ft. and is as thick as a man's arm and is one of the deadliest of vipers. It is found as high up as 11,000 feet above the sea, which probably is the world's elevation record for the habitat of poisonous snake. Two large venomous, desert varieties of the horned viper, commonly known as Horned puff-adder, occur in South Africa, viz., *Bitis cornuta* and *Bitis nasicornis* the former having a beautiful coloration. This is the largest pitless viper in the world. Three other important vipers in this continent may be mentioned, they are the Night adder or Demon adder (*Causus rhombeatus*) and the Atractaspis species, a small burrowing gaboos both found in tropical and South Africa, and the Gaboon viper which inhabits the forest tracts of Africa.

The vast majority of poisonous snakes in America are pit-vipers. The best-known is the rattle snake, of which there are 13 known species. There are two genera (i) *Sistrurus*, with two species (*S. miliarius* and *S. catenatus*), confined to the Southern United States and Northern Mexico. Both are small, do not exceed 2½ ft. in length, (ii) *Crotalus*. The chief varieties of which are *C. terrificus*, *C. scutulatus*, *C. confluentus*, *C. durissus*, *C. horridus*, *C. carastes* and *C. adamanteus*. The tail in these snakes terminates in a series of articulated, horny cup-shaped shells, numbering 21 or more in a full grown specimen, and when disturbed or irritated, the snake vibrates these with such rapidity as to produce a rattling sound, which may be heard 60 feet away. The most dreaded species in the rattler group is the surly, quick-tempered Diamond-backed rattle snake (*C. adamanteus*) of Texas and the swamps of Florida. It is so named from the marking on the back resembling the facets of a diamond. The banded timber rattle (*C. horridus*) snake, with black longitudinal bands on its head and neck, occurs in the Eastern United States. These two are the largest members of the group and attain a length of 8 feet. *Crotalus terrificus* (cascavalla or dog-faced rattle) ranges from Mexico to Argentina. There is also a small species called the 'Side winder,' which lives in the deserts

of South Western United States. It has a pair of blunt horn-like projections above the eyes and appears to be the American replica of the horned viper of the old world.

Central America, the West Indies and Tropical South America are other regions of the New world where venomous snakes abound. The most dreaded among these is the 'Jararaca' (*Bothrops neuweidii*, boliviana or maximilian viper), a fierce and aggressive serpent about 6 feet long. It is the deadliest snake in Brazil and accounts for over 50 per cent. of the deaths from snake-bite in the country. The second most deadly snake in Brazil is *Crotalus terrificus*, which is followed by the aggressive water Moccasin (*Ancistrodon piscivorus*) or water viper and the 'Fer-de-lance' (*Lachesis lanceolatus*) whose tail ends in a horny spine, which scrapes harshly against rough objects. The giant 'Bush master' (*Lachesis mutus*) is still another terrible snake of Brazil. One other remarkable poisonous reptile of Brazil deserves notice. It is the tiny, brownish green 'Flying Reptile' which seldom exceeds 8 inches in length. It is stated that this reptile can jump long distances at a high speed. The Boa constrictor ranges from tropical Mexico to Brazil. It is the largest snake in the New world, and in the Amazon basin grows to a length of 30 ft. All boas, unlike pythons, are viviparous, the young ones being about 3 feet long at birth. Like the python, the boa is a non-poisonous snake, having no poison apparatus.

Australia is most remarkable in the character of its serpents. Viperine snakes are comparatively few and non-venomous. The snakes here consists of Flapinoes, snakes allied to the kraits, cobras and the coral snakes. Australia has about 105 species of poisonous snakes, all colubrids. In all there are 5 genera of a deadly type, all of which are fore-fanged. Arranged in the order of deadliness, they are: the 'Taipan' or Giant Brown Snake (*Oxyuranus maclelleni*). The Death adder (*Acanthophis porphyriacus*) maximum length 3 ft., the Tiger snake (*Notechis scutatus*) length 5½ ft., the Black snake (*Pseudochis porphyriacus*) 6 or 7 ft., and the copperhead or superb snake (*Dendrosonia superba*) 5 ft. The Taipan is the largest of poisonous snakes in Australia and grows to a length of 10 ft. or more. It is savage and aggressive. The fangs in a large specimen are about half an inch long, and at a single bite it can inject a maximum dose of 35 drops of venom, sufficient to kill 20 persons or more. There are also many species of back-fanged colubrids in Australia.

The principal varieties of pythons occurring outside India are the Reticulated python (*Python reticulatus*) of the Malay peninsula and Indo-China, which grows to a length of 30 feet; the Rock python of Tropical and South Africa (*Python sebae*), the West African python, and the Australian scrub python (*Python sphlotes*) of North Queensland. The python does not occur in Europe, but America possesses two forms allied to it, the Boa constrictor (*Constrictor constrictor*) and the Anaconda (*Eunectes murinus*).

Distribution of the Important Snakes in India

Common English Name	Zoological Name	Vernacular Name	Distribution
GROUP I—SNAKES WITHOUT ENLARGED VENTRALS—HARMLESS			
Blind snakes	<i>Typhlops braminus</i> and other species	.. .	Indian Peninsula, Burma and Ceylon, a few varieties in W. Himalayas, N. W. F. P. and the Punjab
GROUP II—SNAKES WITH NARROW VENTRALS—HARMLESS			
Indian python	<i>Python molurus</i>		India, Ceylon and Burma
Russell's earth snake	<i>Eryx conicus</i>	<i>Padam cootoo</i> , <i>manooli pambo</i> , <i>monadi pada</i> (Vizag) meaning earth dweller; <i>kully pambo</i> meaning mud-snake; <i>domuha</i> , two-mouthed (Hind. and Punj.)	Different parts of India
John's earth snake	<i>Eryx johni</i>	...	Do.
Iridescent earth snake	<i>Xenopeltis unicolor</i>		Burma Hills
Short-tailed earth snake of Burma	<i>Cylindrophis rufus</i>	Burma Hills
Rough-tailed earth snake	<i>Silybura ocellata</i>		Goa, Ghats to Travancore, commonest and most widely distributed

Wall's brackish water snake *Cerberus rhynchops*

Do.

GROUP III—SNAKES WITH BROAD VENTRALS AND SHIELDED HEAD

(a) Sub-Group A—Harmless

Blunt-headed snake,	<i>Amblycephalus monticola</i>	Nil	E. Himalayas and Assam
No name	<i>Ablabes calamaria</i>		Himalayas, W. Ghats and Ceylon
Variegated kukri snake	<i>Oligodon subgriseus</i>	<i>Katla tutta, vanapa pam</i> (Vizag); <i>sanka</i> (Beng.)	Trans Indus; Ind. Peninsula, up to the base of Himalayas as far east as Purnea; Ceylon
No name	<i>Simotes arnensis</i>	Ceylon, Himalayas, Ind. Peninsula, N. W. F. P.
Do.	<i>Simotes cruentatus</i>	Burma
Do.	<i>Simotes cyclyurus</i>	Bengal, E. Himalayas, Assam and Burma
Common wolf snake	<i>Lycodon aulicus</i> and <i>Lycodon striatus</i>	Confused with krait, Common name <i>kauri-wala</i> meaning like <i>covry</i> , <i>garar</i> (U. P.); <i>soovar pambu</i> , i.e., wall snake (S. India); <i>shunguvorian</i> (Travancore)	Ceylon and Maldives, Ind. Peninsula, westward it extends throughout Punjab, Baluchistan, Persia, lower slopes of Himalayas as far east through Brahmaputra and Irrawady basin, Andamans and Nicobars, up to altitude 8,000 ft.

Common English Name	Zoological Name	Vernacular Name	Distribution
Little trinket snake	<i>Coluber helena</i>		Ceylon, Ind. Peninsula and Sindh, W. Himalayas, Burma
No name	<i>Coluber radiatus</i>		Orissa; Bengal, E. Himalayas, Assam and Burma
Dhama or rat snake	<i>Zaocys mucosus</i> and <i>Zaminis mucosus</i>	Dhama (Beng., Hind. and Mar.); <i>surey pamboo</i> , <i>jair potoo</i> (Tamil.); <i>mywe let pat</i> , <i>lim bivi</i> (Burm).	Burma, Ceylon, Ind. Peninsula; and as far as Central India, Rajputana and Sindh; up to Sutlej valley; altitude 5,000 to 7,000 ft.
Slender dhama	<i>Zaocys korros</i>	...	Do.
No name	<i>Zaocys ventrimaculatus</i>		Baluchistan, Sindh, Punjab, Rajputana, Gujrat, W. Himalayas
No name	<i>Zaocys fasciolatus</i>		Peninsular India (to Punjab and Bengal)
No name	<i>Zaocys diadema</i>	...	N. W. India (West of Farukhabad and North of Gujrat)
Common pond snake	<i>Tropidonotus piscator</i>	<i>Neer kolee</i> or <i>neer mandalee</i> (S. India); <i>ye mywe</i> (Burma); <i>thane pamboo</i> (Tamil); <i>holay havu</i> (Canarese)	Ceylon, Ind. Peninsula, Nilgiris, Coonor; up to altitude 5,700 to 6,000 ft.

Buff-striped keelback	<i>Tropidonotus stolidus</i>	Ceylon, Ind. Peninsula, Assam and Burma
Common green whip snake	<i>Dryophis mycterizans</i> and <i>D. perroteti</i>	<i>Kankotii pambu</i> , i.e., the eye plucker; <i>kumbirimuken</i> (Singhalee)	Ceylon, Annamally Hills and S. India, Burma and Siam, Western Ghats (N. Canara, Nilgiris) •
Buff whip snake	<i>Dryophis prasinus</i>	E. Himalayas, Burma. Assam and Bengal
Bronze-back tree snake	<i>Dendrophis pictus</i> , <i>dendrolaphis tristis</i> (<i>daudin</i>)	<i>Hal-danda</i> , i.e., like rice stalk, <i>katta kaluma</i> , i.e., black mouth (Ceylon); <i>villoni</i> (Canarese); <i>rooka</i> (Mar.); <i>bet an chora</i> (Beng.)	Himalayas, Indian Peninsula as far east as Bengal, Ceylon and Burma
Golden tree of carpet snake	<i>Chrysopelea ornata</i>	<i>Kallajin</i> (Beng. and Hind.)	Ceylon, W. Ghats (south of Goa), E. Himalayas, Assam and Burma
Golden common brown tree snake	<i>Dipsadomorphus gokool</i> , <i>Dipsadomorphus trigonatus</i>	Bengal, Assam and Burma, Ind. Peninsula (to Baluchistan and Himalayas), Ceylon
Burmese brown tree snake	<i>Dipsadomorphus multi maculatus</i>	Assam and Burma
Sind sand snake	<i>Psemmophis schokari</i>	Sindh, Punjab and Baluchistan
No name	<i>Psemmodynastes pulverulentus</i>	E. Himalayas, Assam and Burma

Common English Name	Zoological Name	Vernacular Name	Distribution
(b) Sub-Group B—Poisonous			
Common Indian krait	<i>Bungarus caeruleus</i> <i>Bungarus arcuatus</i>	<i>Anali</i> (Madras); <i>kattu variyan</i> (Tamil); <i>yenna variyan</i> (Tamil); <i>godi nagera</i> (Mysore); <i>kala gandait</i> , <i>dhāman chiti</i> (Hind.)	Ceylon, Ind. Peninsula, up to Baluchistan, Almor, Indus Basin, Ganges Basin; up to altitude 5,400 ft.
Banded krait	<i>Bungarus fasciatus</i>	<i>Raj samp</i> , <i>sankni</i> (Beng.); <i>koclea krait</i> (N.W.F.P.); <i>ngan-wa</i> , <i>na f m - y u e</i> , <i>gnandawja</i> , <i>my u e - m i n</i> (Burma)	Common in Upper Burma, Assam, West of Bengal, Brahmaputra Basin, Mahanadi Basin, Irrawady Basin, south of Himalayas and south of India as far as Godavari. Tenasserim, Indo-China, South China, Malay Peninsula and Archipelago
Cobra	<i>Naja naja</i> <i>Naja tripudians</i>	<i>Nag samp</i> , <i>kala samp</i> , <i>corni nag</i> , <i>sankh nag</i> (Hind.); <i>sarpam</i> , <i>moorookan</i> , <i>nalla pamboo</i> (S. Ind.); <i>nagoo havu</i> (Mysore); <i>na ga gokurra</i> , <i>keutah</i> (Beng.); <i>gohmanna</i> (Behar); <i>chajh-wala</i> (N.W.F.P.); <i>chamchamar</i> (Phastu); <i>mywe hock</i> (Burma); <i>toodong sta</i> (Malaya)	Ceylon, Ind. Peninsula, Assam and Burma, whole of India (from Himalayas to Ceylon, and Burma to Sind) up to altitude 6,000 ft

King cobra or hamadryad	<i>Naja bungarus</i>	Throughout India, with the exception of Ceylon (Rajputana, Sind, Punjab and Bengal) up to altitude of 7,000 ft.
Slender coral snake	<i>Callophis trimaculatus</i>	...	From South India. Deccan, Canara, Bengal to Burma Hills
Maclelland's coral snake	<i>Callophis maclellandi</i>	...	Himalayas as far as Kasauli to Nepal, Sikkim, Khasia Hills through Assam to Burma and South China and Formosa
Sea snakes	<i>Hydrophis coronatus</i> <i>Enhydrina valakadien</i> <i>Dietera robusta</i>	Indian Ocean

GROUP IV—SNAKES WITH BROAD VENTRALS, SCALY, AND NOT SHIELDED HEADS

(a) Sub-Group A: Pitless Vipers—Without a pit in the loreal region of the head

Saw scaled viper	<i>Echis carinata</i>	<i>Viridan, pamboo, soorootai pamboo; ratta pamboo, korattai (S. India); kalu havu (Mysore); phoorsa (Bomb.); afai (Delhi); kuppur (Sind); phisi (N. W. F. P.); ghari b a (Egypt)</i>	Throughout India, from Cape Comorin to Himalayas preferably in sandy and dry areas, common in Trichinopoly. Scarce in Bengal. To the north it extends to Rajputana, Punjab, Sind and Baluchistan to Transcaucasia. Up to the altitude of 8,000 ft.
------------------	-----------------------	---	--

Common English Name	Zoological Name	Vernacular Name	Distribution
Indian daboia or Russell's viper	<i>Vipera russelli</i>	<i>Tic polanga</i> (Ceylon); <i>mandali, kanardi virian</i> (S. India); <i>ghanas kked-chitra</i> (Bomb. & Gujrat); <i>korail</i> (Sind); <i>chandira bora, uloo bora</i> (Beng.); <i>mwe bwe</i> (Burma)	Whole of Indian Empire from Ceylon to Himalayas and from Burma to Sind. Common in the Punjab, Irrawady and Brahmaputra Basin. Up to altitudes 2,000 to 4,000 ft. and as far as 7,000 ft.
(b) Sub-Group B : Pit Vipers—With a loreal pit in the loreal region			
Common green viper (bamboo snake)	<i>Lachesis gramineus</i>	<i>Myne sein</i> (Burma); <i>nagu kheeyo</i> (Siam); <i>ular daun, i.e., leaf snake</i> (Malaya)	Most plentifully and most widely distributed. From Malay to Burma, Andamans, Nicobar, Eastern Ghats and Nilgiris. To the west of Himalayas up to Sutlej valley. Up to altitude of 1,500 to 6,000 ft.
Green tic	<i>Lachesis trigonocephalus</i> and other species	<i>Green tic polonga</i>	Peculiar to Ceylon
Common Himalayan viper	<i>Ancistrodon himalayanus</i>		Confined to Himalayas, Khasi Hills (up to 5,000 to 12,000 ft) Lidder valley of Kashmir
Hump-nosed viper	<i>Ancistrodon hypnale</i>	Hills of Ceylon, Western Ghats of India, up to 3,000 to 6,000 ft.
Cantor's viper	<i>Trimeresurus cantoris</i> and other species	...	Andamans and Nicobar

ANIMALS CONFUSED WITH SNAKES

Snakes are creeping, limbless animals. Naturally other creatures having similar external characters are often mistaken for them. The lower jaws of snakes are not joined in the middle; the tongue is long, forked, protrusible and can be withdrawn into a sheath at the base inside the mouth. They have no mobile eyelids and external ears. Certain lizards which have practically no limbs can be easily mistaken for snakes. They have movable eyelids and external ear openings. Some of them also have protrusible forked tongue, but in addition possess well developed limbs. The 'blind worm' or 'slow worm' looks like a snake but it is only a limbless lizard. Certain burrowing amphibious creatures may occasionally be mistaken, but they have their vent opening at the end, whilst snakes have this opening between the tail and the rest of the body. Eels are often mistaken for sea snakes. Some of these are big and have scales, and may have no fins. Usually fish breathe by gills, but the snakes breathe by lungs. Earth-worms have the characters of being small and burrowing and have no scales on the body, which is ringed and segmented.

TYPES OF FISH RESPONSIBLE FOR IMPACTION IN AIR AND FOOD PASSAGES OF MAN

ANABAS AND COLISA. These are labryrinthid fishes which are provided with organs of aërial respiration and in consequence are very lively even out of water. They are provided with series of backwardly directed spines on the gill-covers and in front of the dorsal and anal fins. These fishes when impacted in the throat with the head directed inwards are very difficult to pull out.

NESTACEMBELUS. It is a compressed eel-like fish with a series of sharp, strong and backwardly directed spines in front of the dorsal and anal fins. There are also spines on the gill-covers.

THERAPON. It is percoid fish with a number of backwardly directed spines in the vertical fins and on the gill-covers.

CYNOGLOSSUS. The scales are ctenoid and the rays of the vertical fins extends right on to the head. The form is tongue-like and liable to slip down the throat.

The treatment in cases of this type is the same as of a foreign body lodged in the food and air passages. These cases are surgical emergencies and hardly any time is available to prepare for an operation on elaborate scale. The immediate treatment consists in doing a tracheotomy as a life-saving measure.

MINERAL NUTRIENTS

Their Functions in the Body, Deficiency Symptoms and Dietary Sources

CALCIUM (Ca).

Functions. Building of bones and teeth; Coagulation of blood; Ion balance; Heart, nerve and muscle functions; Enzyme activation; Essential for lactation.

Deficiency symptoms. Poor development of bones and teeth; Rickets; Brittle bones; Dental caries; Excessive bleeding; Tetany; Heart atony; Hyperirritability.

Dietary sources. Foods, see page 1637. *Chemical compounds*—calcium lactate, calcium gluconate, calcium glycono-phosphate, dicalcium phosphate.

CHLORINE (Cl).

Functions. Regulation of osmotic pressure in blood and tissues; Aid to digestion; Essential to normal gastric secretion; Activation of enzymes.

Deficiency symptoms. Digestive disturbances; Loss in body weight; Poor water retention; "Salt hunger"; "Miner's cramps"; Achlorhydria,

Dietary sources. Bread, cheese, oysters, ham, sauerkraut, banana, bran, buttermilk, cabbage, celery, cocoonut, dates, eggs, endive, fish, molasses, potato, spinach, tomato. *Chemical compounds*—sodium chloride (common salt).

***COPPER (Cu).**

Functions. Essential for the utilization of iron in synthesizing haemoglobin (it is doubtful whether this action of copper is of any therapeutic importance); Aids tissue respiration.

Deficiency symptoms. Aæmia; Restricted growth; Impaired respiration; Poor utilization of iron; Weakness.

Dietary sources. Foods, see page 1637. *Chemical compounds*—copper sulphate, copper pyrophosphate. (Copper is poisonous in larger amounts).

IODINE (I).

Functions. Thyroxine formation; Functioning and size of thyroid gland; Regulation of basal metabolism; Protection against goiter.

Deficiency symptoms. Enlarged thyroid gland (this may be followed by either too much or too little thyroxine secretion—basal metabolism becoming too high or too low). Subnormal basal metabolism; Lowered mental activity; Nervous disturbances; Over-weight.

Dietary sources. Codliver oil, fish, halibut, lobsters, oysters, shrimp, barley, beans (green), bran, butter, carrots, cherries, oats, spinach. *Chemical compounds*—sodium iodide, potassium iodide. "Iodized salt" (0.02 per cent. NaI). (The iodine content of vegetables and fruits varies greatly with the locality).

IRON (Fe).

Functions. Hæmoglobin formation; Oxygen transport; Tissue respiration; Development of blood cells; Normal complexion.

Deficiency symptoms. Anæmia; Low vitality; Decreased hæmoglobin and red blood cells, Pallid complexion; Retarded growth.

Dietary sources. Foods, see page 1637. *Chemical compounds*—ferrous sulphate, iron citrate.

MAGNESIUM (Mg).

Functions. Necessary for muscle activity; Ion balance; Laxative effect; Enzyme activation.

Deficiency symptoms. Nervousness; Digestive disturbances; Retarded growth; Vasodilation; Spasticity; Rapid heartbeat; Arrhythmia.

Dietary sources. Almonds, barley, beans, bran, brussels sprouts, chocolate, corns, peanuts, peas, prunes, raisins, rye, spinach, walnuts, banana, beans (green), beef, beets, blackberry, cabbage, carrots, cheese, cocoanut, currants, dates, figs, fish, milk, oatmeal, oysters, parsnips, potatoes, raspberry, rice. *Chemical compounds*—magnesium citrate, magnesium sulphate (Epsom salts), magnesium hydroxide (milk of magnesia).

MANGANESE (Mn).

Functions. Important for normal growth; Helps tissue respiration.

Deficiency symptoms. Subnormal growth; Poor tissue respiration.

Dietary sources. Banana, beans, beets, bran, chocolate, peas, leafy vegetables, whole grain. *Chemical compounds*—manganous chloride, manganous sulphate.

PHOSPHOROUS (P).

Functions. Building of bones and teeth; Activation of enzymes; Essential for metabolism of carbohydrates and fats; Buffer action in blood and muscles; Essential constituents of all cells.

Deficiency symptoms. Poor development of bones and teeth; Retarded growth; Perverted appetite; Loss in weight; Weakness; Rickets.

Dietary sources. Foods, see page 1637. *Chemical compounds*—glycero-phosphates, lecithin, dicalcium phosphate, disodium phosphate.

POTASSIUM (K).

Functions. Normal growth; Ion balance; Muscle function; Buffer action; Osmotic pressure in cells and fluids.

Deficiency symptoms. Nerve disorders; Irregular heart action; Poor muscular control; Loss in body weight; Poor digestion.

Dietary sources. Beans, bran, molasses, olives, parsnips, potatoes, raisins, spinach, apricots, asparagus, banana, beef, beets, cabbage, carrots, cauliflower celery, chocolate, cocoa, coconut, currants, dates, figs, grapes, lettuce, milk, mushrooms, nuts, peaches, peas, pineapple, plums, prunes, rhubarb tomatoes, turnips. *Chemical compounds*—sodium potassium tartrate, potassium sulphate, potassium chloride, potassium acid tartrate.

SODIUM (Na).

Functions. Regulation of osmotic pressure in cells and fluids; Ion balance in tissues; Buffer action in blood stream.

Deficiency symptoms. Nerve disorders; Irregular heart action; Poor muscular control; Loss in body weight; Poor digestion.

Dietary sources. Blood, bread, cheese, crackers, oysters, spinach, wheat germ, beef, beets, bran, carrots, celery, eggs, milk, musk-melon, olives, pumpkin, raisins, strawberry, turnip. *Chemical compounds*—sodium chloride, sodium bicarbonate, disodium phosphate, sodium potassium tartrate.

SULPHUR (S).

Functions. Required as cystine or cysteine or their combinations for the synthesis of body proteins (thiosulphate feeding and high protein diets often relieve eczema and dermatitis); When oxydized to sulphate, plays an important role in ion balance of tissues.

Deficiency symptoms. Dermatitis; Retarded growth (restricted growth and death result from a prolonged deficiency of cystine or cysteine-containing proteins in the diet. An adequate supply of good protein leads to the formation of inorganic sulphate in the body, as a result of tissue oxydation of cystine).

Dietary sources. Beans, bran, cheese, cocoa, eggs, fish, meat (lean), nuts, peas, bread, brussels sprouts, cabbage, cauliflower, macaroni, oats, onion, oysters, turnip, wheat. *Chemical compounds*—magnesium sulphate, sodium sulphate.

VITAMINS

Biological and Chemical Properties, and Distribution

Vitamin A (Antiophthalmic). See page 182.

Positive effects. Essential for normal vitality of epithelial cells;

Increases resistance to infections; Promotes growth; Increases life span; Aids in maintaining normal glandular functions.

Deficiency symptoms. *Mild.* Poor resistance to infections; Retarded growth; Lack of vigor; Poor appetite; Decreased Lactation; Dry skin; Diarrhoea; Night blindness. *Extreme.* Xerophthalmia; Infections through epithelia: eyes, tear ducts, tongue, alimentary tract, ear canal, sinuses, bladder, kidneys; Sterility; Weakness; Loss in weight; Atrophy of glands; Calculi in kidneys and bladder.

Chemical Properties. A sterol (alcohol of high molecular weight) $C_{26}H_{50}O$? Carotene ($C_{40}H_{56}$), the yellow colouring matter of most vegetables and fruits, is converted in the body to vitamin A (colourless); Heat stable; Moderately sensitive to Oxydation; Stable to acids and alkalis; Soluble in oils and fats; Almost insoluble in water, Gives an intense blue colour with $SbCl_5$.

Dietary sources. See 'Food Values', Page 1626.

Vitamin B Complex.

Vitamin B was originally regarded as a single substance. Recently, however, this vitamin has been divided into at least five factors, with the possibility of a sixth, and is called Vitamin B Complex. The table on page 1643 indicates the general view at the present time of the six factors in Vitamin B Complex. It is very doubtful whether or not all these vitamins are necessary for the human subject. From the general point of view the vitamin has been divided into two substances, B_1 and B_2 . In food-stuffs the different factors are often associated with each other.

Vitamin B_1 (Antineuritic). See page 192.

Positive effects. Essential for normal condition and functioning of nerve tissue; Stimulates appetite; Promotes growth; Aids digestion and assimilation; Related to lactic acid metabolism.

Deficiency symptoms. *Mild.* Weakness; Digestive disturbances; Poor appetite; Retarded growth; Slow heartbeat; Nervousness; Decreased peristalsis; Poor assimilation and lactation. *Extreme.* Beriberi; Polyneuritis; Paralysis; Atrophy of glands; Loss in weight; Intestinal infections; Convulsions; Gastric atony; Head retraction; Atrophy of musculature.

Chemical properties. Low molecular-weight; Stable towards dry heat, but destroyed by autoclaving; Soluble in water; Insoluble in oils and fats; Basic nitrogen compound; Readily absorbed by charcoal and Fuller's earth.

Dietary sources. See 'Food Values', Page 1626.

Vitamin B_2 (G or PP) (Antipellagric). See page 194.

Positive effects. Improves growth; Promotes general health; Prolongs active life-span.

Deficiency symptoms. *Mild.* Digestive disturbances; Impaired growth; Lack of vigor; Shortened life-span; Poor lactation. *Extreme.* Pellagra (other factors besides vitamin B_2 may be involved in pellagra);

Vitamin B Complex

The following Table indicates the general view at the present time of the six factors in Vitamin B also known as Vitamin B complex

Factor	Remarks on Designation	Observations from Animal experiments	Characteristic Properties
B ₁	The "Antineuritic vitamin" (Eijkmann) 1897. Torulin (Peters) Anti-beri-beri vitamin. B.P. factor (Goldberger). Vitamin F (Sherman).	Required by rat for growth. Deficiency causes condition known as "poly-neuritis" or experimental "beri-beri" in rats, dogs and pigeons.	Unstable to alkali. Relatively stable to acid.
B ₂	The Antidermatitis factor or Antipellagra vitamin (Goldberger) 1926. P.P. factor (Goldberger). Vitamin G (Sherman). Possibly the vitamin D of Funk and Lecoq.	Required by rat for growth. A deficiency produces in rats and dogs abnormal condition of the skin and tissues resembling to some extent pellagra. Apparently not necessary for pigeons.	Stable to acids Moderately stable to alkalis Thermostable in neutral solution.
B ₃	A factor described as the "third pigeon factor" by Williams and Waterman 1927. Not identical with the B ₃ of Reader now designated B ₄ .	Not required for growing rats but necessary for pigeons.	Thermolabile.
B ₄	First described by Reader and formerly designated B ₃ by her. Probably identical with the "vitamine d'utilisation nutritif" of Lecoq.	Required by rat and also, probably by pigeons.	Unstable to alkalis.
B ₅	Described by Carter, Kinnersley and Peters.	Probably required for the growth of rats.	Thermostable.
B ₆ (or Y)?	Chick and Copping	Rats	Stable to heat and alkali.

Dermatitis; Weakness; Break-down of central nervous system; Cataract; Loss of hair; Ulceration of tongue; Loss in body weight of intestines; Atony.

Chemical properties. Soluble in water; Stable to heat; Fairly stable to oxidation, acids, and alkalis; Thought to be identical with or similar to lactochrome.

Dietary sources. See 'Food Values', page 1626.

Vitamin C (Antiscorbutic). See page 196.

Positive effects. Essential for normal conditions of endothelial cells; Favours good teeth development; Improves appetite; Stimulates growth; Essential to tissue respiration.

Deficiency symptoms. *Mild.* Tender joints; Retarded growth; Defective teeth; Poor resistance to infections; Weakness; Restlessness; Digestive disturbances, Weakened blood capillaries; Poor lactation; Lesions in endothelial tissue; Headache. *Extreme.* Scurvy; Haemorrhages, Swollen joints and gums; Paralysis; Loose teeth; Beaded ribs; Fragile bones; Sterility; Respiratory and intestinal infections; Lesions in bone marrow and teeth; Hypertrophy of adrenals. Atrophy of musculature.

Chemical properties. Ascorbic acid ($C_6H_8O_6$); Very sensitive to alkalis and oxidation; Fairly stable in weak acid solutions; Generally destroyed by drying and by cooking exposed to air, and not by cooking in steam; Soluble in water; Insoluble in oils; Strong reducing agent; 2,6-Dichlorophenol indophenol serves as a good titrating agent.

Dietary sources. See 'Food Values', page 1626. Cooking in open vessel may readily destroy most of the vitamin C value of foods, except the acid juices.

Vitamin D (Antirachitic). See page 186.

Positive effects. Regulates metabolism of lime and phosphorous; Essential to growth of bone and development of teeth; Favours good body form, Controls blood calcium level.

Deficiency symptoms. *Mild.* Poor assimilation of lime and phosphorous; Poor deposition of lime and phosphorous in teeth and bones; Restlessness; Lack of vigor; "Bow legs"; Low blood-calcium and phosphate; Predisposition to dental caries. *Extreme.* Rickets; Softened bones; Enlarged joints; Curved spine; "Pigeon breast"; Beaded ribs; Retarded growth; Severe loss of lime and phosphorous; Lesions in bones and teeth.

Chemical properties. Formula $C_{27}H_{44}O$; Formed by irradiation of ergosterol (the vitamin is also formed in human and animal bodies when the skin is exposed to direct sunlight or ultraviolet radiation); Stable to heat, alkalis and acids; Fairly stable to oxydation; Soluble in oils and fats; Insoluble in water.

Dietary sources. See 'Food Values,' page 1626.

Vitamin E (Antistatility). See page 190.

Positive effects. This vitamin is so widespread and stable that a significant deficiency in human diets is unlikely.

BALANCED DIET

*For NON-VEGETARIANS substitute meat, fish, egg, etc., for milk. Condiments may also be omitted.
 Costs have been calculated at wholesale rates in Bombay for a family of five members.

WINES AND OTHER BEVERAGES

The energy value of spirituous liquors is not always confined to their alcoholic content. The carbohydrate contained in them may be either sugar or starch, the former is fruit sugar in natural wines, or cane sugar which is added to the liquors. Malt liquors contain the unfermented portion of the malt sugars, chiefly malto dextrins and dextrin. The spirits are carbohydrate-free, the dry wines contain only a negligible quantity, while the sweet wines have an appreciable amount, and so too have the port and sherry group. Liqueurs are exceedingly rich in cane sugar, while malt liquors owe their fat forming qualities as much to carbohydrate as to alcohol.

Composition of a Few Common Alcoholic Beverages

CHAMPAGNE. Alcohol (12 to 14 per cent.), sugar (6 to 24 gr. per oz.), energy value (22 calories per oz.).

PORT. Alcohol (20 to 23.2 per cent.), sugar (16 to 36 gr. per oz.), energy value (35 calories per oz.).

BURGUNDY. Alcohol (9 to 13 per cent.), sugar (nil, or just a trace), energy value (18 calories per oz.).

SHERRY. Alcohol (15.4 to 24.7 per cent.), sugar (0 to 18 gr. per oz.), energy value (31 calories per oz.).

BRANDY. Alcohol (40 per cent.), energy value (64 calories per oz.). The energy value of other spirituous liquors such as Whisky, Gin and rum, is the same as that of brandy.

MALT LIQUORS (Beer and stout). Alcohol (4 to 6 per cent.).

Beers—12 calories per oz.

Stout—13.5 calories per oz.

Composition of Other Beverages

TEA (0.5 oz. to 1 pint water). Carbohydrate 0.6 per cent.

COFFEE (1 oz. to 1 pint water). Carbohydrate 0.7 per cent.

COCOA (0.5 oz. to 1 pint water). Carbohydrate 1.1 per cent.

COCOA (0.5 oz. to 1 pint milk). Carbohydrate 6.0 per cent.

COCOA (sweetened, not as prepared for drinking). Protein 18.3 per cent.; fat 26.7 per cent.; carbohydrate 37.5 per cent.; calories 464.

CARBONATED DRINKS (bottle soda, sarsaparilla, brich beer, root beer, * gingerale). Carbohydrate 8.0 per cent.

CHOCOLATE (not as prepared for drinking). Protein 12.4 per cent.; fat 52.2 per cent., carbohydrate 24.8 per cent.; calories 619.

Principal Food Grains of India

CEREALS

The grain of the grasses is a complete fruit; in a few familiar cases (barley) it commonly retains, as an additional and firmly attached covering, a pair of paleæ. In all cases where these floral envelopes adhere to the winnowed grain they must be removed by some mechanical operation before the cereal can be used as human food; the harshness of these envelopes as well as the indigestibility of the large amount of fibre which they contain necessitate this treatment.

A considerable and often excessive proportion of starch is a characteristic feature of the composition of these grains.

Avena sativa Linn. Oats; (Hind.—Wilāyī-jau, jāf). Cultivated in some parts of India. Almost perfectly adjusted food so far as chemical composition and ratio of nutrients are concerned. Contains nitrogenous substance 10.25, starch 50 to 60, and fat 5.27 per cent.; calories per ounce 115; little Vitamin A, moderately rich in B.

Eleusine coracana Gaertn. (Sans.—Rājika, rāgi; Hind. & Beng.—Marāū). Several cultivating varieties of which var. *stricta* Roxb. often surprisingly productive. Widely cultivated in Himalayan districts, the Punjab, N. W. F. P., Oudh, Bihar, Bengal, Madras, Mysore (where it forms food for four-fifths of population), and Bombay. Largely eaten by labouring and poorer classes; somewhat difficult of digestion, produces flatulence, astringent; in Darjeeling fermented liquor is prepared from grains. Husked *rāgi* contains albuminoids 7.3, starch 73.2, and oil 1.5 per cent.

Hordeum vulgare Linn. (Syn.—*Hordeum sativum* Pers.)—Barley; (Hind.—Jav, jao; Beng.—Jab). Six sided variety usually grown in India; by far the largest quantity grown in N. W. F. P. and the Punjab; to a much less degree in Ajmer, Merwara, Bombay, C. P., and Madras; generally sown in October and November, reaped in February and April. As prepared for food in India, generally considered rather difficult of digestion. Contains protein 10, starch 56 to 66, and fat 1.87 per cent.; calories per ounce 100; little Vitamin A but moderately rich in B.

Oryza sativa Linn. The Rice; (Sans.—Dhanya; Hind.—Chaul, chāwāl—cleaned rice; Beng.—Dhān; Tam.—Arisi). Staple food of great majority of Indians, especially in Madras, Bengal, Assam, Bihar, Orissa, Bombay, Kashmir, and Burma. Good number of varieties in cultivation. Several kinds of rice found in the market and named after some prominent character; thus there is *Patni*, from centre of export; *Peshdewari*, because handled by up-country merchants; *Bāsmati*, fine flavoured, etc. Some are coarse grained, short and plump like the Burma rice, or long, plump and coarse grained like *dest* or indigenous rice, e.g., *Aus*, *Nagri*, *Patni*. Others are finer grade rice with long and fine fruit like *dadkhani*, or long and medium such as *Peshdewari* and *Kamini bhog*, etc.; these are more digestible than coarse grained ones.

RICE PREPARED FOR MARKET IN VARIOUS WAYS:—

Husks are prepared for removal from paddy or *dhān* in three ways:

(1) *Atap* or sun-dried rice prepared by drying the paddy in the sun. Separation of the husk is facilitated by sprinkling cold water or soaking the paddy in the same prior to drying in the sun. This method does not destroy enzymes of the grain. Fine, middle, and coarse grades of rice prepared in this way are available under different vernacular names.

The coarse grade varieties are generally implicated with beri-beri and epidemic dropsy.

(ii) *Siddhā* or parboiled rice prepared by soaking paddy in large vessels and then boiling it over slow fire. This parboiled rice is dried on platforms before husking. Most enzymes are killed, and surface proteids in the grains coagulate during this operation. Rices prepared in this way are also available in the above mentioned grades of which the middle and the coarse grades are implicated with epidemic dropsy.

(iii) *Balam* rice consists of paddy husked after sprinkling hot water or steeping in the same. Heat to which the paddy is subjected is not sufficient to kill the enzymes or to coagulate proteids; takes less time in swelling the grain than in (i). This can be had only as the middle grade variety and is implicated with epidemic dropsy.

Removal of husks is carried out in 2 ways :—

(a) *Anchattā*, by hand : with wooden pestle and mortar, or it being beaten on a platform with wooden beam (*dhenki*). Hand pounding leaves a good deal of pericarp on the grains. (b) *Kalchattā* or machine removal carried out in mills. In the first place the husks are removed by passing the grain through milling stones, screens, and winnowing machines. The kernels are then decorticated, and the outer cuticle with much of the gluten layer of the grain and the embryo are removed; this constitutes the rice bran or meal. This rice is known as unpolished rice.

Finally the grains are polished. In this process a film of gluten and starch cells is removed, and the fine powder thus obtained is technically called rice polishings; the polished grains are then screened in various grades and sizes.

The terms *atap*, *siddhā*, etc., do not denote the different types of rice but the different modes of preparation that are followed before it is sent out to the market.

Thus parboiled rice kills living cells and enzymes; machine milling and polishing removes embryo and delicate starch cells and exposes raw surfaces to bacterial and fungal attack.

Old or seasoned rice is preferred to new; the common habit of throwing away water in which it has been boiled is not good, it involves loss of mineral matter in which rice is notoriously deficient; steam cooking is advocated. Rice eating people of the poor class suffer from dyspepsia, diarrhoea, dysentery, and anaemia through imperfectly cleaned rice; polished rice is considered to be a main cause of beri-beri, due to deficiency of Vitamin B. Composition varies in different forms; on the whole poor in proteins and fats; on average protein 7, starch 76, and fat 1.29 per cent.; calorific value 1630 (per lb.), of boiled rice 525.

Panicum colonum Linn. 'Shama' Millet; (Hind.—Sawānk; Beng.—Shama; Tel.—Wundu). Abundant throughout plains, ascending to 6,000 ft. in Himalayas; in parts of the Punjab also cultivated. Grain collected for food in many parts, especially Northern India, by the poor. Husked seeds contains nitrogenous substance 11.8, starch 74, and fat 3.12 per cent.

P. miliaceum Linn. The Indian Millet; (Hind.—Chenā; Beng.—Chínā; Tam.—Varagu). Largely grown in many parts of India, especially Purniah district. Contains protein 10.6, starch 60.2, and fat 3.89 per cent.

* *P. miliare* Lamk. The Little Millet; (Hind.—Kutkī; Beng.—Gondulā; Tam.—Shamai). Cultivated to some extent in many districts, grown in the Punjab up to Kheri Pass, Nepal, and Central India. Mostly consumed by poor classes. Contains albuminoids 9.1, starch 69.0, and oil 3.6 per cent.

Paspalum scrobiculatum Linn. The Koda Millet; (Hind.—Kodá, kodaká; Beng.—Kodoá, dhán; Tel.—Allu). Cultivated in many parts of India during rainy season. Used by large number of Indians especially in the districts of Mirzapur, Gorakhpur, Patna, Shahabad, Saran, Bhagalpur, Purniah, and Santal Parganas. Husked grains contain albuminoids 7.0, starch 77.2, and oil 2.1 per cent., not considered wholesome diet; unless special precautions are taken, it is liable to act as narcotic poison.

Pennisetum typhoideum Rich. The Bulrush Millet, Spiked Millet; (Hind.—Bájrá; Tam.—Cambu). Largely cultivated as rainy-season crop especially in N. W. F. P., Oudh, Bihar, Bombay and S. India. Used mostly by poor as principal food, supposed to be heating, for this reason consumed mostly in winter in Northern India and Bihar. Unhusked grains contain albuminoids 10.4, starch 71.5, oil 3.3, potash 0.4, and phosphoric acid 0.68 per cent.

Setaria italica Beauv. (Syn.—*Panicum italica* Linn.). The Italian Millet; (Hind.—Kangni; Tam.—Tennai). Generally cultivated although in comparatively small amount in plains and on hills upto 6,500 ft. Largely used in Patna, Saran, Bhagalpur, Dinajpur, and Purniah. Generally regarded nutritious and digestible, in some places considered rather heating. Composition as in *P. miliaceum* Linn.

Sorghum vulgare Pers. The Indian or Great Millet, Guinea Corn; (Sans.—Zárna; Hind. & Beng.—Juár; Tam.—Cholam). Extensively cultivated generally as hot weather, occasionally as cold weather crop. Common food for labouring classes, easily digestible, less wholesome than maize. Contains nitrogenous substance 9 to 10, starch 60 to 70, and fat 4 to 5 per cent.

Triticum vulgare Villars. (Syn.—*T. sativum* Lamk.). The Wheat, (Hind.—Gheén, kanak; Beng.—Gín; Tam.—Godumai). Under this name are grouped all the species and varieties of wheat, numbering 12, according to the classification by Howard and Howard in "*Wheat in India*". They are extensively cultivated in the whole of Northern India up to Gangetic Delta, in Southern India, the whole of tableland above the Ghats, and many other places up to 18,000 ft. in the Himalayas and Tibet. Used in three different forms *súji*, *maida*, and *atta*; staple article of food in provinces where rice is not used; best of all diets used by Indian races if taken as whole wheat flour *atta*. Chemical composition varies a good deal, on average contains nitrogenous substance 11 per cent. or more, starch 53 to 70, and fat 1.65 to 2.08 per cent.; calorific value of flour 1625 (per lb.); has little Vitamin A, moderately rich in B.

Zea Mays Linn. Maize, Indian Corn; (Sans.—Yavanala; Hind.—Bhuttá, makai; Tam.—Makká-sholam). Cultivated in many parts of India; sown in June and July, cut in September. In the Punjab, N. W. F. P., and throughout Benares, Patna, and Bhagalpur Divisions, assumes the position of staple article of food especially for the peasantry. Contains nitrogenous substance 9 to 10, starch 60 to 70, and fat 4 to 5 per cent.; calories 96 per ounce; yellow maize moderately rich in Vitamins A and B. Not considered as wholesome as wheat, thought to be rather heating.

BUCKWHEAT

Fagopyrum esculentum Moench. (Punj.—Kálá trumbá, pháprá; Nep.—Titaphápur). Cultivated in several parts of Northern India, especially in hills, ascending up to 11,500 ft. in Kumaon. Used by poor classes. Contains albumin 16.2, starch 63.6, and oil 3.4 per cent.

(Note.—About 6 species of Buckwheat are grown in India; composition of the fruits does not differ very widely from the millets).

PULSES

The seeds of leguminous plants, generally known as pulse, differ chemically from the cereal grains in several particulars. They contain a higher percentage of protein, rarely yield less than 2½, and often as much as 4 per cent. of mineral matter or ash, and sometimes contain rather more fat—a constituent which may rise to 17 per cent. in soya-beans or even 50 per cent. in pea-nuts—see below and under edible oils. The digestibility of the proteins in pulse, however, has been usually regarded as low as compared to the corresponding compound in cereals. Slow but thorough cooking of the seeds is essential. It is also desirable to wash most kinds of pulse in cold water. A brief soaking in water to which a little carbonate of soda has been added, especially in the case of lentils, has a useful effect; the alkaline liquor removes a part of the bitter principle present in the pulse, and is then thrown away.

Cajanus indicus Spreng. The Pigeon-pea; (Sans.—Adhakī tubarfā; Hind. & Beng.—Arhar; Tam.—Thovaray). Extensively grown throughout India upto 6,000 ft. in Himalayas; sown in June or July and reaped in December to March. One of the best, easily digestible, sometimes produces costiveness. Contains protein 21.70, carbohydrate 54.06, and fat 2.50 per cent.

Cicer arietinum Linn. The common Gram or Chick-pea; (Hind.—Chanā, chholā; Beng.—But; Tam.—Kadalai). Extensively cultivated as 'rabi' crop throughout India, especially Northern Provinces and the Nilgiris. Much eaten by the poor; considered antibilious. On an average contains protein 19.91, carbohydrate 54.22, and fat 4.34 per cent.

Dolichos biflorus Linn. Horse Gram or Kooltee; (Hind.—Kālthī; Beng.—Kurti-kalai; Tam.—Kollu). Wild in Himalayas to Ceylon and Burma, ascending, up to 3,000 ft. in Sikkim; sometimes cultivated. Eaten by the poor, continued use said to cause cedematous swellings in some districts. Contains albumin 22.5, starch 56, and fat 1.9 per cent.

D. Lablab Linn. The Lablab-bean; (Hind.—Śim, lobiā; Beng.—Shim; Tam.—Mutcheh). Wild and cultivated throughout India upto 7,000 ft. in Himalayas. Ripe seeds and green pods both used as vegetable. Composition varies, on an average contains albumin 17.1, starch 57.4, and oil 0.8 to 2.3 per cent.

Glycine Soja Sieb. & Zucc. (Syn.—*Soja hispida* Moench). The Soya bean; (Hind.—Bhat; Beng.—Gari-kulay). Extensively cultivated throughout India and in Eastern Bengal, Khasia Hills, Manipur, the Naga Hills, and Burma generally as 'kharif' crop; often found as weed on fields. Very few vegetable products are so rich as this bean in proteins and in fat or oil; proteins of fairly good quality. Contains nitrogenous substance 35, carbohydrate 26 (in dry substance), and fat 17 per cent.

Lathyrus sativus Linn. The Jarosse or Gesse, The Vetchling; (Hind.—Khesārī; Beng.—Teorā; N. W. F. P.—Churāl). Cultivated all over India, from the Northern indigenous area to Southern, Eastern, and Western Presidencies as cold weather crop. Eaten by the poor; reason to suspect occasional presence, in injurious proportion, of poisonous bitter principle; almost universally regarded in Bengal as unwholesome and deranging digestion. Contains nitrogenous substance 24.9, starch 30, and fat 2.2 per cent.

Lens esculenta Moench. The Lentil; (Hind.—Masūr; Tam.—Misarpurpur). Grows on almost any soil; cultivated in all parts of India especially N. W. Provinces, C. P., and Madras as cold weather crop. Highly nutritious; found useful in treatment of chronic constipation. Contains protein 25.47, carbohydrate 55.03, and fat 8 per cent.

Phaseolus aconitifolius Jacq. The Aconite-leaved Kidney Bean; (Hind.—Moth; Beng.—Banmudgā kheri; Tam.—Tulka-pyre). Found

throughout India upto 4,000 ft. in North-West. Cultivated specially in U. P., Bihar, Purniah District, and Assam generally as 'kharif' crop. Contains albumin 23.8, starch 56.6, and fat 0.6 per cent.

Phaseolus lunatus Linn. The Lima or Duffin Bean; (Hind.—Kursum-bulle-pullie; Beng.—Bunbur-butti; Punj.—Lobiyá). Resembles French bean and frequently referred as such. Cultivated almost everywhere. Seeds much esteemed as 'dal'. Contains nitrogenous substance 17.3 to 18.9, starch 58 to 63, and fat 0.5 to 1.3 per cent.

P. Mungo Linn. The Green Gram; (Hind.—Múṅg). Universally cultivated upto 6,000 ft., also wild. Highly esteemed, resorted to in sickness. Contains protein 23.62, carbohydrate 53.45, and fat 2.69 per cent.

P. radiatus Linn. (Hind.—Urad; Beng.—Mash-kalai; Punj.—Másh, máli; Tam.—Patchay-pyre). Most esteemed of all pulses. Contains protein 22.33, carbohydrate 55.22, and fat 1.95 per cent.

P. trilobus Ait. The Three-lobed Kidney Bean; (Hind & Beng.—Mugáni; Tam.—Pani-pyre). Distributed throughout India, wild and cultivated from 7,000 ft. in Himalayas to Ceylon and Burma. Highly nutritious, much esteemed by certain classes, eaten by the poor only.

P. vulgaris Linn. The Kidney, French, or Haricot Bean (Hind.—Bakla; Punj.—Bábrí; Tel.—Bari galá). Universally cultivated in tropical, sub-tropical, and temperate regions, nowhere known in wild state. Unripe pods used as green vegetable, ripe pods often unwholesome but highly nutritious. Contains nitrogenous substance 16 to 25, starch 53 to 63, and fat 1.75 per cent.

Pisum sativum Linn. The Garden Pea; (Hind.—Matar; Beng.—Burra mattar; Tam.—Pattanie). A familiar garden herb; cultivated all over India as 'rabi' crop. Green pods largely eaten before general crop is cut. Contains nitrogenous substance 23.35, starch upto 50, and fat 1.88 per cent.

Vigna Catjang Endl. The Chowbe of India, Tow Cok of China, Catjang Beans; (Hind.—Lobiá; Beng.—Barbati; Punj.—Rawán; Tam.—Caramunny-pyre). Commonly cultivated as 'kharif' crop; white seeded form generally considered best. Thought to be rather heating and less digestible than 'urad' or 'múṅg'. Contains albumin 24, starch 57, and fat 1.3 to 3 per cent.

Principal Edible Oils of India

VEGETABLE OILS

Aleurites triloba Forst. (Syn.—*A. moluccana* Willd.). The Belgaum or Indian Walnut, the Candle-Nut; (Sans.—Akshota; Hind.—Akhrot; Tam.—Náttu-akrotu-kottai). Cultivated or wild in many parts of S. India, N. W. F. P., and the Punjab, etc. Nuts yield 50 per cent. amber coloured, very fluid, odourless Nut oil or Artist's oil called 'kekuna' in S. India.

Amacardium occidentale Linn. The Cashew-nut; (Hind. & Bomb.—Kájá; Beng.—Hijli bádám; Tam.—Mundiri). Found in coast forests of India, Chittagong, Tenasserim, Andaman Islands, and S. India. Kernels yield about 40 per cent. light yellow, bland oil, very nutritious as food; finest quality equal to almond oil, considered superior to olive oil.

Amchis hypogaea Linn. The Ground Nut, Earth Nut, or Pea Nut; (Sans.—Buchanaka; Hind.—Múṅghali; Beng.—Chiner-bádám; Bomb.—Bhái-chane; Tam.—Nilak-kadalai). Generally cultivated throughout India, chiefly S. India and Bombay, certain parts of Bengal, more rarely Upper India; grows best on dry, sandy soil. Seeds yield 37 to 50 per cent. clear, straw coloured oil, resembling olive oil in taste; contains

252 calories per ounce, very little Vitamins A and D. Substitute for olive oil.

Bassia butyracea Roxb. The Indian Butter Tree ; (Hind.—Phalwára; Nep.—Chárf). Sub-Himalayan tree from Kumaon to Bhutan between 1,000 to 5,000 ft. Seeds yield a concrete, of hog's lard consistency, inodorous, delicate white coloured oil called 'phulwa' containing 34 parts fluid oil and 6 parts vegetable matter. 'Ghee' adulterant.

B. latifolia Roxb. The Butter or Mahuá Tree ; (Sans.—Madhuka ; Hind. & Beng.—Mahuá, mahwá ; Tam.—Káttu-irrupai). Extending from Kangra, Kumaon, and Oudh, through the Central Provinces and Chota Nagpur to the Western Ghats ; plentiful in Gujrat, C. P., and Bombay Presidency. Kernels yield thick, concrete, greenish yellow oil eaten by Gonds and other Central India tribes. Very inexpensive substitute and adulterant for 'ghee'.

B. longifolia Linn. The Mowa or Mahuá Tree of S. India ; (Sans.—Madhúka ; Hind.—Mohuá ; Beng.—Mohuvá ; Bomb.—Mahwá ; Tam.—Illupi). Large evergreen tree of S. India and Ceylon ; common in Kanara, Mysore, Malabar, the Anamallays and the Circars. Seeds yield yellow, semi-solid oil which becomes rapidly rancid in plains. 'Ghee' adulterant.

Brassica campestris Linn. To this species belong the turnip, the rape, coleseed, colza, and other forms known in Europe. The Indian forms are :—

Var. 1. **dichotoma**, sp. Roxb. (Bazar name.—Káli sarsón). Small, dark or light brown, smooth or minutely rugose seeds yield colza oil.

Var. 2. **glauca**, sp. Roxb. Rape-seed ; (Bazar name.—Rará-sarsón). About 30 per cent. oil is obtained from this white or light yellow, occasionally deep coloured, smooth seeded variety. Largely used in diet, pickles, preserves, curries, and for other culinary purposes.

Var. 3. **Toria** Duthie & Fuller. Resembles somewhat the summer rape of Germany, the *navette d'été* of France ; (Hind.—Tóriyá). Abundantly grown in districts bordering on the Himalayan Terai.

B. juncea H. f. & T. The Rái or Indian Mustard ; (Hind.—Rái ; Beng.—Rái sarishá). Abundantly cultivated. Seeds yield 20 to 25 per cent. oil ; much purer than that from *B. campestris*, without peculiar rancid smell of rape, clearer in colour.

B. nigra Koch. The Black or True Mustard ; (Hind.—Rái, kálí rái ; Beng.—Rái sarishá ; Tam.—Kadagho). Cultivated in various parts of India and Tibet, chiefly on hills. Seeds yield about 23 per cent. of bland, inodorous oil. Substitute for lard or 'ghee' ; extensively used in cooking.

Buchanania latifolia Roxb. (Sans., Hind., & Beng.—Piyál ; Tam.—Mowda). Found in hot, drier parts of India, from Kumaon ascending to 1,500 ft., and Oudh, through Central India and to Western Peninsula, Burma and Tenasserim. Kernels yield 50 per cent. pale, straw-coloured, limpid, sweet and wholesome oil called 'chironji.' Substitute for almond oil in medicinal preparations and confectionary.

Carthamus tinctorius Linn. The Safflower, Wild or Bastard Saffron ; (Hind. & Beng.—Kusum ; Sans. & Tam.—Kushumbha). Cultivated as dye-plant all over India. Both kinds of fruits—one the cultivated, white and glossy, the other 'karar' smaller, similar shaped, mottled or dusted, brown grey, and white—yield very clear, yellow oil ; 40 seeds of fruit yielding $3\frac{1}{2}$ seeds of oil. Used for culinary purposes.

Cocos nucifera Linn. The Cocoa-nut Palm ; (Sans.—Nárikela ; Hind.—Náriyal ; Tam.—Tenna). Cultivated in hot damp regions of India, Burma, and Ceylon, especially near sea ; with several cultivated

varieties. Sliced kernel, dried at ordinary temperature yields 80 to 50 per cent. pale yellow, nearly as fluid and limpid as water in tropical climate, of the consistency of lard in temperate climate and of fine white colour, sweet oil liable to become rancid in short time; contains 252 calories per ounce, little Vitamin A and very little D.

Cucumis Melo Linn. The Sweet Melon ; (Sans.—Kharvujá ; Hind. & Bomb.—Kharbújá ; Tam.—Vellari-verai). Extensively cultivated for its fruit in sandy basins of rivers. Seeds yield sweet edible oil. Fruit chiefly eaten as such and not allowed to ripen, hence supply of melon oil not extensive.

Eruca sativa Lamk. (Sans.—Siddartha ; Hind.—Táramítrá ; Beng.—Shwet-sarsha). Closely allied to mustards; extensively cultivated as cold weather crop in Northern and Central India, ascending upto 10,000 ft. in Western Himalayas. Oil from seeds used to certain extent as food, sometimes employed in preparation of sweet-meats.

Garcinia Morella Desr. The Gamboge Tree ; (Sans., Hind., & Beng.—Tamal ; Tam.—oil=Makki). Found in forests of Eastern Bengal, the Khasia Mountains, the Western Peninsula (Malabar and Kanara), and Ceylon. Semi-solid, yellow fat procurable in moderate quantities from seeds. Used as substitute for 'ghee' by the poor.

Gossypium herbaceum Linn. The Cotton Plant ; (Sans.—Karpas ; Hind., Beng., & Bomb.—Kapás=the floss ; Tam.—Parutti). Under this name are grouped series of forms for convenience sake, cultivated. Seeds yield faint yellow cotton-seed oil, liquid at ordinary temperature, with distinctly higher refractive index than that of lard. Substitute for linseed oil which it resembles in taste and odour, contains 252 calories per ounce, very little Vitamin A. Suitable for culinary purposes when purified.

Guizotia abyssinica Cass. Niger Oil ; (Hind.—Kálá-tíl ; Beng.—Rámtil ; Tel.—Valesulá). Extensively cultivated in various parts of India. Shining black achenes yield 35 per cent. clear, limpid, pale, sweet oil; largely employed for culinary; chief substitute for 'ghee' among poor; extensively used to adulterate gingelly and castor oil.

Helianthus annuus Linn. The Sunflower ; (Sans. & Beng.—Suria-mukhi ; Hind.—Súrajmukhi ; Tel.—Aditya bhakti-chettu). Largely cultivated in China and Tartary, also in Russia, Germany, Italy, and France; to a small extent in India, chiefly in gardens. Oil from seeds, when pure, said to be equal to olive or almond oil for culinary and table purposes and used for adulterating these.

Impatiens Balsamina Linn. The Garden Balsam ; (Hind.—Gul-mendi ; Punj.—Bantil ; Beng.—Dupati ; Bomb.—Terada). Plentiful in the North-West Himalayas about 3,000 ft.; cultivated in gardens. Seeds yield edible oil.

I. racemosa DC. Common in Temperate Himalayas; from Simla, 5,000 to 7,000 ft., to Sikkim, 6,000 to 12,000 ft. Seeds yield edible oil.

I. Roylei Walp. Common in Temperate Western Himalayas from Nepal to Marri, 6,000 to 8,000 ft. Oil from seed edible.

I. sulcata Wall. Frequent in Temperate Himalayas, 7,000 to 12,000 ft. Seeds yield edible oil.

Juglans regia Linn. The Walnut Tree ; (Sans.—Akshota ; Hind. & Beng.—Akhrot ; Kash.—Dún ; Tam.—Akrottu). Found wild and cultivated in Temperate Himalayas and Western Tibet, from Kashmir and Nubra eastwards from 3,000 to 10,000 ft., also in Manipur and Ava Hills. Albuminous kernels afford about 50 per cent. clear, sweet oil; first oil which escapes on expression termed 'virgin' and reserved for feeding purposes; almost colourless, with feeble odour, not disagreeable flavour; Sp. Gr. 0.928 at 15°C, thickens to butter-like consistence at 15°C, solidi-

fies to white mass at 27½°C. Largely used as substitute for olive oil in some European countries, but not considered as first class alimentary oil.

Linum strictum Linn. (Punj.—Basant, babsant). Found on the Punjab hills extending to Peshawar and Marri and in Tibet; grown in Afghanistan on account of oil-yielding seed. Oil very probably does not differ essentially from ordinary linseed oil.

L. usitatissimum Linn. Linseed; (Sans.—Atasi; Hind.—Alsī; Beng.—Tīsi; Bomb.—Alāsi; Tam.—Al-*hi-virai*). Cultivated chiefly for oil throughout plains of India upto 6,000 ft. Seeds nearly always adulterated, especially with rape; yield of oil varies, weight for weight, white seed is said to give more oil and has thinner cuticle than red; 30 to 35 per cent. of oil obtainable from seed; contains 252 calories per ounce, very little Vitamin A. Linseed oil is very little used in India as food; in country about Nagpur used as an article of diet and the purgative properties not perceptible.

Olea europæa Linn. The Olive. Attempts made to cultivate in various parts of India but with little success except in Kashmir near Garhi. Tree flowers but fruits seldom set. Oil much consumed as article of food by Europeans; contains 250 calories per ounce, very little Vitamin A.

Papaver somniferum Linn. The Opium or White Poppy; (Sans.—*Ahiphena*; Hind., Beng., & Bomb.—*Afīm*; Tam.—*Posta-Katol*). Cultivated throughout the country especially in Native States. Permission to cultivate in India governed by regulation regarding opium. Poppy seed-oil yield dependant on freshness of the seed; 85 per cent. obtainable; readily bleaches on exposure to the sun and becomes transparent and almost tasteless, has no intoxicating properties;

Perilla ocimoides Linn. (Hind.—*Bhanjirā*; Naga.—*Kenia*; Kumaon.—*Bhangarā*). Common in Tropical and Temperate Himalayas; from Kashmir to Bhutan at 1,000 to 10,000 ft., also Khasia mountains 3,000 to 6,000 ft., often cultivated on Himalayas 4,000 to 5,000 ft. for small aromatic seeds. Aromatic oil used by hill-men of North-West Himalayas and Manipur for culinary purposes

Pistacia Terebinthus Linn., var. *mutica* Aitch. et Hemsley. The Terebinth Tree; (Hind. & Bomb.—*Kābuli mustakī*; Punj.—*Khinjak*; Baluch.—*Ban, wan, gwan*). Commonly grown in Baluchistan. Kernels yield mixture of essential and fatty oil which is eaten as a relish with 'karut' (dried oxygal) and bread.

P. vera Linn. The Pistachio Nut; (Hind., Beng., & Bomb.—*Pistā*). Forming forests at 3,000 ft. upwards, usually on sand stone formations in Syria, Damascus, Mesopotamia, Terek, Orfa, and Khorasan; extensively cultivated in Syria, Palestine, and Persia; a few trees cultivated here and there in the North-West India. Nuts contain 60 per cent. fatty, greenish, sweet-flavoured aromatic oil; occasionally used as food, but rapidly becomes rancid.

Prinsepia utilis Royle. (Hind.—*Bhekal*; Punj.—*Gurindā, rārf*). On dry rocky hills of Temperate Himalayas, from Hazara to Sikkim and Bhutan, 3,000 to 9,000 ft., also on Khasia Hills. Seeds yield an oil much used in North-West Himalayas for food.

Prunus Armeniaca Linn. The Apricot, Mishmus, or "Moon of the *thful*"; (Hind.—*Khubāni, zardālū*; Punj.—*Hārī*). Commonly cultivated between Indus and Sarda, in North-West Himalayas, the Punjab plains, and in Afghanistan; fruit ripens well up to 10,000 ft., but best between 6,000 and 9,000 ft.; very frequently spontaneous. Seeds yield clear oil, of pale yellow colour, contains hydrocyanic acid, has pleasant flavour with odour of bitter almonds. Extensively used in North-West Himalayas, especially Kashmir, for cooking.

Prunus Persica Benth. & Hook. *f.* The Peach and Nectarine; (Hind. & Panj.—Ará). Widely spread all over North-West Himalayas and occurs near almost every village upto 10,000 ft., S. India, Ceylon, and Burma. Oil from kernels resembles that of bitter almonds; substitute for the same. Used in the North-West Himalayas and Kashmir for cookery.

Sesamum indicum DC. Gingelly or Sesame oil; (Sans.—Tila; Hind., Beng., & Bomb.—Til; Tam.—Yellu-cheddie). Commonly grown as autumn or even winter crop throughout warmer parts of India and as summer one in colder almost exclusively for oil-yielding seeds. Black seed form 'Kálá til' more common and yields superior oil than white form 'Safed til'. Gingelly oil clear limpid, colour varies pale yellow to dark amber, odourless, not liable to become rancid; frequently adulterated with ground-nut oil, resembles olive oil in many properties, contains 252 calories per ounce, very little Vitamin A. Used for human consumption, sweet-meat making and for adulterating the oil of almonds and 'ghee.'

Theobroma Cacao Linn Cultivated in Southern Presidency and Ceylon. Light yellowish, opaque, solid oil called 'Cacao butter' obtained by pressing warmed seeds; these when shelled yield 45 to 50 per cent. oil. Cacao butter dry at ordinary temperatures, unctuous to touch, but brittle enough to break into fragments when struck exhibiting dull waxy fracture, has pleasant odour of chocolate, melts in mouth with bland, agreeable taste; Sp. Gr. 0.961, fuses between 20° to 30°C, does not become rancid from exposure.

Viburnum coriaceum Blume. (Nep.—Bará gorakuri; Kumaon.—Kálá timaliyá). Common on Himalayas from the Punjab to Bhutan at 4,000 to 8,000 ft., also found in Khasia Hills, the Nilgiris, and Ceylon. Nepalese use the oil from seed.

ANIMAL FATS AND OILS

Beef marrow. Large hollow bones of ox contain fat (marrow) which is identical with tallow, with characteristic taste due to cellular tissue which accompanies it; reddish, hard, tallowy, exhibits granular structure when set after melting, consists of 70 per cent. palmitin and stearin, 30 per cent. olein, becomes rancid sooner than tallow, melting point 45°C. Used for alimental purposes, as an addition to soups.

Beef tallow. Prepared from fat of ruminating animals (oxen, cows, steers, and calves) by melting crude tallow and pressing residual cellular tissue, particles of flesh, etc. It is hard and solid, pale yellow or white, tasteless, inodorous in fresh state, assuming after short time rather unpleasant characteristic smell without becoming rancid. Consists almost entirely of palmitin, stearin, and olein, proportions of which vary according to the parts of animal whence tallow is derived; softest and richest in olein from scrotum, hardest and richest in stearin from intestines; iodine number (thermal) 40°C., contains 0.34 gm. of protein per oz. Used as food-stuff for cooking and frying, in a special form as substitute for butter.

Butter. Prepared mostly from cow's and buffalo's milk by continuous and strong agitation; buffalo's milk richer in fat; composition varies considerably, 85 per cent. fat to 86 per cent. water. Because of water and casein butter turns quickly rancid, which is avoided by kneading it with 8 to 4 per cent. of common salt after thorough washing, better by keeping it in melted condition until thoroughly clarified and then separating it from precipitated water and casein. Apart from traces of colouring matter, lecithin, cholesterol, etc., pure butter consists solely

of tri-glycerides of fatty acids; colour varies from very pale to fine deep yellow. Melting point of cow's butter 31° to 31.5°C. , iodine number generally 26.0 to 35.1, rich in Vitamin A, contains little of D, calories per lb. about 3,500. Generally, however, in India it is carefully remelted by itself on fire when a froth, mainly consisting of unremoved casein, collects on the surface of the liquid which is removed and used as 'Ghec'.

Butter (artificial), oleomargarine, etc. Prepared from constituents of beef tallow by special processes and worked up with milk and vegetable oils. Greatly resembles, even identical with natural butter in appearance, consistency and flavour.

Goose fat. From accumulations of fat interspersed among tissues and under the skin of goose by carefully melting cut-up fat and straining to separate the product from cellular tissue. White to pale yellow, translucent, granular, frequently almost liquid at 10° to 12°C. , of agreeable flavour, does not easily turn rancid, melting point 25° to 26°C. , iodine number 71.5.

Hare fat. White, occasionally somewhat yellowish, with characteristic smell and mild agreeable taste, consistency rather softer than that of lard; melting point 44° to 46°C. ; solid, insoluble fatty acids 95.47 per cent.

Hog's lard. From fatty portions of hog, especially those lying beneath the skin and between intestines; that from the exterior fatty integument surrounding entire carcase immediately below the skin (especially on back and sides) is more solid and curdy, more easily melted out than from interior of the body. Fat more consistent during January and February than during warmer seasons and richer in stearin, summer fat contains more olein; best quantity and quality in consistency and appearance supplied by intestinal fat of young pigs. Hog's lard is white, granular, of salvy or pappy consistency; with agreeable, rather sweet, fatty taste; turns rancid quickly on exposure to air, consists of olein, palmitin, stearin, and 0.23 per cent. of unsaponified matter, iodine number 59.0, contains very little of Vitamin A. Prepared like tallow. Used for alimental purposes as edible fat and for cooking and frying.

Lard oil. Obtained by pressing hog's lard at 0°C. leaving behind tallow. Thinly fluid like olive oil, pale yellow.

Mutton tallow. Prepared from accumulation of fat in flesh and tissues of sheep like beef tallow. Similar to that of ox but less highly coloured, white, rather hard, brittle, initially inodorous, assumes characteristic smell and taste of mutton after brief exposure to air, becomes rancid very quickly when smells like goat's fat; Sp. Gr. 0.860 at 100°C. , consists of about 70 per cent. stearin and palmitin (margarine) and 30 per cent. of olein. Uses similar to those of beef tallow.

Principal Indian Oils and Fats used in Medicine

Albizia Lebbek Benth. The Siris Tree. In leprosy.

Aleurites triloba Forst. (Syn.—*A. moluccana* Willd.). The Belgaum or Indian Walnut. Mild purgative, dressing for ulcers, castor oil substitute.

Allium Cepa Linn. The Onion. Expectorant, diuretic, stimulant.

A. sativum Linn. The Garlic. Stimulant, rubefacient, used externally in paralytic and rheumatic affections.

Anomum subulatum Roxb. Aromatic stimulant.

Anacardium occidentale Linn. The Cashew-nut. Irritant, rubefacient, vesicant, externally used in leprosy.

Aqui'aria Agallocha Roxb. The Eagle-Wood. Internally in fevers, externally in colic.

Arachis hypogæa Linn. The Ground Nut. Substitute for olive or salad oil.

Argemone mexicana Linn. The Mexican or Prickly Poppy. In ulcers and eruptions.

Atalantia monopylla Coll. The Wild Lime. In chronic rheumatism.

Bassia butyracea Roxb. The Indian Butter Plant. In rheumatism and contraction of the limbs.

B. latifolia Roxb. The Butter or Mahua Tree. In cephalalgia and skin diseases.

B. longifolia Linn. The Mahua of S. India. Detergent, in skin diseases.

Beef tallow. For ointments.

Benincasa cerifera Savi. The White Gourd Melon. Anthelmintic.

Brassica campestris Linn. Embrocation, skin preservative.

Buchananla latifolia Roxb. Almond oil substitute.

Butter. Emollient, cooling, stomachic, and variety of purposes.

Cæsalpinia Bonducella Fleming. Fever-nut. Anthelmintic, useful in convulsions and palsy.

Calendula officinalis Linn. Marigold.

Calophyllum Inophyllum Linn. The Alexanderian Laurel. External use in rheumatism.

C. Wightianum Wall. In leprosy, cutaneous affections, scabies, rheumatism.

Carthamus tinctorius Linn. The Safflower. In rheumatic pains, paralytic affections, ulcers.

Cedrus Libani Barrel, var. *Deodara* Loud. The Deodar, Himalayan Cedar. In inflated skin, ulcers, eruptions, sore feet in cattle, leprosy, skin diseases.

Celastrus paniculatus Willd. The Black Oil. In rheumatic pain, fistulæ, sinuses, beri-beri; diaphoretic, diuretic, nervine tonic.

Cocos nucifera Linn. The Cocoa-nut Palm. In burns, baldness, that from shell in ringworm.

Croton oblongifolius Roxb. Purgative.

C. Tigllium Linn. The Purging Croton. Drastic purgative, powerful hydragogue, cathartic, counter irritant; in dropsy, apoplexy, paralysis.

Cuminum Cyminum Linn. The Cumin. Stimulant.

Cynometra ramiflora Linn. In leprosy and other cutaneous diseases.

Dalbergia lanceolaria Linn. In rheumatism.

D. Sissoo Roxb. The Sissoo. Wood yields empyreumatic medicinal oil.

Dipterocarpus a'atus Roxb. The Gurjun oil. In leprosy.

D. tuberculatus Roxb. The Eng Tree. In leprosy, ulcers.

D. turbinatus Gært. f. (Syn.—*D. laevis* Ham.). The Gurjun or Kanyin Oil. Externally and internally in leprosy, ringworm, gonorrhœa, mucous discharges.

Dugong oil. Oil of the Sea Hog, the Yungan or Mooda Hoor. Substitute for cod-liver oil.

Gossypium herbaceum Linn. The Cotton Plant. Liniment in rheumatic affections.

Guzotia abyssinica Cass. Niger Oil. See Sesamum Oil.

Gynocardia odorata R. Br. The Chaulmoogra. In rheumatism, phthisis, leprosy, psoriasis, skin diseases, etc.,

Helarrhena antidysenterica Wall. The Kyrchi.

Hydnocarpus venenata Gært. In Cutaneous diseases, leprosy, substitute for chaulmoogra oil.

- Hydnocarpus Wightiana** Bl. In ulcers; substitute for chaulmoogra.
- Jatropha Curcas** Linn. Purgative, also external application.
- Lard** (fat of the pig). In inflammation, bruises, sprains, eruptions, eczema, erysipelas, etc.
- Linum usitatissimum** Linn. The Linseed. Aperient, in the preparation of liniment for burns, external application.
- Mallotus philippinensis** Muell. The Monkey Face Tree. Cathartic.
- Melaleuca Leucadendron** Linn. The Cajput. Stimulant, diaphoretic.
- Mella Azadirachta** Linn. The Neem or Margosa Tree. Anthelmintic, antiseptic; externally to ulcers, in rheumatism, headache, skin diseases.
- Mesua ferrea** Linn. Externally for sores, embrocation in rheumatism.
- Moringa pterygosperma** Gærtn. The Horse Radish Tree. In gout and acute rheumatism.
- Myristica malabarica** Lamk. Stimulating application in indolent ulcers, detergent, anti-rheumatic.
- Nerium odorum** Soland. Sweet-scented Oleander. In cutaneous diseases and leprosy.
- Olea europæa** Linn. The Olive. Emollient, nutrient, mild laxative, demulcent.
- Papaver somniferum** Linn. The Opium or White Poppy. Demulcent, substitute for linseed oil.
- Petroleum**. Embrocation.
- Pistacia vera** Linn. The Pistachio Nut. Demulcent, restorative.
- Pongamia glabra** Vent. In skin diseases, rheumatism, leprosy.
- Prinsepia utilis** Royle. Rubefacient, in rheumatism and pain due to fatigue.
- Ricinus communis** Linn. The Castor Oil Plant. Mild demulcent, laxative.
- Sarcostigma Kleinii** W. & A. In rheumatism.
- Schleichera trijuga** Willd. The Lac Tree. To scalp for hair growth, original Macassar oil.
- Semecarpus Anacardium** Linn. f. The Marking Nut Tree. In rheumatism and leprosy.
- Sesamum indicum** DC. The Gingelly or Sesame Oil. Demulcent, in piles and dysentery.
- Strychnos Nux-vomica** Linn. The Nux-vomica or Strychnine Tree. External application in chronic rheumatism.
- Taraktogenos** Kurzii King. The Chaulmoogra. In leprosy and many skin diseases.
- Vernonia anthelmintica** Willd. The Purple Flea-Bane.
- Xanthium Strumarium** Linn. Bur-weed.

Principal Edible and Poisonous Fungi of India

Contrary to the general belief, the number of kinds of fungi that are really poisonous is comparatively few. There are several species of fungi eaten indiscriminately in India and, indeed, if properly cooked, few are dangerously poisonous. If macerated in vinegar before being cooked, and if eaten with plenty of bread, there is almost no danger. Cases of fungus poisoning, however, are not unheard of in India, but the subject is, at present, very imperfectly known and the literature hardly throws any light whatsoever. The safest proceeding, therefore, is to learn to recognise the good species, and never to eat a fungus until its identity is certain. Researches of Dupetit indicate that all edible mushrooms contain a poisonous principle, which is destroyed at a temperature of 100°C. and mushrooms rendered innocuous.

Although strict botanical determination cannot be too strongly emphasised, yet a few characters by which a wholesome mushroom may be recognised are :—(i) They are found growing in fields or in open grassy places in forests (ii) They are scattered, each rising direct from the ground (iii) The stem should break easily when touched, it should spring from the centre of the pileus The cap should be thick relatively to the gills. (iv) They should not be acid in flavour nor smell. (v) The bright rosy or pink gills and the absence of any yellow stain when bruised are two good tests. It does not, however, follow that fungi, not answering to the above, are all poisonous; indeed, *Hydnum repandum* and *Cantharellus cibarius* are both acid, yet are excellent articles of food.

The available nutrient material of edible fungi is very small, their chief value is as a flavouring agent or condiment giving palatability to the plainer but more nutritious foods, and adding welcome variety to meals

EDIBLE FUNGI

Besides the following, there are, no doubt, many other forms widely used as food in India but, owing to the meagreness of the literature on the subject, complete list cannot be given.

Agaricus campestris Linn. The Mushroom; (Sans.—Chattrak; Kash.—Mánskhel, Beng—Banger chhátá; Sant.—Ot; Bomb.—Alombe) Generally in damp *debris* throughout India during rainy season; universally eaten fresh or dried.

A. mitto Pers Kurrum

A. ostreatus Jacq. (Cutch & Bomb.—Phanasa-alambe, or vulgarly phansamba). Grows upon stumps of old jack-trees (phanas).

Cantharellus cibarius Fr Kashmir, Peshawar, Mussoorie.

Collybia albuminosa (Berk) Betch (Syn.—*Leptota albuminosa* Berk).—(Beng.—Durga-chhátá). Bengal, C. P., and Berar. Grows from inside the termites' nests; eaten with relish.

Coprinus comatus (Battara) Fr. The Mushroom; (Hind & Punj—Khumbi, khumb). Punjab, United Provinces, and several other parts of India. Eaten fresh or dried. Collected during rainy season.

Entoloma microcarpum Berk & Broome. (Beng.—Wee-chhátá). Bengal. Grows on the surface of outer crusto of termites' nests; commonly eaten by villagers.

Fistulina hepatica Fr. Darjeeling.

Helvella crispa Fr. Common in Afghanistan.

Hirneola polytricha Mont. (Syn.—*Exidea polytricha* Mont.). Belgaum, Poona, Dharwar, Nidungayam, Malabar, and Burma.

Hydnum caralloides Scop. Darjeeling 7,500 ft., Chitral, N. W. F. P. (common) and Afghanistan. In crevices of old tree-trunks; collected during August; dried in the sun and largely used.

H. repandum Linn. Mussoorie, United Provinces.

Lactarius deliciosus Fr. Sikkim.

Lentinus subnudus Berk. Common in Bengal, Kadala, and Bombay. On dead branches of logs. Eaten by Kholes fresh and young.

Leptota mastoidea Fr. Bengal.

L. procera (Scop.) Sacc. Saharanpur.

Lycoperdon sp. Puff-balls, Bengal, Kashmir and many parts of Western Himalayas.

Melanogaster durissimus Cooke. Truffle. Simla (abundant), Kangra. Occasionally eaten.

Morchella esculenta Pers. The Morell; (Punjab.—Guchhian—plains, *káná kach*—hills). Fleshly fungus abundant in Kashmir, Chamba and many parts of Northern Punjab.

Pleurotus cretaceus Massee. (Vern.—Dhingri). Peshawar and C. P. On wood.

P. fimbriatus Bolt. C. P. and Benar.

Polyporus squamosus (Huds) Fr. Darjeeling, 7,500 ft.; Pangi, N. W. Himalayas. On dead wood.

Truffles. Stewart describes some being found in Kashmir. Badwar has recently collected some blackish-brown ones from the Kagan valley, locally known as 'usri'. They are highly flavoured and their presence in the soil is discovered by the villagers by smell in September-October when they are said to develop the flavour best. Goats are also said to dig out some during grazing and eat. (Also see *Melanogaster durissimus* above).

Volvaria diplasia Berk & Broome. (Beng.—Pawal-chhátá). Bengal, Burma.

V. terrestria Berk & Broome. (Beng.—Poal-chhátá). Bengal. Grows on heaps of waste paddy straw.

(In addition Stewart mentions another species as being freely eaten in the Punjab, which is known as 'shirán' in the Jhelum and 'bat-bakri' in the Kair valley. It is a thin, flat, ragged-looking fungus, yellow above and with white gills below, which is found on dead trees in various parts of the Punjab Himalayas at 8,000 to 8,500 ft. He also mentions an 'underground mushroom' of doubtful species found near Multan, called 'boinphal').

POISONOUS FUNGI

Very little information is available on the Indian poisonous fungi. From time to time cases of fungus poisoning are reported but, it is to be regretted, no further attention has been paid. *Stropharia semiglobata* (Batsch) Quel. from Khasia Hills, *Hypholoma fasciculare* (Huds) Fr. from Darjeeling and Simla, and *Lactarius vellereus* Fr. from Sikkim, are regarded as poisonous. There is also evidence on record that there exists in Bengal a fungus which closely resembles an edible form but which contains *amanitine* or *muscarine*, the poisonous principle of *Amanita muscaria*, by eating which symptoms closely resembling those of intoxication rapidly ensue. Furthermore, *muscor* has been regarded as harmful in India since ages, and the pickles and all edible stuff attacked by it are not thought fit for eating. There are, however, some foreign fungi which are definitely reported to be poisonous. *Amanita phalloides*—the death cap—is responsible for perhaps 90 per cent. of the deaths caused by fungus poisoning in Europe, England, and U. S. A. It is the most dangerous fungus known and very small quantities will cause intense suffering and often death. There are, indeed, several other species of the genus that are very poisonous, e.g., *Amanita muscaria*—fly agaric—and *A. pantheriana*—warted agaric, etc. *Leptota cristata*—crested agaric—and several other small species of *Leptota* are regarded with suspicion and should be avoided. *Volvaria gloiocephala*—glutinous agaric—and its allies have always been regarded as poisonous, but there is recent evidence that they may be eaten without ill effects. *Psalliota xanthoderma*—yellow staining mushroom—has caused illness in some cases,

Parasites of Meat, Fish and Edible Crustacea
MEAT

	Name of parasite	Size	Producing in man	Whether condemned for food
Beef	(a) <i>Cysticercus bovis</i>	6 mm	<i>Taenia saginata</i>	Condemned
	(b) <i>Sarcocystis miescheriana</i>	30 mm × 5 mm (Egypt, Ceylon and India), 2 mm in Europe	Nothing	Not condemned
	(c) <i>Oncocerca gibsoni</i> , adults and larvae contained in nodules	Size of a marble	Nothing	Condemned for its bad appearance
Pork	(a) <i>Cysticercus cellulosæ</i>	6 mm	<i>Tænia solium</i>	Condemned
	(b) Larval <i>Trichinella spiralis</i>	About 600 µ	Adult <i>Trichinella spiralis</i> , giving rise to larval forms in the muscle	Condemned
	(c) <i>Sarcocystis miescheriana</i>	1 mm in Europe	Nothing	Not condemned
Mutton	<i>Sarcocystis miescheriana</i>	1 mm in Europe Cysts often found calcified	Nothing	Not condemned

FISH

	Name of parasite	Size	Producing in man	Whether condemned for food
Fresh-water fishes	Plerocercoids of <i>D. latus</i>	1.5 cm. \times 1 mm.	<i>D. latus</i>	Condemned
	Cercariae of <i>Clonorchis sinensis</i>	2 mm	<i>Clonorchis sinensis</i>	Condemned
Marine fishes	Cercariae of <i>Heterophyes heterophyes</i> ?		<i>H. heterophyes</i>	Condemned
	(a) Larval Ascarids	2 cm. \times 1 mm.	Nothing	Not condemned
	(b) Adult hair-like nematodes	2 to 3 cm.	Nothing	Not condemned
	(c) Larval cestodes	Globular, about 6 mm.	Nothing	Not condemned

EDIBLE CRUSTACEA

	Name of parasite	Size	Producing in man	Whether condemned for food
Crabs and crayfish	Cercariae of <i>Paragonimus westermani</i>	About 2 mm.	Adult <i>Paragonimus westermani</i>	Condemned

(Parasitology, Blacklock and Southwell)

MEAT, FISH AND EDIBLE CRUSTACEA AS A VEHICLE IN THE SPREAD OF DISEASES

Food poisoning	Through ingesting meat or fish. Infected with <i>Bact. enteritidis</i> , <i>Bact. arthricke</i> , <i>Bact. paratyphosum</i> B and Hirschfeld's bacillus, <i>Proteus vulgaris</i> , etc.
Botulism	Due to ingestion of fresh and tinned meats and fish infected with <i>Cl. Botulinum</i> .
Tuberculosis	Due to ingested meats infected with <i>Myco. tuberculosis</i> .
Anthrax	Due to ingestion of meat of an animal infected with <i>B. anthracis</i> .
Enteric group of fevers		...	Due to ingesting infected shell fish, oysters, etc.

FOOD OTHER THAN MEAT, FISH, AND EDIBLE CRUSTACEA AS A VEHICLE IN THE SPREAD OF DISEASES

Bacterial :

Food poisoning	Due to infected canned and tinned fruits and vegetables by <i>Bact. enteritidis</i> , etc. <i>Proteus vulgaris</i> . <i>Bact. paratyphosum</i> A, B and C. Detection of the organism is difficult.
Botulism	Due to canned and tinned fruits and vegetables and milk infected with <i>Clostridium botulinum</i> . The appearance of food may be normal. A most powerful exotoxin produced which is heat stable.
Actinomycosis	Due to chewing, infected grain, splinters of straw, etc.
Tuberculosis	Due to ingestion of unboiled or unpasturised milk, from animals, infected with <i>Myco. tuberculosis</i> var. <i>homonis</i> or <i>bovinis</i> . In India most of the cases are direct infections from a case of tuberculosis.

Undulant fever	Due to ingestion of unboiled or unpasturised milk, from goats infected with <i>Br. melitensis</i> and preparations such as butter or cheese prepared from milk. <i>Br. abortus</i> causes similar fever.
Septic throat	Due to ingestion of milk infected with Streptococci. The cow in this case is often a passive carrier of organisms of human origin.
Cholera	Due to ingesting <i>V. cholerae</i> in milk and vegetables infected through carriers or convalescents.
Enteric group of fevers		...	Due to ingesting <i>Bact. typhosum</i> , <i>Bact. paratyphosum</i> , A.B., Hirschfeld's bacillus in milk and vegetables infected through carriers or convalescents.
Diphtheria	Due to ingesting <i>C. diphtheriae</i> infected milk. Rare mode of transmission.
Scarlet fever	Due to ingesting <i>Strep. scarlatinae</i> in milk infected through carriers.
Dysentery	Due to ingesting milk and vegetables infected through carriers of <i>Bact. shigae</i> , <i>Bact. flexner</i> , <i>Bact. sonne</i> , etc.
Summer diarrhoea of infants		...	Do. of <i>Bact. morganii</i> .

Spirochætal:

Spirochætal jaundice	...	Spirochætes in rats' urine, (?) contaminating food.
----------------------	-----	---

Protozoal:

Amœbic dysentery	{	Infective cysts on food.
Balantidial dysentery		

Helminthic:**(a) DUE TO CESTODES:**

Cysticercosis due to larvæ of <i>Tania solium</i>	...	Eggs of <i>Tania solium</i> in food.
<i>Hymenolepis</i> infection	...	Eggs in food.
Hydatid; due to larva of <i>Tania granulosa</i>	...	Eggs of <i>Tania granulosa</i> in food.

(b) DUE TO TREMATODES:

<i>Fasciola</i>	{	infections	...	{	Infective encysted cercariæ on water vegetables.
<i>Fasciolopsis</i>					

(c) DUE TO NEMATODES :

<i>Ascaris</i>	} infections	{ Infective eggs on food, especially vegetables.
<i>Trichuris</i>		
<i>Strongyloides</i>	} infections ...	{ Infective (filariform) larvæ on food, especially vegetables.
<i>Ancylostoma</i>		
<i>Necator</i>		

WATER AS A VEHICLE IN THE SPREAD OF DISEASES

Bacterial :

Enteric group of fevers.	...	Due to drinking of water polluted by—
		1. <i>Bact. typhosum</i> .
		2. <i>Bact. paratyphosum</i> A, B, and C.
		<i>V. cholerae</i> .
Cholera	1. <i>Bact. shiga</i>
Dysentery	2. <i>Bact. flexneri</i> (and flexner group)
		3. <i>Bact. sonnei</i>
		4. <i>Bact. dispar</i> , etc.

Spirochætal :

Spirochætal jaundice	Spirochætes from rats' urine in water.
--------------------------	-----	--

Protozoal :

Amœbic dysentery {	}	Infective cysts in water.
Balantidial dysentery {		

Helminthic :

(a) DUE TO CESTODES :

- | | | |
|--|-----|---|
| (1) Cysticercosis due to larvæ of <i>Tænia solium</i> . | ... | Eggs of <i>Tænia solium</i> in water. |
| (2) <i>Hymenolepis</i> infection. | ... | Eggs in water. |
| (3) <i>Sparganosis</i> due to infection with plerocercoids of <i>Dibothriocephalus</i> sp. | ... | (?) Proceroid in <i>Cyclops</i> in water. |
| (4) Hydatid : larvæ of <i>Tænia granulosa</i> . | ... | Eggs of <i>Tænia granulosa</i> in water. |

(b) DUE TO TREMATODES :

- | | | |
|---|-----|--|
| (1) <i>Schistosoma</i> infection (all species). | ... | Infective cercariæ in water. |
| (2) <i>Fasciola</i> infection | } | Infective encysted cercariæ from gass, etc., in water. |
| (3) <i>Fasciolopsis</i> infection | | |

(c) DUE TO NEMATODES :

- | | | |
|---|-----|---|
| (1) <i>Ascaris</i> infection | } | Infective eggs in water. |
| (2) <i>Trichuris</i> infection | | |
| (3) <i>Strongyloides</i> infection | | |
| (4) <i>Ancylostoma</i> infection | } | Infective filariform larvæ in water. |
| (5) <i>Necator</i> infection | | |
| (6) <i>Dracunculus medinensis</i> infection | ... | Fully-grown infective larvæ in <i>Cyclops</i> in water. |

Posological Table

	IMPERIAL	METRIC
*Acetanilidum (Antifebrinum)	2 to 5 gr.	0·12 to 0·8 gm.
Acidum Acetylsalicylicum ...	5 to 15 gr.	0·8 to 1 gm.

PRESCRIPTIONS

(The following prescriptions are mainly based on the Pharmacopœa of the School of Tropical Medicine, Calcutta)

BATHS (Balnæ)

Alkaline bath (Balneum alkalinum). Sodium bicarbonate 1 oz., water (warm) 6 gal.

Bran bath (Balneum furfuris). Wheaten bran 2 oz., water (100° F.) 1 gal. Bran is tied in a muslin bag which is put into the bath.

Sulphur bath (Balneum sulphuris). Precipitated sulphur 2 oz., sodium thiosulphate 1 oz., dilute sulphuric acid $\frac{1}{2}$ oz., water up to 1 pint. Each pint to be added to a bath containing 30 gal. of water at 90° to 100° F.

CAPSULES (Capsulæ)

Chenopodium capsule (Capsulæ chenopodii). Oil of chenopodium 10 min. in each. Dose—3 capsules (one every hour).

Creosote capsule (Capsulæ creosoti). Creosote 1 to 5 min. in each.

Gentian violet capsule (Capsulæ methylrosanilini). Gentian violet 1 gr. in each.

Hexylresorcinol capsule (Capsulæ hexylresorcinolis). Hexylresorcinol 15 gr. in hard gelatin capsules (to be freshly filled up).

CAUSTICS (Caustica)

Silver nitrate caustic (Causticum argenti nitras). Silver nitrate 1 in 10 solution. Sticks may also be used

Trichloroacetic acid caustic (Causticum trichloroaceticum). Trichloroacetic acid 1 in 3 solution. It is applied lightly with a brush till the part painted appears to be uniformly whitish.

COLLODION (Collodium)

Collodion of chrysarobin (Collodium chrysarobinum). Chrysarobin $\frac{1}{2}$ dr., salicylic acid 20 gr., collodion 1 oz

CONFECTIONS (Confectionis)

Confection of senna (Confectio sennæ). Powdered senna 90 gr., jalap 30 gr., ginger 10 gr., coriander oil $\frac{1}{2}$ min., treacle (by weight) up to 1 oz. Dose—1 to 2 dr.

Confection of sulphur (Confectio sulphuris). Sublimed sulphur $\frac{1}{2}$ oz., potassium acid tartrate 1 dr., treacle (by weight) 1 oz. Dose—1 to 2 dr

The strengths of the solutions used in these prescriptions correspond to those in B. P. 1932.

CREAMS (Cremoris)

Calamine cream (Cremor calaminæ). Zinc oxide $\frac{1}{2}$ dr., prepared calamine $\frac{1}{2}$ dr., lime water 4 dr., almond oil up to 1 oz.

Magnesium sulphate cream (Cremor magnesiæ sulphatæ.) Magnesium sulphate 24 oz., phenol 1 dr., glycerine 12 oz. Heat Mag. Sulph. to 100°C., powder while hot. Add glycerine and phenol gradually.

DRAUGHTS AND MIXTURES**DRAUGHTS (Haustus)**

Anthelmintic draught (Haustus anthelminticus). Chenopodium oil 16 min., tetrachlorethylene 48 min., magnesium sulphate draught 2 oz. Mix and shake vigorously immediately before use.

Aperient draught (Haustus sennæ compositus). Magnesium sulphate $2\frac{1}{2}$ dr., spirit of chloroform 10 min., infusion of senna up to 1 oz.

Bromide draught (Haustus bromidi). Potassium bromide 10 gr., sodium bromide 10 gr., compound tincture of cardamom $\frac{1}{2}$ dr., peppermint water up to 1 oz.

Carbon tetrachloride draught (Haustus carboni tetrachloridi). Carbon tetrachloride 48 min., magnesium sulphate draught 2 oz. Mix and shake vigorously immediately before use.

Chloral and bromide draught (Haustus chloral et bromidi). Chloral hydrate 15 gr., potassium bromide 15 gr., liquid extract of liquorice 2 min., chloroform water up to 1 oz.

Lupulus and bromide draught (Haustus lupulus et bromidi). Tincture of lupulus 1 dr., potassium bromide 10 gr., spirit of chloroform 10 min., water up to 1 oz.

Magnesium sulphate draught (Haustus magnesiæ sulphatis). Magnesium sulphate 4 dr., citric acid 5 gr., peppermint water up to 2 oz.

Morphine draught (Haustus morphinæ). Solution of morphine hydrochloride 1 dr., water up to 1 oz.

Paraldehyde draught (Haustus paraldehydum). Paraldehyde 2 dr., syrup of orange 1 dr., chloroform water up to 1 oz.

Sodium sulphate draught (Haustus sodi sulphatis). Sodium sulphate 4 dr., peppermint water 1 oz.

Stimulant draught (Haustus stimulans). Spirit of ether 20 min., aromatic spirit of ammonia 1 dr., compound tincture of cardamom 1 dr., spirit of chloroform 10 min., water up to 1 oz.

MIXTURES (Misturæ)

Alkaline mixture (Mistura alkalina). Sodium bicarbonate 15 gr., sodium citrate $\frac{1}{2}$ dr., chloroform water up to 1 oz.

Ammonium chloride mixture (acid) (Mistura ammonii chloridi acida). Ammonium chloride 10 gr., dilute hydrochloric acid 10 min.,

magnesium sulphate 30 gr., liquid extract of liquorice 30 min., chloroform water up to 1 oz.

Ammonium chloride mixture (alkaline) (*Mistura ammonii chloridi alkalina*). Ammonium chloride 10 gr., sodium citrate 20 gr., liquid extract of liquorice 30 min., chloroform water up to 1 oz.

Asthma mixture (*Mistura asthmatica*). Potassium iodide 3 gr., potassium bicarbonate 5 gr., tincture of belladonna 5 min., ethereal tincture of lobelia 10 min., chloroform water up to 1 oz.

Asthma mixture with ephedra (*Mistura asthmatica cum ephedrina*). Tincture of ephedra 20 min., asthma mixture up to 1 oz.

Asthma mixture with kuth (*Mistura asthmatica cum kuthi*). Liquid extract of kuth $\frac{1}{2}$ dr., asthma mixture up to 1 oz.

Basham's mixture (*Mistura ferri perchloridi composita*). Solution of perchloride of iron 15 min., dilute acetic acid 20 min., solution of ammonium acetate 2 dr., glycerine $\frac{1}{2}$ dr., water up to 1 oz.

Bismuth mixture (*Mistura bismuthi*). Bismuth oxy-carbonate 15 gr., sodium bicarbonate 15 gr., compound tragacanth powder 10 gr., chloroform water 1 oz.

Calcium lactate mixture (*Mistura calcii lactatis*). Calcium lactate 10 gr., chloroform water up to 1 oz.

Carminative mixture (*Mistura carminativa*). Magnesium carbonate (heavy) 10 gr., aromatic spirit of ammonia 30 min., spirit of chloroform 20 min., compound tincture of cardamom 25 min., cinnamon water up to 1 oz.

Carminative mixture with rhubarb (*Mistura carminativa cum rheo*). Tincture of rhubarb 10 min., sodium bicarbonate 10 gr., peppermint oil $\frac{1}{2}$ min., spirit of ether 10 min., aromatic spirit of ammonia 15 min., chloroform water up to 1 oz.

Chalk mixture (*Mistura cretæ co.*). Aromatic powder of chalk 20 gr., tincture of catechu 30 min., syrup of ginger 30 min., peppermint water up to 1 oz.

Charcoal mixture (*Mistura carbonis ligni*). Charcoal 1 dr., liquified phenol 2 min., chloroform water 1 oz.

Cholagogue mixture (*Mistura sodii sulphatis co.*). Sodium sulphate 30 gr., sodium phosphate 20 gr., sodium salicylate 10 gr., sodium bicarbonate 20 gr., sodium benzoate 10 gr., spirit of chloroform 10 min., distilled peppermint water up to 1 oz.

Cinchona febrifuge mixture (*Mistura cinchoninæ*). Cinchona febrifuge 10 gr., citric acid 20 gr., magnesium sulphate 1 dr., water 1 oz.

Cinnamon mixture (*Mistura cinnamomi*). Cinnamon oil 30 min., acacia gum 2 gr., syrup of tolu 30 min., water up to 1 oz.

Codeine mixture (*Mistura codeinæ*). Codeine phosphate $\frac{1}{2}$ gr., sodium sulphate 1 dr., liquid extract of jambul 1 dr., tincture of nuxvomica 5 min., glycerine of glycerophosphate, 1 dr., compound infusion of gentian up to 1 oz.

Creosote mixture (*Mistura creosote*). Creosote 2 min., acacia 1 gr., lemon oil $\frac{1}{2}$ min., gluside $\frac{1}{2}$ gr., water up to 1 oz.

Diaphoretic mixture (*Mistura diaphoretica*). Potassium acetate 20 gr., potassium citrate $\frac{1}{2}$ dr., solution of ammonium acetate 2 dr., spirit of nitrous ether 10 min., chloroform water up to 1 oz.

Diuretic mixture (*Mistura diuretica*). Potassium acetate 10 gr., potassium citrate 30 gr., liquid extract of punarnava 1 dr., infusion of buchu up to 1 oz.

Dysentery mixture (*Mistura dysenterica*). Magnesium sulphate $\frac{1}{2}$ dr., sodium sulphate $\frac{1}{2}$ dr., spirit of chloroform 5 min., cinnamon water up to 1 oz.

Expectorant mixture (sedative) (*Mistura expectorans sedativa*). Sodium bicarbonate 10 gr., compound tincture of camphor $\frac{1}{2}$ dr., tincture of ipecacuanha 10 min., syrup of tolu $\frac{1}{2}$ dr., chloroform water up to 1 oz.

Expectorant mixture (stimulant) (*Mistura expectorans stimulans*). Sodium bicarbonate 10 gr., ammonium carbonate 5 gr., tincture of squill 10 min., infusion of senega up to 1 oz.

Flatulence mixture. Menthol 4 gr., aromatic spirit of ammonia 1 oz., spirit of chloroform 1 oz. Dose—1 teaspoonful with water.

Gentian mixture (acid) (*Mistura gentianæ acida*). Dilute hydrochloric acid 15 min., tincture of nux vomica 5 min., compound infusion of gentian up to 1 oz.

Gentian mixture (alkaline) (*Mistura gentianæ alkalina*). Sodium bicarbonate 15 gr., tincture of nux vomica 5 min., infusion of rhubarb 4 dr., tincture of ginger 10 min., spirit of chloroform 10 min., compound infusion of gentian up to 1 oz.

Gentian and rhubarb mixture (*Mistura gentianæ cum rhei*). Peppermint oil 1 min., bicarbonate of soda 10 gr., tincture of nux vomica 5 min., spirit of chloroform 10 min., rhubarb infusion 4 dr., compound infusion of gentian up to 1 oz.

Hexamine mixture. No. I. Hexamine 1 gr., Orange Syrup $\frac{1}{2}$ dr., water up to 1 oz. No. II. acid sodium phosphate 20 gr., water up to 1 oz.

Hypophosphite mixture (*Mistura hypophosphite*). Calcium hypophosphite $7\frac{1}{2}$ gr., sodium hypophosphite $7\frac{1}{2}$ gr., glycerine 20 min., infusion of quasia up to 1 oz.

Iodide mixture (*Mistura potassii iodidi*). Potassium iodide 10 gr., potassium bicarbonate 10 gr., chloroform water up to 1 oz.

Iodide and salicylate mixture (*Mistura potassii iodidi et sodii salicylici*). Potassium iodide 5 gr., sodium salicylate 10 gr., sodium bicarbonate 10 gr., potassium bromide 5 gr., compound infusion of gentian up to 1 oz.

Iron mixture (*Mistura ferri*). Iron and ammonium citrate 30 gr., glycerine 20 min., water up to 1 oz.

Iron and arsenic mixture (*Mistura ferri arseni*). Iron and ammonium citrate 5 gr., arsenical solution 4 min., tincture of nux vomica 5 min., glycerine 10 min., water up to 1 oz.

Iron and digitalis mixture. Iron perchloride lotion 10 min., tincture of digitalis 10 min., dilute phosphoric acid 10 min., glycerine 10 min., distilled cinnamon water up to 1 oz.

Iron and strychnine mixture (*Mistura ferri et strychninæ*). Solution of ferric chloride 10 min., sodium sulphate 20 gr., strychnine hydrochloride solution 3 min., glycerine 15 min., water up to 1 oz.

Kaolin mixture (*Mistura kaolini*). Kaolin 2 to 4 dr., cinnamon water 1 oz. or more.

Mercuric biniodide mixture (*Mistura hydrargyri biniodidi*). Solution of mercuric chloride $\frac{1}{2}$ dr., potassium iodide 10 gr., compound tincture of cardamom 20 min., water up to 1 oz.

Mercuric chloride mixture (*Mistura hydrargyri perchloridi*). Solution of mercuric chloride $\frac{1}{2}$ dr., compound tincture of cardamom 20 min., water up to 1 oz.

Quinine mixture (*Mistura quininæ*). Quinine sulphate 10 gr., citric acid 15 gr., spirit of chloroform 10 min., water up to 1 oz.

Sodium salicylate mixture (*Mistura sodii salicylas*). Sodium salicylate 10 gr., sodium bicarbonate 20 gr., water up to 1 oz.

Tonic mixture (bitter) (*Mistura amara*). Dilute phosphoric acid 15 min., tincture of nux vomica 5 min., spirit of chloroform 10 min., compound infusion of gentian up to 1 oz.

Triple carbonate mixture (*Mistura Tricarbonatum*). Sodium bicarbonate 10 gr., bismuth oxycarbonate 10 gr., magnesium carbonate (heavy) 10 gr., peppermint water 1 oz.

Triple sulphate mixture (*Mistura ferri aperiens*). Ferrous sulphate 2 gr., quinine sulphate 3 gr., magnesium sulphate 1 dr., arsenical solution 2 min., dilute sulphuric acid 5 min., peppermint water up to 1 oz.

Valerian mixture (*Mistura valerianæ*). Tincture of ammoniated valerian $\frac{1}{2}$ dr., potassium bromide 10 gr., spirit of cajuput 5 min., chloroform water up to 1 oz.

White mixture (*Mistura alba*). Magnesium sulphate 1 dr., magnesium carbonate (heavy) 10 gr., peppermint water up to 1 oz.

Yellow mixture (*Mistura flava*). Sodium bicarbonate 10 gr., infusion of gentian 1 oz.

DRINKS (*Potus*)

Imperial drink (*Potus imperialis*). Acid potassium tartrate 60 gr., juice of half a fresh lemon, sufficient sugar, boiling water 1 pint. Infuse, stirring occasionally till cold, then strain.

Ispaghula drink (*Potus ispaghulæ*). Ispaghula $\frac{1}{2}$ to 1 oz., cold water 1 pint. Soak for 2 hours.

DROPS (*Guttæ*)

Alkaline drop (ear) (*Guttæ alkalinæ*). Sodium bicarbonate 20 gr., borax 20 gr., glycerine 2 dr., water up to 1 oz.

Carbolic drop (ear) (*Guttæ phenolis*). Liquified phenol 5 min., rectified spirit $\frac{1}{2}$ oz., water $\frac{1}{2}$ oz.

Cocaine and carbolic acid drop (ear) (*Guttæ cocainæ et phenolis*). Liquified phenol 5 min., cocaine hydrochloride 5 gr., menthol 5 gr., glycerine 1 oz.

Homatropine drop (eye) (*Guttæ homatropinæ*). Homatropine hydrobromide 4 gr., distilled water 1 oz.

Spirit drop (ear) (*Guttæ spiritus*). Glycerine of boric acid and rectified spirit in equal parts.

Zinc sulphate drops (*Guttæ zinci sulphatis*). Zinc sulphate 2 dr., boric acid 4 gr., distilled water 1 oz.

EMULSIONS (*Emulsiones*)

Castor oil emulsion (*Emulsio oleum ricini*). Castor oil 1 dr., mucilage of acacia 1 dr., compound tincture of cardamom 20 min., peppermint water up to 1 oz.

Cod liver oil emulsion (*Emulsio olei morrhuæ*). Cod liver oil 2 dr., mucilage of acacia 1 dr., glycerine 10 min., water up to 1 oz.

ENEMAS (*Enemata*)

Alkaline enema (*Enema alkalinum*). Sodium bicarbonate 1 dr., normal saline 1 pint.

Compound enema (*Enema compositum*). Tincture of asafœtida 30 min., castor oil $\frac{1}{2}$ to 1 oz., turpentine oil 1 to 2 dr., olive oil 4 dr., soap enema 2 pints.

Glucose enema (*Enema glucosæ*). Glucose 1 oz., sodium bicarbonate 1 dr., normal saline up to 1 pint. Dose—4 to 6 oz. (To be retained).

Glycerine enema (*Enema glycerinum*). Glycerine and warm water in equal parts. Glycerine 2 dr. to 1 oz. according to age.

Saline enema (*Enema saline*). Sodium chloride $1\frac{1}{2}$ dr., water 1 pint.

Soap enema (*Enema saponis*). Soft soap 1 oz., water 2 pints.

Starch and opium enema (*Enema amyli cum opio*). Tincture of opium 30 min., mucilage of starch 2 pints. (To be retained).

FOMENTATION (*Fotus*)

Boric acid fomentation (*Fotus acidî borici*). Boric acid 6 dr., water (boiling) 1 pint.

GARGLES (Gargarismata)

Alum gargle (*Gargarisma aluminis*). Alum 10 gr., tincture of myrrh 5 min., water up to 1 oz.

Carbolic acid gargle (*Gargarisma phenolis*). Glycerine of carbolic acid 15 min., water up to 1 oz.

Chinosol gargle (*Gargarisma chinosolis*). Chinosol 2 gr., water 10 oz.

Potassium chlorate gargle (*Gargarisma potassii chloratis*). Potassium chlorate 10 gr., tincture of myrrh 5 min., water up to 1 oz.

Potassium permanganate gargle (*Gargarisma potassii permanganatis*). Potassium permanganate 1 dr., dilute sulphuric acid 15 min., water 8 oz.

INHALATIONS (Inhalationes)

Benzoin inhalation (*Inhalatio benzoini*). Compound tincture of benzoin 1 dr., water at 150°F. 1 pint. To be used in Nelson's inhaler.

Creosote inhalation (*Inhalatio creosoti*). Creosote 4 dr., chloroform 4 dr., menthol 10 gr., 10 drops in an inhaler every 2 hours.

Menthol and turpentine inhalation (*Inhalatio mentholis et terebinthinæ*). Menthol 1 dr., oil of turpentine 1 dr., chloroform 1 dr., rectified spirit 2 dr.

Pine oil inhalation (*Inhalatio pini*). Pine oil 5 min., magnesium carbonate (light) diffused in 1 dr. of water 4 gr., water at 150°F.

INJECTIONS (Injectiones)

Avenyl injection (*Injectio avenyl*). Avenyl 0.25 per cent. in oil hydnocarpus; 0.5 per cent. in ester.

Berberine injection (*Injectio berberis*). Berberine (acid) sulphate 2 per cent. solution in water. To be given subcutaneously around the ulcers.

Pituitrin and adrenalin injection (*Injectio pituitrinum et adrenalium*). Pituitrin 0.3 c.cm., adrenalin 0.2 c.cm. To be given intramuscularly.

Quinine injection (intravenous) (*Injectio quinina*). Quinine bihydrobromide 7½ gr., sterile normal saline 20 c.cm. To be given very slowly.

INSUFFLATION (Insufflatio)

Ephedrine insufflation (*Insufflatio ephedrinæ*). Ephedrine alkaloid 5 gr., menthol 5 gr., camphor 5 gr., liquid paraffin up to 1 oz. Each constituent to be dissolved separately in a portion of liquid paraffin with gentle heat and mixed together.

LINCTUS (Linctus)

Diamorphine linctus (*Linctus diamorphinæ*). Diamorphine hydrochloride 1 gr., syrup of tolu 4 dr., syrup of virginian prune 4 dr., glycerine 3½ dr. Dose—¼ to 1 dr.

Paregoric linctus (*Linctus paregoricum*). Compound tincture of camphor, oxymel of squill, and syrup of tolu, in equal parts. Dose—1 teaspoonful.

Terpheroin linctus (*Linctus terpheroini*). Terpene hydrate 1 gr., acetomorphine hydrochloride 1/20 gr., menthol 1/20 gr., alcohol 10 min., glycerine 1 dr.

• **LINIMENTS** (*Linimenta*)

A. B. C. liniment (*Linimentum A. B. C.*). Liniment aconite, liniment belladonna and liniment chloroform, in equal parts.

Anodyne liniment (*Linimentum camphoræ et opii*). Camphor 10 gr., liniment of opium 2 dr., olive oil 1 oz.

Calamine liniment (compound) (*Linimentum calaminæ compositum*). Prepared calamine ½ dr., zinc oxide ½ dr., liquefied phenol 3 min., almond oil ½ oz., lime water up to 1 oz.

Calamine liniment (simple) (*Linimentum calaminæ simplex*). Olive oil 2 dr., calamine lotion up to 1 oz.

White liniment (*Linimentum album*). Olive oil 1 oz., solution of ammonia 1 oz., turpentine oil 1 oz.

Wintergreen liniment (*Linimentum gaultheriæ*). Oil of wintergreen 4 dr., menthol 2 dr., soft paraffin ½ oz., olive oil 1 oz.

LOTIONS (*Lotiones*)

Acridlavine lotion (*Lotio acridlavina*). Acridlavine 5 gr., water 1 pint.

Aluminium lotion (*Lotio aluminis*). Solution of aluminium acetate 1 dr., water 7 dr. It should be applied on plain gauze or muslin piece.

Bismuth and mercury lotion (*Lotio bismuthi et hydrargyri*). Bismuth oxynitrate 10 gr., mercuric chloride 1 gr., compound tragacanth powder 10 gr., water up to 1 oz.

Boric acid lotion (*Lotio acidi borici*). Boric acid 20 gr., water 1 oz.

Calamine lotion (*Lotio calaminæ*). Prepared calamine 2 dr., zinc oxide 1 dr., glycerine 20 min., lime water 1 oz.

Calamine lotion (compound) (*Lotio calaminæ composita*). Prepared calamine 1 dr., zinc oxide 1 dr., glycerine 1 dr., lead subacetate lotion (strong) 20 min., coal-tar solution 10 min., lime water up to 1 oz.

Eusol lotion (*Lotio eusol*). Eupad 4 dr. (consisting of equal parts of boric acid and bleaching powder), water 1 pint. To stand for 24 hours with frequent shaking and strain through muslin.

Gentian violet lotion (*Lotio methylosanilini*). Gentian violet 20 gr., absolute alcohol 1 dr., water up to 1 oz.

Ichthyol lotion (*Lotio ichthyol*). Ichthyol 10 to 20 per cent. solution in water.

Lead lotion (*Lotio plumbi*). Lead subacetate lotion (strong) 10 min., glycerine 1 dr., water up to 1 oz.

Optochin lotion (*Lotio optochinum*). Ethyl hydrocupreine hydrochloride (optochin) 10 gr., water 1 pint.

Picric acid lotion (*Lotio acidi picrici*). Picric acid 25 gr., water 10 oz.

Red lotion (*Lotio rubra*). Zinc sulphate 2 gr., tincture of lavender 5 min., water up to 1 oz.

* **Resorcin lotion** (*Lotio resorcinolis*). Resorcin or euresol $\frac{1}{2}$ dr., spirit of ether $\frac{1}{2}$ dr., castor oil 10 min., rectified spirit $1\frac{1}{2}$ dr., water up to 1 oz.

* **Resorcin and mercury lotion** (*Lotio resorcinolis et hydrargyri*). Resorcin $\frac{1}{2}$ dr., sandal wood oil 5 min., mercuric chlorides $\frac{1}{2}$ gr. glycerine $\frac{1}{2}$ dr., rectified spirit 2 dr., water up to 1 oz.

Silver nitrate lotion (*Lotio argenti nitratis*). Silver nitrate 5 to 15 gr., spirit of ether 1 dr., distilled water 1 oz.

Sulphur lotion (compound) (*Lotio sulphuris composita*). Precipitated sulphur 1 dr., salicylic acid 10 gr., compound tragacanth powder .10 gr., water 1 oz.

Sulphur lotion (white) (*Lotio sulphuris alba*). Sulphuretted potassium 15 gr., zinc sulphate 15 gr., water up to 1 oz.

Sulphur lotion (yellow) (*Lotio sulphuris flava*). Precipitated sulphur 20 gr., absolute alcohol 2 dr., glycerine 10 min., lime water 2 dr., water up to 1 oz.

Tannic acid lotion (*Lotio acidi tannici*). Tannic acid 12 gr., water up to 1 oz.

Zinc and copper sulphate lotion (*Lotio zinci et cupri*). Zinc sulphate 6 gr., copper sulphate 6 gr., water 1 oz.

Zinc sulphate lotion (*Lotio zinci sulphatis*). Zinc sulphate 10 gr., water 1 oz.

NOSE WASH (*Collunarium*)

Alkaline nose wash (*Collunarium alkalinum*). Sodium bicarbonate 15 gr., sodium chloride 15 gr., borax 15 gr., sugar 30 gr., water 1 oz. Mix two tablespoonfuls with double the quantity of tepid water and sniff.

OIL (*Oleum*)

Catheter oil (*Oleum lubricans*). Phenol 1 dr., castor oil 4 dr., almond oil $2\frac{1}{2}$ oz.

*For gray or light-haired person use euresol instead of resorcin.

OINTMENTS (Unguenta)

Acridiflavine ointment (1 in 1,000) (Unguentum acridiflavini). Acridiflavine $\frac{1}{2}$ gr., vaseline 1 oz.

Beta-naphthol ointment (Unguentum beta-naphtholis). Beta-naphthol 30 gr., vaseline 1 oz.

Bismuth ointment (Unguentum bismuthi). Bismuth oxychloride 15 gr., olive oil 2 dr., liquefied phenol 10 min., soft paraffin up to 1 oz.

Boric acid ointment (Unguentum acidi boric). Boric acid 1 dr., vaseline 1 oz.

Brilliant green ointment. Brilliant green 10 gr., rectified spirit 1 dr., soft paraffin 1 oz.

Compound chrysarobin ointment (Unguentum chrysarobin co.). Chrysarobin 40 gr., ichthyol 30 gr., salicylic acid 30 gr., vaseline up to 1 oz.

Dilute ammoniated mercury ointment (Unguentum hydrargyri ammoniati dilutum). Ammoniated mercury 5 to 10 gr., soft paraffin 1 oz.

Ichthyol ointment (Unguentum ichthyolis). Ichthyol 1 part, paraffin ointment 9 parts.

Mercuric nitrate ointment (Unguentum hydrargyri nitratis) Mercuric nitrate 40 gr., olive oil 4 dr., liquid paraffin 4 dr.

Resorcin ointment (Unguentum resorcinolis). Resorcin $\frac{1}{2}$ dr., vaseline 1 oz.

Resorcin and mercury ointment (Unguentum resorcinolis et hydrargyri). Resorcin $\frac{1}{2}$ dr., mercuric chloride 2 gr., zinc oxide ointment 1 oz.

Rose ointment (Unguentum rosæ). Lanolin 1 part, white wax 1 part, almond oil 2 parts, rose water 2 parts.

Salicylic acid ointment (Unguentum acidi salicylici). Salicylic acid 30 gr., vaseline 1 oz.

Sulphur ointment (Unguentum sulphuris). Sublimed sulphur 1 dr., vaseline 1 oz.

Tar and salicylic ointment (Unguentum picis cum acido salicylico). Solution of coal tar $\frac{1}{2}$ to 1 dr., salicylic acid 30 gr., zinc oxide 15 gr., vaseline 1 oz.

Whitfield ointment (Unguentum acidi salicylici et benzoici). Salicylic acid 15 gr., benzoic acid 15 gr., cocoanut oil 4 dr., lanolin 4 dr.

Wintergreen ointment (Unguentum gaultheriæ). Oil of wintergreen 2 dr., menthol 1 dr., vaseline up to 1 oz.

•

PAINTS (Pigmenta)

Aconite paint (Pigmentum aconiti). Tincture of aconite 2 dr., tincture of myrrh 2 dr., tincture of iodine 2 dr.

Alum Paint (Pigmentum aluminis). Alum 10 gr., dilute sulphuric acid 1 oz.

Belladonna paint (Pigmentum belladonnæ). Green extract of belladonna 4 dr., glycerine 4 dr.

Chrysarobin paint (Pigmentum chrysarobini). Chrysarobin 40 gr., gutta percha 1 dr., chloroform 1 oz.

Creosote and salicylic acid paint (Pigmentum creosotæ cum acido-salicylico). Salicylic acid 2 dr., creosote 2 dr., glycerine up to 1 oz.

Formalin paint (Pigmentum formaldehydi). Formalin $\frac{1}{2}$ dr., glycerine 1 oz.

Ichthyol and belladonna paint (Pigmentum ichthyolis et belladonnæ). Ichthyol 2 dr., green extract of belladonna 2 dr., glycerine up to 1 oz.

Iron paint (Pigmentum ferri perchloridi). Solution of perchloride of iron 4 dr., glycerine 4 dr.

Lichen paint. Resorcin $1\frac{1}{2}$ dr., salicylic acid 1 dr., phenol 1 dr., mercuric chloride 5 gr., glycerine 1 dr., rectified spirit 5 dr., water 5 dr.

Mandl's paint (Pigmentum Mandl). Iodine 6 gr., potassium iodide 20 gr., peppermint oil 5 min., glycerine 1 oz.

Menthol paint (Pigmentum mentholis). Menthol 2 dr., camphor 2 dr., chloral hydrate 2 dr.

Resorcin and benzoin paint (Pigmentum resorcinolis et benzoini). Resorcin $\frac{1}{2}$ dr., compound tincture of benzoin 1 oz.

Resorcin and carbolic paint (Pigmentum resorcinolis et phenolis). Resorcin $\frac{1}{2}$ dr., spirit of peppermint 20 min., liquefied phenol 3 min., glycerine up to 1 oz.

Resorcin and iron paint (Pigmentum resorcini et ferri). Resorcin 15 gr., menthol 4 gr., glycerine of perchloride of iron 1 oz.

Ringworm paint (Pigmentum tineæ). Resorcin 1 dr., salicylic acid 1 dr., liquefied phenol $\frac{1}{2}$ dr., glacial acetic acid 1 dr., glycerine 2 dr., compound tincture of benzoin 6 dr.

Salicylic acid paint (Pigmentum acidi salicylici). Salicylic acid 1 dr., extract of cannabis indica 10 gr., collodion flexile 1 oz.

PASTE (Pasta)

B. I. P. P. (Pasta bismuth et iodoformi). Bismuth subnitrate 1 dr., iodoform 2 dr., vaseline 5 dr.

Lassar's paste (Pasta lassari). Zinc oxide 2 dr., salicylic acid 10 gr., starch 2 dr., soft paraffin 4 dr. (Modified—zinc oxide 24 gr., starch 24 gr., lanolin $\frac{1}{2}$ oz., liquid paraffin $\frac{1}{2}$ oz.)

PILLS (Pillulæ)

Belladonna pill (compound) (Pillula belladonnæ composita). Extract of belladonna $\frac{1}{2}$ gr., menthol $\frac{1}{2}$ gr., extract of valerian 2 gr.

Codeine and cascara pill (Pillula codeinæ et cascariæ sagradæ). Codeine phosphate $\frac{1}{2}$ gr., aloin $\frac{1}{2}$ gr., extract of hyocyanus $\frac{1}{2}$ gr.,

extract of nux vomica $\frac{1}{4}$ gr., extract of euonymin 1 gr., extract of cascara sagrada 2 gr., glycerine with tragacanth—sufficient quantity.

Colocynth and mercury pill (compound) (*Pilula colocynthidis et hydrargyri composita*). Compound colocynth pill 3 gr., blue pill $\frac{1}{4}$ gr., extract of hyoscyamus 1 gr.

Iron arsenate pill (*Pilula ferri et arsenatis*). Iron arsenate $\frac{1}{10}$ gr., extract of nux vomica $\frac{1}{6}$ gr., quinine sulphate 2 gr., extract of gentian—sufficient quantity.

Quarter grain pill (*Pilula aloinæ composita*). Aloin $\frac{1}{4}$ gr., podophyllin $\frac{1}{4}$ gr., extract of nux vomica $\frac{1}{4}$ gr., iridin $\frac{1}{4}$ gr., extract of gentian—sufficient quantity.

POULTICES (Cataplasmata)

Kaolin poultice (antiphlogistine) (*Cataplasma kaolini*). Kaolin $\frac{1}{4}$ oz., boric acid 20 gr., thymol 1 gr., wintergreen oil 1 min., peppermint oil 1 min., glycerine 1 oz. Heat kaolin on water bath for 1 hour and then add the rest.

Linseed poultice (*Cataplasma lini*). Crushed linseed 4 oz., water (boiling) 10 oz. Add slowly crushed linseed to the boiling water constantly stirring and spread $\frac{1}{4}$ inch thick layer on lint or calico.

Starch poultice (*Cataplasma amvli*). Starch 1 oz., boiling water 10 oz. Make a paste with a little cold water and then add boiling water.

POWDERS (Pulveres)

A. P. C. powder (*Pulvis A. P. C.*). Aspirin 5 gr., phenacetin 2 gr., caffeine citrate 3 gr.

Bismuth and ipecacuanha powder (*Pulvis bismuthi et ipecacuanhæ*). Bismuth salicylate 10 gr., compound ipecacuanha powder 5 gr.

Calamine powder (*Pulvis calaminæ*). Prepared calamine 2 dr., camphor 1 dr., starch 1 oz.

Calomel powder (*Pulvis calomel*). Calomel $\frac{1}{4}$ gr., Sodium bicarbonate 5 gr. Dose—one powder every half hour till three or four such to be followed by a saline purgative.

Carbonate powder (double) (*Pulvis carbonatum duplicatum*). Bismuth oxycarbonate 1 oz., sodium bicarbonate $\frac{1}{4}$ oz. Dose—one teaspoonful.

Carbonate powder (triple) (*Pulvis carbonatum triplicatum*). Bismuth oxycarbonate 1 oz., magnesium carbonate (heavy) 1 oz., sodium bicarbonate $\frac{1}{4}$ oz. Dose—one teaspoonful. Maclean's powder contains calcium carbonate as well.

Rhubarb powder (*Pulvis rhei*). Powdered rhubarb root 10 gr., sodium bicarbonate 2 gr., powdered ginger 2 gr.

Santonin powder (compound) (*Pulvis santoninum compositum*). Santonin 3 gr., calomel 2 gr., sodium bicarbonate 5 gr.

Sulphur and camphor powder (*Pulvis sulphuris et camphoræ*). Camphor 1 oz., precipitated sulphur 1 oz., zinc oxide 1 oz., boric acid 1 oz., starch 4 oz., kaolin 2 oz.

Zinc and boric powder (*Pulvis zinci et acidi borici*). Boric acid, zinc oxide and starch in equal parts.

SPIRITS (*Spiritus*)

Mercury spirit (*Spiritus hydrargyri perchloridi*). Mercuric chloride 2 gr., alcohol 70 per cent. 1 oz.

Soap spirit (*Spiritus saponis*). Soft soap 1 oz., rectified spirit 2 oz. To be used as a shampoo.

SPRAY (*Nebula*)

Alkaline spray (*Nebula alkalina*). Sodium bicarbonate, sodium chloride and borax, each 15 gr., phenol 5 gr., spirit of peppermint 15 min., glycerine 1 dr., water up to 1 oz.

Compound eucalypti spray (*Nebula eucalypti composita*). Oil of eucalyptus 3 min., oil of cinnamon 3 min., thymol 3 gr., chloretone 6 gr., menthol 3 gr., camphor 4 gr., liquid paraffin 1 oz.

NEW AND NON-OFFICIAL REMEDIES

Acetylcholine bromide. The drug is used in counteracting paralysis of the intestine after laparotomy and intestinal operations. It is useful in post-operative gas distension and pain and to a certain extent to relieve acute constipation. It is also of value in certain types of vascular disturbances associated with arteriolar spasm. It is usually administered by intramuscular injection in doses of 0.1 gm. in 1 c.cm. of a solvent.

Albargin (*Silver gelatose*). This is a yellowish white powder containing gelatose (10 gm.). It is soluble in water and alcohol and contains 15 per cent. of silver. It is used in gonorrhœa in 0.2 per cent. solution (1 in 500) and is considered to be superior to protargol. It is efficacious when used as an instillation as 0.5 to 3 per cent. solution in ophthalmia neonatorum and phlyctenular conjunctivitis. In chronic bacillary dysentery encouraging results have been obtained by rectal injections of 30 gr. of the drug dissolved in 30 oz. of water. It is frequently used as a colonic lavage in ulcerative colitis with good results.

Alepoi. This is a selected fraction of the sodium salts of hydno-carpus acids. The powder is soluble in water and the solution is used for intramuscular and intravenous injections in leprosy. The usual dose for intramuscular and subcutaneous injections is 1 c.cm. of a 3 per cent. solution and for intravenous injections 1 c.cm. of a 1 per cent. solution increased by 1 c.cm. up to 5 or 10 c.cm. The injections are given twice a week.

Aptile-benzoic acid. It is a local analgesia, solution containing benzoamine (B.P.) 3 per cent., benzyl alcohol 5 per cent. and ether 10 per cent. in sterilised olive oil. The drug is injected in 2 c.cm. doses

round the vulvar region in pruritus vulvæ. Total injections number from 8 to 30, repeated at weekly intervals.

Aolan. See page 1418.

Argyrol (Vitellin). It is silver in combination with a wheat proteid and contains 30 per cent of silver. It forms a black solution in water. A 5 per cent. solution has proved valuable in gonorrhœa, but the drug is chiefly used in ophthalmic practice, instillations of 25 per cent. being painless and most reliable in gonorrhœal ophthalmia and ophthalmia neonatorum and acute conjunctivitis. It is used also as a 2 per cent. ointment with paraffin basis in eczematous conjunctivitis and keratitis and has been successfully injected in 1 per cent. solution in ulcerative colitis and dysentery.

Atebrin. See page 602.

Atebrin-musonat. This form of atebtrin has come into prominence through trials made during the recent epidemic in Ceylon. It is simply an improved form of a soluble atebtrin salt suitable for injection, the word 'musonat' being merely a fancy name coined for facility of laboratory reference. Trials of this form of atebtrin have been made in Ceylon by Blaze (General Hospital, Colombo) and Simoons of Heidelberg who went to Ceylon for the purpose. Discussing the parenteral administration of atebtrin, these workers refer to the findings of Hecht, who has shown that when atebtrin is taken by the mouth much of it is retained in the upper intestine, liver, and bile, and that it circulates in these organs before reaching the peripheral blood. After continued administration a point is reached when the liver becomes saturated and the atebtrin overflows into the peripheral circulation. It is known that atebtrin when given orally has no effect on the clinical picture for some days. It has also been suggested that toxic symptoms, when they appear, are caused by an exceptionally high concentration of atebtrin in the liver and upper intestine. If these conjectures are correct, parenteral administration of atebtrin should have an immediate effect, and this intramuscular injection caused no toxic or unpleasant symptoms. A single injection of 0.375 gm. had a remarkable effect on the clinical picture, but recrudescence usually occurred in a few days. Two similar injections on successive days, however, proved sufficient to control the temperature within forty-eight hours, and in four days all forms of benign tertian parasites, and the ring forms of malignant tertian, were destroyed. Crescents are not affected and must be destroyed by plasmoquine. The intravenous route is harmless, but is not satisfactory for routine treatment. The relapse rate after atebtrin-musonat has yet to be studied.

Atophan (Phenyl quinoline-carboxylic acid). It increases uric acid output and hence is used in gouty arthritis. *Dose.*—7½ gr., two or three times a day. An alkaline mixture is given along with this drug. See also novatophan.

Avenyl. It is a compound of mercury for the treatment of leprosy complicated with syphilis. It is given in the form of a 0.25 per cent. solution in hydnocarpus oil or a 0.5 per cent. solution in moogrol, of which 1 c.cm. increased to 4 c.cm. or more, is injected subcutaneously.

Avertin or tribromethyl alcohol. It has recently come into use as a basal anæsthetic for rectal administration. It is a white crystalline substance requiring protection from light and air to avoid decomposition. Avertin is rapidly absorbed by the rectal mucous membrane, is non-irritant and induces a smooth anæsthesia free from excitement and lasting for about two hours. About $1\frac{1}{2}$ to 3 gr. for each $2\frac{1}{5}$ lb. body weight are required and injected as a 3 per cent. solution in distilled water or physiological saline. The full degree of anæsthesia is attained in about half an hour, and if not deep enough may be supplemented by gas and oxygen or ether. This is required in about two thirds of patients when less than 2 gr. per $2\frac{1}{5}$ lb. body-weight are given. It is wise to avoid its use where hepatic disease is present, though the evidence that avertin itself affects hepatic function is yet uncertain. It has been used in eclampsia with success. Rectal diseases, peritonitis and cachectic conditions are also contra-indications to its use.

Bayer 205. See page 466.

Bee venom. It is a preparation containing the venom of bee stings for the treatment of rheumatism. The major part of the protein is fixed and discarded during the process of manufacture and the venom is suspended in normal saline containing 0.5 per cent. of phenol. Bee venom is supplied as a course of 12 ampoules containing progressively stronger doses. The first ampoule contains the equivalent of half a normal bee sting, this dose being known as 5 units. The injection should be given well under the skin to avoid local reaction.

Benzyl benzoate or spasmodin. It is a liquid though the pure salt is a solid. A number of benzyl esters lowers the tonus of smooth muscles and are relatively non-toxic. All these substances have been used in a variety of conditions in which the spasm of smooth muscle is present such as colics, dysmenorrhœa, asthma, whooping cough, etc. Benzyl benzoate is given in emulsion containing 2 to 5 min. in each dose. Benzyl formate and succinate are given in doses up to 20 gr.

Berberine sulphate. See page 451.

Bilecol. See page 727.

Bile salts. Taurocholate and glycocholate of sodium, from ox-bile, have been used as solvents for gall-stones and in chronic constipation and dyspepsia. Sodium taurocholate has been recommended for gouty obesity and dyspepsia in doses of 2 to 6 gr. in keratin coated pills. Sodium glycocholate appears to be a useful cholagogue for congestion of the liver, gall-stones, constipation and melancholia in doses of 2 to 6 gr. Infantile marasmus has been treated with bile salts, average dose is $\frac{1}{2}$ gr. of the mixed salts for infants of three months.

Buchi oil (*Psorale corylifolia*). It is used externally for leucoderma.

Bromural or dormigene. It is a monobrom-iso-valerianyl urea, in white crystals. This substance possesses very marked hypnotic powers beyond the small amount of bromine (36 per cent.) contained in its full hypnotic dose of 10 gr., the sedative action being mainly due to its isopropyl constitution. It induces apparently natural sleep within about 20 minutes with safety, and without producing any untoward effects. It has been given in 2 gr. doses with benefit in whooping cough and various neurotic conditions, but it has no narcotic action. The drug is best given in tablets or dissolved in hot liquid when a speedy effect is

desired. It has proved valuable in epilepsy, neuroses occurring at the menopause and in sea-sickness.

Calcium gluconate. It contains (anhydrous) 9.3 per cent. of calcium. It is indicated in diseases requiring calcium therapy. Taken by mouth, it is well absorbed. Given intramuscularly it is painless and non-irritant. It is better tolerated than calcium chloride when given intravenously. It is said to be almost specific in hay fever and extensively used in many respiratory diseases, debility, malnutrition, neurasthenia and other affections. The oral dose is 1 to 2 dr. three times a day and for intramuscular or intravenous injections it is given in doses of 10 c.cm. of a 10 per cent. solution.

Campolon. It is an extract of the effective factor of liver tissue, which on clinical trial has proved highly efficacious in macrocytic anæmias and is free from all by-effects. It is prepared for administration by intramuscular injections; 2 c.cm. is equivalent to 500 gm. of fresh liver.

Cannabinon. It is a purified and very soft resin obtained from Indian hemp. It occasionally proves inert. It has been given with good results in the sleeplessness of mania in doses of $\frac{1}{2}$ to 1 gr. rubbed up with sugar of milk. *Haschisch* is the name given to a brownish powder prepared from the alcoholic extract, which is variable in its effects.

Carbarson. See page 411.

Carbo ligni. It is a powerful oxidising agent, owing to the amount of oxygen absorbed by it, and it is used as an antidote in poisoning by phosphorus and by alkaloids such as morphine, strychnine, etc., rendering them inert. Half ounce of it neutralises 1 gr. of the alkaloid but its administration should not interfere with the use of the stomach pump, emetics and purgatives, which should follow. Internally, wood charcoal is administered in flatulent conditions of the stomach and intestines as an absorbent and deodoriser.

Cardiazol. See page 249.

Casein. It is the albuminoid substance present in milk and constitutes the chief bulk of cheese. It is employed as the basis of many artificial foods as Plasmon, Virogen, Casumen, Nutrose, etc. The last mentioned substance consists of pure caseinate of sodium, 1 oz. of which dissolved in a pint of heated milk, may be used as a food in marasmus, diarrhoea and stomach diseases.

Catechu. It is a valuable local astringent and may be used as gargles or lozenges for spongy gums, mercurial and ulcerative stomatitis. The action of the drug is exactly like tannic acid and is a useful remedy for diarrhoea when combined with opium, kino and chalk. The usual dose is 5 to 15 gr.

Cerium oxalate. This and also the sulphocarbolate have been used in the vomiting of pregnancy, some forms of gastric irritation, in chronic diarrhoea, hysteria, epilepsy and migraine. They are white powders given in 3 gr. doses with an equal amount of powdered sugar.

Chaulmoogra oil and its derivatives. See page 923.

Chlorotone. It is a hypnotic, local anæsthetic and anti-emetic.
Dose.—5 to 20 gr.

Cignolin. It is dioxyanthranol, a non-staining preparation of chrysophanic acid. It forms an useful external application in psoriasis in strengths of $\frac{1}{4}$ to 1 per cent. solution in benzol or acetone.

Colchicine. It is the active principle of colchicum, suitable for hypodermic injection in 1/32 gr. doses in painful joint affections, chronic rheumatism, and gouty troubles. Colchicine salicylate, which is now obtainable in capsules, containing 1/250 gr. dissolved in methyl salicylate, is also known as Colchisal.

Coramine (Pyridine- β -carbonic acid diethylamide). It is a synthetic substance having a camphor-like action. It is used in shock, cardiac asthenia following infectious diseases, arteriosclerosis, renal affections, bronchial asthma, poisoning with narcotics and asphyxia of the new-born. The drug is held to be a substitute for camphor, strychnine and caffeine since in cases of collapse it has a stimulating action on the central nervous system and on the circulatory and respiratory apparatus. It is water soluble. *Dose.*—1 to 2 c.cm. of the liquid, with a little water orally; 1 to 2 ampoules (each 1.1 c.cm.) hypodermically, intramuscularly or intravenously.

Cryogenin (Meta-benzamine-semicarbazide). It is a crystalline, sparingly soluble coal-tar derivative, with antipyretic properties resembling those possessed by phenacetin. It has been given in 3 to 24 gr. doses. The drug is a useful antipyretic in fevers.

Cyclopropane. Lucas and Henderson (1929) first suggested the use of cyclopropane or trimethylene as an anæsthetic agent. It is a colourless gas possessing a sweetish odour and is inflammable. The gas is available compressed in steel bottles at a pressure of 75 lb. The gas is administered by the method of a closed circuit employing carbon dioxide absorption with an oxygen percentage greater than 20. The usual practice is to employ a cyclopropane-oxygen mixture. In the absence of high oxygen concentrations respiratory failure is apparently produced when the proportion of cyclopropane rises to 45 per cent. Anæsthesia produced by the drug is quiet with a good muscular relaxation. Premedication with morphine and hyoscine reduces the amount of cyclopropane necessary to secure full surgical anæsthesia. Recovery is rapid and excepting nausea and vomiting post-anæsthetic complications are rare. The anæsthetic is of particular value in thoracic surgery.

Damiana. This name is given to a drug (*Turnera diffusa*, var. *aphrodisiaca*) long used by the Mexicans as a stimulant to the reproductive centres. The leaves and flowers are the parts used in medicine as aphrodisiac. It has been tried with some success in melancholia. It is a mild laxative and bitter. Good results have been obtained from it in cases of sexual debility and hypochondriasis. *Dose.*—1 dr. of the fluid extract (1 in 1), or 2 to 8 gr. of the extract. The drug is also said to be tonic and diuretic.

Decholin. It consists of dihydrochloric acid, an oxidation product of cholic acid derived from natural bile acids. Both it and its sodium salt are used in functional insufficiency of the liver, to outline the bile ducts at operation, and in cholecystography to accelerate the appearance of the gall bladder shadow and to hasten the removal of the

residual 'opacol' from the biliary apparatus, in cardiac decompensation with hepatic congestions, cirrhosis of the liver and similar conditions associated with ascites. *Dose*.—4 to 8 gr., three times daily after meals for a period of 4 to 6 weeks.

Digifortis (in ampoules). Each ampoule contains 1 c.cm. of a solution that presents the whole of the active principles of digitalis without inert matter. Each ampoule contains the equivalent of one digifortis tablet *gr* 10 min. of the liquid digifortis for oral use. The activity of digifortis solution in each c.cm. ampoule is 0.8 international unit. By the mouth it is given in doses of 15 to 30 min.

Digoxin. It is a pure glucoside of digitalis prepared from the Austrian foxglove, *Digitalis lanata*. It is absorbed and eliminated more rapidly than digitalis. The drug is mainly indicated in cases of auricular fibrillation with a high ventricular rate with or without congestive failure sometimes attended with severe vomiting and where a rapid response to treatment is required. It can be administered both orally and intravenously. The initial dose, depending upon the body weight of the patient, is 1.00, 1.25 or 1.50 mgm. (4 to 6 tablets each containing 0.25 mgm.), followed six hours later by 0.25 mgm., and then the same dose every six hours until the ventricular rate falls to 60 to 70 per minute. The intravenous dose is 0.75 to 1.00 mgm., and this can be followed after an interval of 4 to 6 hours by digoxin given by mouth.

Divinyl ether. Divinyl oxide, divinyl ether, vinethene as it is called represents ethylene plus ether and is used as an anæsthetic. It is a colourless liquid more volatile than ether and possessing a sweetish ethereal odour. It is less irritating to the respiratory tract and can be administered either by the open drop method or by the closed method with or without carbon dioxide. The anæsthesia is characterised by rapid induction and quick recovery. The rate of administration during induction by the open method should be about one drop per second and the average amount necessary for the maintenance of anæsthesia is 2 c.cm per minute. Muscular relaxation is complete within a short time the anæsthetic is administered. Post anæsthetic complications are also never marked.

Emmenin complex. This is an orally active oestrogenic hormone derived from the placenta. It is regarded as a hydrolysable complex of trihydroxy-œstrin, the potency of which is increased in the presence of ovarian tissue. It supplements the oestrogenic activity of the hypo-functioning ovary and is indicated in the treatment of menopausal disturbances, menstrual headache, dysmenorrhœa and oligomenorrhœa. The usual dose is one teaspoonful daily in water.

Entero-vioform (Iodochlorhydroxy quinoline). The drug is a grayish yellow powder, almost insoluble in water and sparingly in alcohol; it contains 40 per cent. of iodine and is absorbed to some extent from the bowel as it is partly excreted in the urine. It is given orally in chronic amoebiasis and other parasitic intestinal diseases. The usual dose is 0.75 gm. daily in three capsules of 0.25 gm. each for ten days, the course being repeated after a week's rest to total 15 gm.

Glycine (Aminoacetic Acid). It is acetic acid with one of the hydrogen atoms replaced by the amino group. It is a white crystalline substance with a sweetish taste, readily soluble in water, non-toxic and

when administered orally acts as a diuretic like amino-acids in general. The drug has given encouraging result in the treatment of progressive muscular dystrophy, in myasthenia gravis and in similar conditions of deficient muscular tonus. The drug has been found to be more useful in myasthenia gravis when used in conjunction with ephedrine. *Dose*.—10 to 30 gr.

Ergosterol (Irradiated). This is extensively used in diseases where vitamin D is indicated. Vitamin D is necessary to ensure calcium and phosphorus absorption for the treatment of rickets. The drug has also been suggested in the treatment of general spasmophilia, tetany, laryngismus stridulus, osteomalacia and certain idiopathic steatorrheas. *Dose*.—usually 2 to 5 mgm.

Eucortone and eschatin. These are two preparations of the active extract of suprarenal cortex used in the treatment of Addison's disease. It is now established that continued administration will restore and maintain good health in patients with Addison's disease. Patients in the stage of collapse should receive from 20 to 60 c.cm. daily, given in divided doses by intravenous injections.

Eukodal (Dihydroxy-codeinon hydrochloride). It has been introduced as a substitute for morphine. It is said to have a more rapid action, does not produce vomiting, and lead to tolerance upon repeated administrations. It is also less apt to produce constipation. *Dose*.—up to $\frac{1}{4}$ gr.

Euonymi cortex. The drug possesses tonic, hydragogue, cathartic, diuretic and antiperiodic properties. The drug has a cathartic effect resembling that of podophyllin but very much milder in action. *Dose*.—Euynmin—1 to 2 gr.; (chologogue) $\frac{1}{4}$ to 1 gr.; (cathartic) 1 to 4 gr.

Eupad (Pulvis calcis chlorinatæ et acidi boric). This name is given to equal amounts of dry chlorinated lime and boric acid, 25 parts of which are added to 1000 parts of water to form Rusol. Eupad was extensively used as a dry dressing to wounds during the war. It evolves hypochlorous acid rapidly in contact with water. It has been used intravenously in malignant endocarditis, puerperal septicæmia, pyæmia and other septic conditions.

Euphorbia pilulifera. Pill-bearing spurge, or Australian snake root, or cat's hair, is an asthma remedy. Good results are reported with it in dyspnoea of asthma, emphysema, bronchitis, and in dyspnoea of cardiac origin. It appears to act beneficially upon any kind of spasmodic dyspnoea, probably through its influence over the vagus, but its best effects are seen in ordinary spasmodic asthma, coryza and hay asthma. The gastric irritation arising from its administration can be avoided by giving the dose in a state of free dilution. One grain of the extract or 10 to 30 min. of the B. P. C. tincture (1 in 5 freely diluted) after meals, may be given 4 times a day.

Euphyllin. It is a combination of amphoteric theophylline with ethylenediamine, and is a crystalline yellowish white product containing about 80 per cent. of theophylline. It is distinguished from other purin bodies and particularly from theophylline and its salts by its ready solubility in water, its rapid absorption quality and its completely non-irritating powerful action. It is used as a diuretic, particularly in the

treatment of œdema of cardiac origin or when complicated with arterio sclerosis. Of particular significance is the fact that euphyllin surpasses all other purin bodies as a peripheral vasodilator. The remarkable vasodilatation of the coronary system accounts for the success obtained in the various manifestations of coronary sclerosis, angina pectoris, cardiac asthma, etc. It is administered orally, rectally, intravenously or intramuscularly and is supplied in the form of tablets containing 0.1 gm. ($\frac{1}{2}$ gr.) suppositories containing 0.36 gm. ($5\frac{1}{2}$ gr.), or ampoules containing 0.48 gm. ($\frac{7}{8}$ gr.) in 2 c.cm. of distilled water.

Eusol (*Liquor acidi hypochlorosi compositus*). The solution contains approximately 0.27 per cent. hypochlorous acid with small amounts of calcium biborate and calcium chloride. The drug may be employed as a lotion or as a bath to wounds and has been extensively used during the war. The object is to secure the maximum effect with minimum irritation. Varicose ulcers, lacerated wounds, severe burns, cystitis (1 in 8 for irrigation), tuberculous sinuses and ulcers, hydatid cyst (douche with 2 pints half strength), septic cellulitis, tuberculous osteomyelitis, necrosis of the lower jaw, acute streptococcal infections, tuberculous empyema, gonorrhœal discharge (1 in 5), tonsillectomy (spray) were a few cases of the many cited by the medical research committee that were successfully treated with eusol and eupad.

Euquinine. See page 583.

Ferrolax. It contains in each teaspoonful, ferrous iron 3 gr., (7 gr. of ferrous carbonate), yeast 30 gr., copper $\frac{1}{10}$ mgm., manganese $\frac{1}{10}$ mgm. and cobalt $\frac{1}{10}$ mgm. It is recommended for the treatment of microcytic anæmia and certain other forms of nutritional anæmias. It has been shown that small quantities of cobalt increase the size of the red blood cells, thus increasing the total volume of the blood. Manganese, it is claimed, reduces the toxic effect of the copper and cobalt and has a direct effect on the endocrine activity. The yeast is added to provide vitamin B. *Dose.*—1 to 2 teaspoonfuls twice or thrice daily before meals.

Ferratin. It is a reddish brown powder, consisting of iron (7 per cent.) in combination with albumin and is prepared from egg albumin and tartarated iron. It is claimed to be a food and the best form of substance for the administration of iron. *Dose.*—5 to 10 gr.

Fibrolysin. It is a double salt of thiosinamin and sodium salicylate and is a white crystalline powder, freely soluble in water. Thiosinamin itself is obtained from oil of mustard by the action of ammoniated alcohol, it is also known as Rhodallin, Allylsulpho-carbamide, and Allyl thio-urea. Fibrolysin is supplied in sterilised ampoules or glass capsules, containing about 40 min. of a 15 per cent. solution for one hypodermic dose corresponding to 3 gr. thiosinamin. Martindale's injection is composed of thiosinamin 20, antipyrine 33, eucaine lactate 0.65 and water to 100 parts and may be used in every case instead of fibrolysin in doses of 8 to 16 min. hypodermically. These injections were at one time considered to have great value in causing the absorption of pathological fibrous tissue.

Fermamint. It is the name given to tablets containing formaldehyde in combination with sugar of milk; they give off small quantities of formaldehyde in the mouth, and are employed in pharyngitis and

tonsillitis. Formolyptol is a composite mouth-wash containing various balsams combined with formaldehyde; its action resembles formosyl gargle, which contains essential oils with formaldehyde.

Fouadin. It is a complex trivalent antimony compound, stated to be sodium antimony pyrocatechin disulphonate of sodium. It is introduced for the treatment of bilharziasis and granuloma inguinale in place of antimony and potassium tartrate. Schistosomiasis is cured by intramuscular injections of 1 to 5 c.cm. of 7 per cent. solution. *Dose.*—1.5 to 5 mls. until a total of 40 to 45 mls. has been given.

Gelsemium. Gelsemium radix has been used as febrifuge, anti-spasmodic and analgesic. It has also been used in acute and chronic neuralgia, toothache, uterine and ovarian pain and chorea. *Dose*—5 to 15 gr.

Gentian violet. The product used therapeutically is purified methyl violet and consists of a mixture of the hydrochlorides of hexa- and pentamethyl pararosaniline with some tetramethyl-pararosaniline hydrochloride. The drug is employed intravenously in septicæmia and endocarditis. It has also been tried in encephalitis. The dye is stated to be specific for Gram-positive group of organisms only. For direct application a solution, 1 in 500 or 1 in 1000, has been recommended. *Dose.*—0.007 gm. per kilo intravenously in a $\frac{1}{2}$ to 1 per cent. aqueous solution. It is also used for intestinal parasites in doses of 1 to 3 gr. by the mouth.

Haliverol. It is a combination of halibut-liver oil with irradiated ergosterol, and is stated to be 60 times as potent in vitamin A, and 250 times as potent in vitamin D as cod-liver oil. Haliverol is darker in colour than cod-liver oil, and has a slightly fishy, but not unpleasant taste. The dose is so small that no difficulty is experienced in administration. It is recommended for the treatment of rickets, malnutrition and tetany in children, and for adults during pregnancy, lactation, and at times of lowered resistance to respiratory infections. Three drops of haliverol is equivalent to one teaspoonful of cod-liver oil. Infants and children can be given up to 30 drops daily. A dose of 10 to 15 drops three times a day is suitable for adults.

Helmitol. It is an anhydro-methylene citrate of hexa-methylene-tetramine. It is employed in similar doses to its parent substance, urotropine as a urinary antiseptic, and acts by the liberation of formaldehyde.

Haliverol. It is a concentrated sterile solution of the anti-anæmic factor of the mammalian liver, prepared for intramuscular injection in the treatment of pernicious anæmia. An initial dose of 4 c.cm. should be given followed by 2 c.cm. daily for 3 or 4 days. A normal blood count is usually obtained after the administration of 10 to 12 c.cm. and can be maintained by doses of 2 c.cm. at intervals of 2 to 6 weeks.

Hepol. It is a concentrated tasteless preparation containing the active principle of liver supplied in the form of capsules, powder and liquid, and also as a sterilised solution for intramuscular injections. The capsules are equivalent to $\frac{1}{2}$ oz. and 1 oz. of fresh liver. Hepol in sterilised solution is supplied in 2 c.cm. and 5 c.cm. ampoules containing the active principle of 40 and 100 gm. of liver but has the

therapeutic activity of at least 1000 gm. taken by mouth. For intravenous injection, the solution may be diluted with four parts of normal saline, and the solution warmed to blood heat before injection. Intravenous injections should be made slowly at not more than 2 c.cm. per minute.

Histamine. It can be injected hypodermically in doses of one mgm. (1/64 gr.), and this is not toxic to man. Its general action is vagotropic and more pronounced in the vagotonics.

Histidine (Larostidin). It consists of a sterile, isotonic 4 per cent. solution of histidine monohydrochloride and is a new and highly successful method of dealing with gastric, duodenal and jejunal ulcers. It is given as subcutaneous or intramuscular injection in doses of 5 c.cm. Treatment consists in the daily administration of one larostidin ampoule for about three weeks. No other therapy is necessary after this. After 4 or 5 larostidin injections pain disappears and nausea, vomiting, hyperacidity, etc., are relieved. After ten days a normal diet may be resumed. Important features of the larostidin treatment are its comparatively moderate cost and its avoidance of special ulcer diet, prolonged rest treatment and operative measures.

Hexylresorcinol (Caprokol, dihydroxy-4-hexyl benzol). It is a stable compound forming white crystals. It is a powerful germicide and the power is retained in both acid and alkaline urine even in high dilution. Given by mouth, the compound is secreted in the urine at a rate producing continuous action in the urinary tract. Early cases of Bact. coli and Staphylococcal infections of the urinary tract have been successfully treated with the drug. It is of value in disinfection of wounds draining the urinary tract. The anthelmintic effect of the drug in hookworm, trichina and ascaris infections, has been stated to be good. *Dose.*—2 to 10 gr. thrice daily. Gelatin capsules containing 0.15 gm. in 25 per cent. olive oil solution are taken immediately after each meal thrice daily, three to four being taken on each occasion.

Hydnocarpus oil (Oleum hydnocarpi, B. P. 1932). It is a fatty oil obtained by cold expression from the seeds of *Hydnocarpus wightiana*, an Indian tree of the same natural order as *chaulmoogra*, to which it is now preferred. *Dose.*—5 to 15 min. gradually increased to 60 min. by subcutaneous or intramuscular injection, 30 min. gradually increased to 75 min. (See page 917).

Ethyl esters of hydnocarpus oil (Oleum hydnocarpi æthylicum, B. P. 1932). It consists mainly of the ethyl esters of *chaulmoogric* and *hydnocarpic* acids, and is prepared by esterification of the fatty acids of *hydnocarpus* oil with ethyl alcohol. *Dose.*—1 c.cm. intramuscularly.

Sodium hydnocarpate. The sodium salt of the low melting-point fatty acid of *hydnocarpus* oil. *Dose.*—10 c.cm. of a 1 per cent. solution. (See page 926).

Iccoral. It is used as a combined circulatory and respiratory stimulant in infectious diseases, after operations, in cases of poisoning, asphyxia of the new-born, and prophylactically before lumbar anæsthesia. The normal dose is 2 c.cm. of the 5 per cent. solution to be injected intramuscularly, 2 to 4 c.cm. subcutaneously, or 0.5 to 1 c.cm. intravenously (injected slowly). In children, 1 c.cm. of the 0.5 per cent. solution is given.

Iodized oil. It is indicated in bronchiectasis, chronic bronchitis, atelectasis of the lung, bronchial asthma, acute laryngitis and tracheitis. It is definitely contraindicated in acute tuberculosis and acute abscess of the lung. The oil is introduced into the tracheo-bronchial tree after the pharynx, larynx and upper portion of the trachea have been sprayed with 1 per cent. cocaine solution. Warmed iodized oil is dropped directly into the trachea from a 10 c.cm. syringe with attached laryngeal canula. An initial installation of 5 to 10 c.cm. may be given but usually 10 to 20 c.cm. can be given at the first treatment. This is repeated daily for several days.

Isphagula (*Plantago ovata*). See page 416

Kalzana. It is calcium-sodium-lactate, and is given in larger doses than those of 15 gr. and is recommended as a popular preparation for oral calcium administration. It has no advantage over calcium lactate.

Kurchi (*Holarrhena anti dysenterica*). See page 398.

Krysolgan. It is the sodium salt of p-amino-o-aurophenol carbonic acid. It was introduced by Feldt in 1917 for the treatment of tuberculosis. After an extended trial it proved of little use and has been replaced entirely for this purpose by sanocrysin. Krysolgan was also used in the treatment of lupus erythematosus and here proved to have of distinct value. Schamberg has recently shown that sanocrysin is even more effective, and in some cases eruptions of long-standing disappear rapidly after two or three injections. Prolonged and careful treatment may be necessary, however, and some patients are completely resistant to gold treatment. The drug is given intravenously and the initial dose should be from 0.01 to 0.025 gm. (1/6 to 3/8 gr.) dissolved in 5 c.cm. of sterile distilled water. Subsequent doses at weekly intervals are increased by 0.01 gm., with a maximum dose of 0.075 to 0.1 gm. If reactions such as fever, rigors, vomiting, diarrhoea, stomatitis, albuminuria, rashes, or signs of shock occur subsequent doses should be smaller and only continued after the reaction has subsided completely. In the event of a severe reaction the drug must be discontinued. Cases of the disseminated type of lupus erythematosus often show extreme idiosyncrasy to gold salts, and if used at all here, the dose should not exceed 0.005 gm. to begin with, and the maximum dose should not be greater than 0.025 gm.

Leeches. Two varieties of leech are in common use. *Hirudo medicinalis*, the speckled leech, which has six stripes and a yellow spotted belly; and *Hirudo quinquestriata*, the Australian leech, which has five stripes and a spotless yellow belly. Leeches provide a valuable means of counter-irritation, and are particularly useful for the relief of pleuritic or pericardial pain. In the early stages of lobar pneumonia, for instance, half-a-dozen leeches applied to the affected side will frequently secure quick relief. Again, for the pain associated with the engorged liver of heart failure the application of a few leeches often brings relief. They should be applied when possible over areas where gentle pressure will readily arrest any excessive hæmorrhage from the bites, and in applying them they should not be touched by the fingers, but simply inverted on to the skin from a small wooden box. The part should be clean and free from soap or antiseptics and if the

leech refuses to bite, a small scratch with a needle on the skin will readily overcome the difficulty. They should be allowed to drop off in the ordinary way, but if required to be removed a little salt sprinkled over their backs acts as a brisk emetic and they drop off at once. A healthy leech will usually abstract about 2 dr. of blood, and if further bleeding from the bites is required a hot fomentation may be applied or the part may be cupped. Excessive bleeding from leech bites is rare, but if it occurs, pressure and the application of a little adrenalin solution on gauze will arrest it.

Lipiodol. It is an iodised poppy-seed oil containing 40 per cent. of iodine (0.54 gm. per c.cm.). It has an amber colour and faint garlic odour and is practically tasteless. The high content of iodine renders it opaque to X-rays, and it is now used extensively in radiological diagnosis following the pioneer work of Sicard and Forestier in Paris. In the diagnosis of bronchial obstruction or of bronchiectasis a radiograph taken after the introduction of lipiodol into the bronchial tree is frequently indispensable. The oil is introduced under local anaesthesia either by a laryngeal catheter or by a syringe and stout needle through the crico-thyroid membrane. About 20 c.cm. are sufficient to outline the bronchial tree on one side in an adult. For children 5 to 10 c.cm. may be used. It is also used in the radiological survey of bronchial or pleural fistula, urethral strictures, and spinal tumours. For the latter two special varieties of lipiodol are used, *lipiodol radiologique ascendant* containing 10 per cent. of iodine, and *lipiodol radiologique descendant* containing 85 per cent. of iodine. The former is introduced into the subarachnoid space by lumbar puncture in quantities of 1 or 2 c.cm. after withdrawal of a few c.cm. of cerebro-spinal fluid.

Lobeline. It is the alkaloid obtained from *Lobelia inflata* and has a powerful stimulant action upon the respiratory centre, lowering the threshold to carbon dioxide. It has been tried clinically in respiratory failure during anaesthesia, but its effects are uncertain. In morphine poisoning and asphyxia neonatorum it has been used with success. *Dose.*—for adults $\frac{1}{2}$ gr. hypodermically, and for children 1/20 gr.

Marmites. See page 200.

Mercurochrome-220 soluble. See page 747.

Myocrisine (Sodium aurothiomalate). It is a pale yellow powder, containing 50 per cent. of gold. Myocrisine is supplied in aqueous solution and in oil suspension for intramuscular injections in the treatment of pulmonary tuberculosis, rheumatoid arthritis and lupus erythematosus. Myocrisine injections are practically painless, and give rise to no local reactions. The aqueous solution can be given by subcutaneous injections. The ampoules are supplied singly or in boxes of ten in doses of 0.01, 0.05, 0.10, 0.20, 0.3 and 0.5 gm. The injections are given weekly, the dose being gradually increased until an average total dosage of 2 gm. has been given. The course may be repeated after an interval of one month or six weeks.

Methylene blue. The drug is analgesic and is of service in rheumatism and painful nervous affections. It has also been used in malaria, nephritis and retinitis. The usual dose of the drug is 1 to 4 gr. given in pill, cachet or capsule. A dose of 1 gr. has been used hypodermically.

The drug has also been used in 2 dr. doses thrice daily in actinomycosis. It has also been used in other affections such as black water fever, ulcerative colitis (irrigation with 1 in 1,000 solution), cystitis (2 per cent. solution), dysentery (rectal injection with 1 in 5,000), chronic suppurative otitis media and conjunctivitis (1 in 500), intertriginous eczemas (3 to 5 per cent. solution) and purulent discharges from the eye socket (0.1 per cent. solution).

Neostibosan. See page 444

Neptal. It is the mercury salt of salicylaminoacetic acid, and is now used as an alternative to novasurol or salyrgan for the production of diuresis in cardiac cedema. It has the advantage that it may be given by intramuscular injection without local irritation. It is a powerful diuretic in congestive heart failure, and the response is within a few hours, and continues for 48 hours. It is given as a 10 per cent. solution in doses of 1 or 2 c.cm. intravenously or intramuscularly and may be repeated, if necessary, after a few days.

Neotropin. It is a dye of the azo-pyridin series, possessing a marked power of penetration and tissue affinity and is bactericidal even in a dilution of 1 in 520,000, 2 or 3 hours after administration, its presence can be observed by the yellowish red colour of the urine. Neotropin is recommended for the treatment of all bacterial infections of the bladder and kidneys. Its antiseptic properties are not dependent on the reaction of the urine. It is also claimed to have a sedative effect on the acute inflammatory symptoms. Neotropin is supplied in dragees of 0.1 gm. (1.5 gr.) and the dose is 4 to 6 dragees daily after meals. In prolonged treatment an interval of two or three days is advisable after every 5 days treatment.

Novalgin (sodium phenyl-dimethylpyrazolone methyl-amino-methane-sulphonate). It is claimed to be an anti-rheumatic, suitable for the treatment of articular and muscular rheumatism and better tolerated than salicylates. *Dose.*— $7\frac{1}{2}$ to 15 gr. three times daily for adults, and proportionately less for children.

Novasurol. It is the sodium salt of oxy-mercuri-o-chlorophenoxy-acetate of diethyl-barbituric acid, and contains 33.9 per cent. of mercury in a non-ionisable form. It is used as a neutral sterile 10 per cent. solution in doses of 1 c.cm. by intravenous and intramuscular injections. (See page 750).

Novatophan. It is the ethyl ester of methyl-cinchophen, and has been introduced as a substitute for atophan in the treatment of gout and as an alternative to salicylates in the rheumatic diseases. It is a pale yellow crystalline powder without odour or taste, and is nearly insoluble in water and dilute alkalis. Like atophan the drug greatly increases the excretion of uric acid by lowering the renal threshold for this substance. *Dose.*—0.5 gm. or 8 gr.

Nuclein or nucleol. It is a principle of varying and complex composition always containing phosphorus and generally sulphur obtainable from yeast, spleen, liver, milk, yolk of egg, etc. The nuclein from yeast which is chiefly nucleinic or nucleic acid or its soda salt is the one most frequently employed. When nuclein is administered by the mouth or hypodermically, a great increase in the white corpuscles rapidly follows

and the blood serum is found to be strongly toxic to most microbes. Yeast nuclein is soluble in alkaline solutions, it may be given in doses of 10 gr. in water six times a day, or in doses of $\frac{1}{2}$ gr. hypodermically, much larger doses have been given. Mourek's hypodermic solution is made by dissolving $7\frac{1}{2}$ gr. of splenic nuclein in as much as 5 per cent. soda solution as will cause it to dissolve; $7\frac{1}{2}$ gr. carbolic acid are added, and water to 26 dr. Of this $\frac{1}{2}$ to 2 dr. may be injected. A solution of yeast nuclein, of 5 per cent. strength is obtainable, the dose of which is 1 dr.

Omnopon or pantopon. It is a brown powder containing the hydrochlorides of all the twenty alkaloids of opium, half of its weight consisting of morphia. It is said to have less action on the respiratory centre than morphia and it is recommended hypodermically in twilight anæsthesia in 15 min. doses of a 2 per cent. solution; $\frac{1}{6}$ to $\frac{1}{3}$ gr. hypodermically has been given as a hypnotic in mania.

Opocalcium. It is a combination of parathyroid, suprarenal and thymus glands, with the phosphate, glycerophosphate, fluoride, and carbonate of calcium, magnesium phosphate, and manganese nucleinate. It is recommended for the remineralisation of the body in tuberculosis, pregnancy, fractures, etc. Opocalcium associated with irradiated ergosterol is known as irradiated opocalcium. *Dose.*—for adult, six tablets or three dessertspoonfuls of the granules daily, children under ten years should receive half the adult dose.

Ostellin. It is the unsaponifiable fraction of cod-liver oil and contains the active medicinal properties of the oil concentrated 2,000 times. For convenience of administration this extract is suspended in glycerine so that 4 min. are equivalent to 1 dr. of the original oil. It affords a convenient means of giving large doses of vitamins A and D and at the same time avoiding the fatty constituents of codliver oil which are rather apt to cause nausea and digestive disturbances.

Pandigal. See page 248.

Papain or papayotin. It is a ferment prepared from the juice of the unripe fruit of *Carica papaya* in the form of a white powder. It possesses the power of digesting animal substances; 1 dr. will peptonise 200 gr. pressed blood fibrin. Papayotin is, strictly speaking, the milky juice obtained by incisions made into the unripe fruit collected and dried. The words *papain and papayotin are, however, now used synonymously. The ferment will act in an acid, neutral, or alkaline medium which gives it advantages over pepsin. Moreover, the action of papain continues all down the intestines, whilst that of pepsin ceases in contact with the alkaline juices. Its activity is variable, however, and always much less than that of pepsin. There is no other combination which will give so good results in many gastric affections as, papain 3 gr., sodii bicarb. 30 gr., mag. carb. pond. 20 gr., bism. carb 10 gr., morphine hydrochlor. $\frac{1}{18}$ gr. The drug can be given in tablets, with or without soda, and as glycerinum papain of any strength.

* **Para-thormone (Lilly).** It is a stable, aqueous solution containing the active substance of the parathyroid glands of cattle, and is prepared by the method of acid extraction developed by Collip. The extract is standardised by the increase in blood-serum calcium which follows

an injection; 1 unit is defined as 1/100 of the amount required to cause an increase of 5 mgm. in the blood-serum calcium of a 20 kg. dog fifteen hours after injection. The extract is supplied in 5 c.cm. ampoules containing 100 units. To prevent the recurrence of tetany doses ranging from 10 to 25 units daily are usually sufficient. In infants 10 to 20 units daily are advocated. The effect of a single dose reaches its peak in 12 to 18 hours, and continues for 24 to 36 hours. One injection daily or every other day is usually sufficient in chronic tetany.

Peptone. This is a white powder, being the proteins and albuminoids prepared by peptonising meat. Many varieties of peptonised beef, wheat, and milk preparations are available as foodstuffs in dyspepsia. Peptone can be used to produce desensitisation to protein substances and it has been used in the treatment of allergic diseases such as asthma, hay fever, urticaria, Quincke's oedema, eczema and certain diarrhoeal affections; 5 gr. are given, dissolved in 5 c.cm. saline solution, the dose being increased to 15 gr. in the third week. Umber has used a sterile 5 per cent. solution of the alcohol soluble fraction of peptone (Witte) with the addition of 1 per cent. novocaine. This solution he injected in quantities of 5 to 10 c.cm. subcutaneously on three successive days. Schiff used a 33 per cent. solution prepared by mixing water and glycerine to Armour's dry peptone, ensuring solution by friction and gentle heating. The preparation was then filtered and sterilised; 3 min. is a safe initial dose, and this was increased by 1 min. at biweekly or triweekly intervals up to 1 c.cm. He claimed that relief followed such treatment in a considerable number of asthmatic patients, and other writers have established that such treatment has a place in the management of asthma when a definite allergic factor can be shown to be present.

Phanodorm (Cyclohexenyl ethyl-barbituric acid). It is a white powder with bitter taste, and resembles veronal in its actions, but is excreted more rapidly so that its action is not so lasting. It is mainly used as a sedative in nervous insomnia, neurasthenia, and psychoses, in doses of $1\frac{1}{2}$ gr. up to 6 gr.

Phenolphthalein dyes. A number of derivatives of phenolphthalein in which bromine or iodine is combined in the molecule have recently been introduced for testing kidney and liver functions. All of them are excreted in the urine and bile and may be estimated colorimetrically in the former or in the case of the biliary tract their presence may be shown by their opacity to X-rays. Sodium phenoltetraiodophthalein contains about 58 per cent. iodine, and following intravenous injection in doses up to 2.5 gm. as an 8 per cent. solution or administered by the mouth in doses up to 4 gm. in capsules it appears in the normal gall-bladder in sufficient concentration to produce a well-defined shadow on X-ray examination. It is usually given overnight and the stomach is kept empty till the following morning, when a small meal of cream or other fat is given and the radiograms are then taken at intervals. In order to use the dye for the determination of liver function, the amount present in the blood serum is determined $\frac{1}{2}$ hour and 1 hour after the intravenous injection by comparison with standard solutions. Sodium tetrabromophenolphthalein contains about 47 per cent. of bromine and sodium tetraiodophenolphthalein contains not less than 58 per cent.

of iodine both are used to visualise the gall bladder by X-ray examination. The former is given intravenously in doses of 0.1 gm. per kilo, 4 to 5 gm. dissolved in about 40 c.cm. of freshly distilled water being used for an adult. Sodium tetraiodophenolphthalein may be given in this way in smaller doses up to 8 gm., but is more usually administered orally in doses up to 4 gm. in capsules.

Plasmoquine. See page 590.

Protargol (Silver protein or novargin). It is a compound of silver and albumose,* and contains 8 per cent. silver. It is a powerful anti-septic, is very soluble and highly penetrating, and is not precipitated by albumin, and is practically non-irritating. It is a very efficacious remedy for gonorrhoea when injected in $\frac{1}{2}$ per cent. solution three times a day, increased to 2 per cent. A 20 per cent. solution is used as a prophylactic against gonorrhoea. It is extensively used in eye surgery.

Pyridium. It is an azo dye containing 28 per cent. nitrogen. When given by mouth it is absorbed readily, is non-toxic, and non-irritant, and is rapidly excreted through the urinary tract where it has a bactericidal action against staphylococci, streptococci, gonococci, and Bact. coli. It is usually given by mouth in doses of 3 gr. thrice daily in capsules or as tablets; 0.3 per cent. solution is used for urethral injection, which must be prepared with distilled water, as the salts present in tap water may precipitate the free base from the solution.

Radiostol. Radiostol, in the form of pellets or solution in arachis oil, is standardised in terms of the international standard, which contains 1,000 units of vitamin D activity per c.cm. The usual dose for the treatment of rickets, tetany, etc., is two or three pellets or 30 drops of the solution daily. *Radiostoleum* is a similar preparation containing a concentrate of vitamin A added to radiostol. It may be given as the oily solution in doses of 10 to 20 drops daily, or in capsules 1 to 3 daily.

Radio-malt. It is a combination of radiostoleum with measured concentrates of vitamins B₁ and B₂, and is given in doses of 1 to 4 dr. two or three times daily. *Vioosterol* is a similar preparation to radiostol, and contains 10,000 units of vitamin D each c.cm., the daily curative dose for rickets should not be less than 2 c.cm. *Adexolin* is a preparation containing both vitamins A and D; each capsule contains 150 units of vitamin A and 1,000 units of vitamin D, three or more may be given daily as required.

Radium. See page 136.

Salyrgan. See page 751.

Scarlet red. It is a compound of beta-naphthol, diazotised amino-azo-o-toluol, and *scarlet red sulphonate*, which has a marked power of stimulating the growth of epithelial cells, and is used in the treatment of chronic ulcers, wounds and burns in the form of an ointment containing from 4 to 8 per cent. of the dyes.

Soamin. See page 661.

Sodium morrhuate. It is the sodium salt of a fatty acid obtained by the saponification of cod-liver oil. It has recently come into use as a 5 or 10 per cent. solution for the treatment of varicose veins by injection. It has the advantage over quinine solutions that it is non-toxic, and over salicylates that it produces little pain or local inflammatory reaction. From 1 to 5 c.cm. of the 5 per cent. solution is

usually sufficient for a single injection and several veins may be treated at one sitting. Injections should be made with a fine needle from above downwards, and the patient should be standing, so that the veins are full. They should be spaced at intervals of $1\frac{1}{2}$ to 2 inches along the length of vein to be sclerosed. The effect is rapid, thrombosis occurring in the injected veins immediately.

Sodium thiosulphate. See page 694.

Solganal. See page 966.

Somnifaine (liquid hypnotic). It is an alcohol-glycerin-water solution of diethyl and allyl-isopropyl-barbiturates of diethylamine. One c.cm. is equivalent to 0.1 gm. of diethylbarbituric acid and 0.1 gm. of allylisopropyl barbituric acid. Somnifaine is recommended as a powerful hypnotic and sedative. It can be administered by intramuscular or intravenous injection, as well as orally.

Stovarsol. See page 409 and 668.

Sulfosin. It is a suspension of sulphur in olive oil, and is used for non-specific therapy by intramuscular injection. It is given as a course of injections, usually commencing with $\frac{1}{2}$ c.cm. or 1 c.cm. and gradually increasing the doses up to 5 c.cm. Sulfosin has been used in the treatment of bronchial asthma, rheumatoid arthritis, disseminated sclerosis, and various syphilitic affections of the nervous system, particularly general paralysis of the insane.

Taka-diastase. It is a yellowish-white powder, being a ferment produced by cultivating a fungus (*Eurotium oryzae*) on heated rice or bran. It changes in a few minutes 100 times its weight of starch into maltose. 2 to 5 gr. may be given in water, in the dyspepsia caused by starchy foods in cases of hyperacidity of the stomach. It is in this latter condition that the best results of the drug are observed, and it may be prescribed like papain with sodium bicarbonate.

Tannafax. A tannic acid jelly for use in treatment of burns. It is prepared with a water-soluble antiseptic base, it can be easily bathed off when removal of dead tissue is called for.

Thallium acetate. It has recently been introduced for the treatment of ringworm of the scalp especially in children. The exact dose of thallium acetate employed is usually 8 mgm. per kilo of body weight; this is administered at one time, and a second dose should not be given except after an interval of at least 2 months, as the drug is cumulative and requires 2 to 3 months for excretion by the kidneys. The salt is given by mouth dissolved in water. The hair shows signs of becoming loose within 6 to 8 days, and complete epilation is effected in from 16 to 19 days. The hair grows again after 4 to 6 weeks.

Theobromine. It is an alkaloid obtained from the seeds of *Theobroma cacao*, in white, crystalline powder, resembling caffeine in action when given in 10 gr. doses. Its sodium-salicylate compound (Diuretin) is now official. Theobromine calcium salicylate or calcium diuretin containing 48 per cent. of theobromine is used as an alternative to diuretin.

Thiosarmin. This is the name given to sulpharsphenamine prepared by Brahmachary. The doses are like those of sulpharsphenamine and used in syphilis.

Tryparsamide (Moranyl). It is sodium α -phenylglycinamide-p-arsenate, containing 24.6 per cent. of arsenic in pentavalent organic

combination. It is a crystalline powder, freely soluble in water. *Dose* — 1 to 2 gm. weekly, by injections. It is used in neurosyphilis and sleeping sickness.

* **Uroselectan B.** See page 65.

Yatren. See page 405.

Yeast. It is rich in nucleic acid and in vitamin B., is given in doses of a tablespoonful in beriberi and infections such as recurring boils. Levurine is a brown powder prepared by dehydrating yeast, and is given in 1 dr. doses.

DILUTION TABLES

(Metric System)

(Per 1 c.cm. solution)

1 in 100	10.0 mg.	1 in 600	1.66 mg.
1 in 200	5.0 mg.	1 in 700	1.43 mg.
1 in 300	3.33 mg.	1 in 800	1.25 mg.
1 in 400	2.5 mg.	1 in 900	1.11 mg.
1 in 500	2.0 mg.	1 in 1,000	1.0 mg.

(Imperial System)

STRENGTHS OF SALINE SOLUTIONS

NORMAL SALINE. Sodium chloride 90 gr., water 1 pint.

HYPERTONIC SALINE. Sodium chloride 120 gr., water 1 pint.

HYPOTONIC SALINE. Sodium chloride 60 gr., water 1 pint.

ALKALINE ISOTONIC SOLUTION. Sodium chloride 90 gr., sodium bicarbonate 60 to 120 gr., water 1 pint.

NORMAL SALINE WITH GLUCOSE. Sodium chloride 90 gr., glucose 1 oz., water 1 pint.

ROGER'S HYPERTONIC SALINE. Sodium chloride 120 gr., calcium chloride 4 gr., water 1 pint.

Weights and Measures

METRIC SYSTEM

The multiples in the Metric System are denoted by the Greek prefixes: *deka*=10; *hecto*=100, *kilo*=1,000, *myria*=10,000, the sub-divisions by the Latin prefixes: *deci*= $\frac{1}{10}$, *centi*= $\frac{1}{100}$; *milli*= $\frac{1}{1000}$.

Measures of Length

1 Kilometre	Km.	= 1000'0 M.
1 Metre	M.	= 1'0 M.
1 Centimetre	cm.	= 0'01 M.
1 Millimetre	mm.	= 0'001 M.
1 Micron	μ .	= 0'001 mm.
1 Micromillimetre	$\mu\mu$.	= 0'000001 mm.

Measures of Mass (Weight)

1 Kilogram	Kgm.	= 1000'0 Gm.
1 Gramme	Gm.	= 1'0 Gm.
1 Centigram	cgm.	= 0'01 Gm.
1 Milligram	mgm.	= 0'001 Gm.

Measures of Capacity

1 Hectolitre	Hl.	= 100'0 L.
1 Litre	L.	= 1'0 L.
1 Centilitre	cl.	= 0'01 L.
1 Millilitre	mil.	= 0'001 L.
1 Decimil	dml.	= 0'0001 L.
1 Centimil	cml.	= 0'00001 L.

Cubic centimetre (c.c.m.). For practical purposes the cubic centimetre is generally used in the measurement of fluids and is regarded as equivalent to the millilitre (mil.) (1 mil. = 1'000028 c.c.m. approximately).

Drop. It is defined as the drop from a tube, which at 15°C. delivers 20 drops of distilled water to the gramme.

Indian Domestic Measures of Mass

1 Tola	= Wt. of a Rupee (180 Gr.)
1 Chhatak	= 4 Kanchas (5 Tolas)
1 Pown	= 4 Chhataks
1 Seer	= 16 Chhataks 80 (Tolas)
1 Maund	= 40 Seers

The maund and seers used locally in different parts of India are not the same. The above measure used in Bengal are used by all the Railways and Steam Navigation Companies, etc., throughout India.

IMPERIAL SYSTEM

Measures of Mass (Weight)

AVOIRDUPOIS WEIGHT

[Used for measuring all ordinary goods]

1 Ounce (oz.)	= 16 Drachms (dr.)
1 Pound (lb.)	= 16 Ounces
1 Stone (st.)	= 14 Pounds
1 Quarter (qr.)	= 2 Stones
1 Hundredweight (cwt.)	= 4 Quarters
1 Ton	= 20 Hundredweight

TROY WEIGHT

[Used for weighing gold, silver and precious stones]

1 Pennyweight (dwt.)	= 24 Grains (gr.)
1 Ounce (oz.)	= 20 Pennyweights
1 Pound (lb.)	= 12 Ounces
1 Pound Troy = 5,760 grains	
1 Pound Avoir = 7,000 grains.	

APOTHECARIES' WEIGHT

[Now used by apothecaries for retail sale only.]

1 Scruple (scr.)	= 20 Grains (gr.)
1 Drachm (dr.)	= 8 Scruples
1 Ounce (oz.)	= 8 Drachms
1 Pound (lb.)	= 12 Ounces (5,760 gr.)

The 'Grain' has the same weight throughout.

MEASURES OF CAPACITY

1 Fl. Drachm (fl. dr.)	= 60 Minims (min.)
1 Fl. Ounce (fl. oz.)	= 8 Fl. Drachms
1 Pint (pt.)	= 20 Fl. Ounces
1 Gallon (gal.)	= 8 Pints

One 'Minim' is the volume at 62°F. of 0'0114583 grain of water.

English Domestic Measures

1 Teaspoonful	= 1 fluid dr.
1 Dessertspoonful	= 2 fluid dr.
1 Tablespoonful	= 4 fluid dr. ($\frac{1}{4}$ oz.)
1 Wineglassful	= 2 fluid oz.
1 Teacupful	= 5 fluid oz.
1 Tumblerful	= 8 fluid oz.
1 Quart	= 32 fluid oz

CONVERSION OF MEASURES

LENGTH—

1 Kilometre	= 0·6214 mile
	= 1093·6 yards
1 Metre	= 39·3701 inches
	= 3·2809 feet
	= 1·0936 yards
1 Centimetre	= 0·3937 inch
1 Millimetre	= 0·0394 inch
1 Inch	= 2·54 centimetres
1 Foot	= 30·48 centimetres
1 Yard	= 0·9144 metre
1 Mile	= 1·6093 kilometres

CAPACITY—

1 Litre	= 1·7598 pints
	= 0·2203 gallon
	= 0·0858 cubic foot
	= 35·196 fl. oz.
1 c.cm. (mil.)	= 16·89 minims
	= 0·28152 fl. dr.
	= 0·03519 fl. oz.
1 Minim	= 0·0592 c.cm.
1 Pint	= 0·5683 litre
1 Fl. Ounce	= 28·416 c.cm.
1 Fl. Drachm	= 3·552 c.cm.
1 Cubic Foot	= 28·38 litres
	= 6·225 gallons
1 Cubic Inch	= 16·386 c.cm.
1 Cubic Metre	= 35·316 cubic feet
1 Gallon	= 4·54596 litres
	= 0·16037 cubic foot
	(Vol. of 10 lb. water at 62° F.)
1 Eng. Gallon	= 1·2 U.S.A. Gallons
1 U.S.A. Gallon	= 0·833 Eng. Gallon

MASS (Weight)--

1 Kilogram	= 2·2046 pounds (Av.)
	= 85·27 ounces
	= 1·0715 seers
1 Gramme	= 15·43236 grains
	= 0·03527 ounce
1 Milligram	= 0·01548 grain
1 Grain	= 0·0648 gramme
	= 0·00228 ounce
1 Ounce (Av.)	= 28·3495 grammes
	= 437·5 grains
	= 2·4803 tolas
1 Ounce (Tr.)	= 31·104 grammes
	= 460 grains
	= 2·6666 tolas
1 Pound (Av.)	= 453·592 grammes
	= 7,000 grains
	= 0·4861 seer
1 Pound (Tr.)	= 373·25 grammes
	= 5,760 grains
	= 0·4 seer
1 Stone	= 6·35029 kilogram
	= 6·804 seers
1 Hundredweight	= lmd. 14sr. 7½ch.
1 Ton (Av.)	= 27·2 maunds
1 Tonne (Metric)	= 0·984 ton (Av.)
1 Maund	= 82·3 pounds (Av.)
	= 100 pounds (Tr.)
1 Seer	= 80 tolas
	= 0·9881 kilo.
	= 2·0571 pounds (Av.)
	= 2·5 pounds (Tr.)
1 Chattak	= 5 tolas (2 fl. oz.)
1 Tola	= 180 grains
	= 11·664 grammes

Weights of Indian Coins

1 Gold Sovereign	= 128 grains
1 Silver Rupee	= 180 grains
1 Silver 8-anna bit	= 90 grains
1 Silver 4-anna bit	= 45 grains
1 Silver 2-anna bit	= 22·5 grains
1 Nickel 4-anna bit	= 104 grains
1 Nickel 2-anna bit	= 88 grains
1 Nickel 1-anna bit	= 60 grains
1 Copper pice	= 76 grains
1 Copper half-pice	= 88 grains
1 Copper pie (½ pice)	= 25 grains

Arithmetical Memoranda

Ratio of circumference of a circle to diameter	= π = 3·14159 or $\frac{22}{7}$
Circumference of a Circle	= $2\pi r$
Area of a Circle	= πr^2
Surface of a Sphere	= $4\pi r^2$
Volume of a Sphere	= $\frac{4}{3}\pi r^3$
Volume of a Cone	= $\frac{\pi r^2 h}{3}$

WEIGHTS AND MEASURES USED IN DIFFERENT COUNTRIES AND FOREIGN CURRENCY

The Value given is that at par. Current quotations can be obtained from the daily newspapers

Allow 1½ inches for shoes and 6 pounds for clothes.

The average height and weight, in the majority of Indian Races, is lower than that of Europeans. Buchanan gives the average weight of a Bengali at 109 lb., and Lewis, of a U. P. man, at 110 lb.

Buchanan's formula for calculating the weight from the height is 5 feet=100 lb., and add 8 lb. for every full inch above 5 ft.; or in men over 5 ft. 8 in., add 4 lb. for each inch. Example: 5 ft. 6 in.=100+8×6=118 lb.

ANATOMICAL AND PHYSIOLOGICAL NORMALS

In examinations in the pathological or chemical laboratory the following may be considered approximately as normal findings :

ADRENALS. Length 2.4 to 2.8 in. Breadth 1.2 to 1.4 in. Weight 0.17 to 0.21 oz. each. Left usually larger.

APPENDIX. Length, quite variable, 3.5 to 4 in. Diameter 0.25 in. Weight 0.25 to 0.5 oz.

BLADDER. Capacity 16 oz. when normally distended. Thickness of wall 0.1 in. Weight 1 to 2.1 oz.

BRAIN. Weight, female 44 to 45 oz., male 48 to 51 oz. Length 6.5 in. Transverse diameter 5.5 in. Vertical diameter 5 in. Dimensions in female being 0.4 in. less.

GALL BLADDER. Length 3 to 4 in. Diameter 1 to 1.25 in. Thickness of wall 0.04 to 0.07 in. Capacity 1 to 1.5 oz.

HEART. Weight, female 8.8 to 9.8 oz., male 9.5 to 12.7 oz. Length 4.5 to 5.5 in. Breadth 3 to 4 in. Thickness 2 to 3.1 in. Thickness, wall left ventricle 0.35 to 0.47 in., right ventricle 0.1 to 0.12 in.

1712 ANATOMICAL & PHYSIOLOGICAL NORMALS

Circumference, mitral orifice 4.1 to 4.3 in. Circumference, tricuspid orifice 4.7 to 5 in. Circumference, aortic orifice 3 to 3.2 in. Circumference, pulmonary orifice 3.4 to 3.6 in.

INTESTINES. Small intestine, length 22.5 ft.; $2/5$ jejunum and $3/5$ ileum Diameter from 1.85 in. in duodenum to 1.06 in. at the end of ileum. Large intestine, length 70.9 to 76.8 in. Duodenum, length 10.2 to 11.2 in.

KIDNEYS. Weight, left 5.3 oz., right 5 oz. Thickness of cortex 0.4 in. Length 4.5 in. Breadth 2.50 in. Thickness 1.25 in. The left longer and the right thicker.

LIVER. Weight 50 to 60 oz. Greatest transverse diameter 7.9 to 9.5 in. Greatest antero-posterior diameter 3.9 to 5.9 in. Vertical diameter 5 to 6 in.

LUNGS. Weight, combined 36 to 45 oz. Weight, male right lung 24 oz., left lung 21 oz. Weight, female, right lung 17 oz., left lung 14.8 oz. Length 10 to 12 in. Antero-posterior diameter at base 7.8 in. Transverse diameter at base 4 to 5 in. The right lung is shorter, broader and thicker than the left. Dimensions in the female average 1 in. less.

MAMMARY GLAND. Weight in adult 5.25 to 7 oz. Weight during lactation 14 to 31.75 oz.

ESOPHAGUS. Length 10 to 12 in. Diameter of lumen 1.25 in. Thickness of wall 0.3 in. Weight 1.4 oz.

OVARIES. Weight 0.12 to 0.25 oz. Length 1.5 in. Breadth 0.75 in. Thickness 0.5 in.

PANCREAS. Weight, quite variable 2.1 to 4.8 oz. Length varies, averages 6 to 8 in.

PARATHYROIDS. Length 0.2 to 0.25 in. Breadth 0.15 to 0.17 in. Thickness 0.05 to 0.075 in.

PITUITARY BODY. Length 0.3 in. Breadth 0.5 in. Weight 5 to 10 gr.

PROSTATE. Weight 0.8 oz. Length 1.25 to 1.5 in. Breadth 1.5 to 1.75 in. Thickness 1 in.

SALIVARY GLANDS. Parotid, weight 0.8 to 1 oz. Sublingual, weight 0.06 to 0.09 oz. Submaxillary, weight 0.25 to 0.3 oz.

SPLEEN. Weight 5.5 to 6.9 oz. Length 4 to 5 in. Breadth 3 in. Thickness 1 to 1.5 in.

STOMACH. Capacity 1 to 2 quarts. Thickness of wall 0.25 in. Weight 4.5 to 6.2 oz.

TESTES. Weight 0.65 to 0.8 oz. each. Length 1.5 in. Breadth 1 in. Thickness 0.8 in.

THYMUS GLAND. Weight at birth 0.5 oz. and increases to 0.9 oz. at the end of second year when it gradually decreases until gland disappears. Dimensions at birth, length 2.4 in., breadth 1.5 in. and thickness 0.25 in.

THYROID. Transverse diameter 2.4 to 2.8 in. Height 1.2 in. Weight 1 to 1.4 oz.

URETHRA. Male, length 6.4 to 8.25 in.; prostatic 1 to 1.25 in.; membranous 0.6 to 1 in. and the anterior 4.75 to 6 in. Female, length 1.5 in. Diameter of lumen averages 0.25 to 0.6 in.

UTERUS (Virginal). Length 2.8 in. Breadth 1.6 in. Thickness 1 in. Weight 1.4 to 1.8 oz. The dimensions of a multiparous uterus are each increased 1 cm. or more and the weight is increased 0.7 oz. Length of cavity in virgin 2 in. in multiparae 2.25 in.

DENTITION TABLE

MILK TEETH. The first dentition begins at the sixth or seventh month, and is completed by about the second year.

Central incisors	(1)	lower	6th to 8th month
"	(2)	upper	7th to 9th
Lateral incisors	(1)	upper	9th to 10th
"	(2)	lower	10th to 13th
First molars			12th to 14th
Canines			17th to 20th
Second molars			2nd to 3rd year.

The full primary dentition is 20 teeth; 10 in each jaw.

PERMANENT TEETH. First molars, sixth year; central incisors, sixth to seventh year lateral incisors, eighth year; lower canines and first pre-molars, tenth year; upper canines and second pre-molars, eleventh year; second and third molars, from the sixteenth to twenty-fifth year.

RESPIRATION

Two months to two years	35 per minute
Two to six years	23 " "
Six to twelve years	20 " "
Twelve to fifteen years	18 " "
Fifteen to twenty-one years	16 to 18 " "

Respiration in the adult female is usually slightly more rapid than in the male, especially during pregnancy.

PULSE RATE AT VARIOUS AGES

<i>Ages</i>				<i>Beats per minute</i>
In the fœtus in utero	Between 70 and 80
In new-born infants	Between 150 and 140
During first year	Between 140 and 130
During second year	From 130 down to 115
During third year	From 115 down to 100
From seventh to fourteenth year	From 105 down to 95
From fourteenth to twenty-first year	From 90 down to 80
From twenty-first to sixtieth year	Between 75 and 79
In old age	Between 75 and 80

The pulse is generally more frequent in females than in males; during and after exertion, unless long continued; during digestion or mental excitement; also more frequent in the morning than later in the day. It is temporarily accelerated after a sudden change of posture from the recumbent to the sitting, and from either to the standing position, especially during convalescence; and in other states where the action of the heart is feeble.

Classification of the Anæmias

Main groups	Smaller groups	Examples of clinical syndrome	Generic characters of blood picture
1. True secondary anæmia	Due to hemorrhage, external, from mucous surface, or into serous cavities		
	(A) Following external or internal injury	(A) Severed femoral or brachial artery, rupture of spleen or hemothorax	The blood picture will depend on whether the condition is acute or chronic
	(B) Associated with disease of tissues	(B) (i) Alimentary tract from mouth to anus, e.g. (a) from teeth, from gastric, duodenal, typhoid or dysenteric ulcer, or malignant disease, or from (c) hemorrhoids (ii) Respiratory tract, e.g., from nose, or from lung (in phthisis) (iii) Urinary or genital tract, e.g., stone, malignant or benign new growth in kidney pelvis or bladder, ectopic gestation, bleeding into peritoneum, anti or postpartum hemorrhage or metrorrhagia (iv) Other tissues, e.g., suppurating wounds	(A) Will in nearly every instance be acute and (D) chronic, (B) and (C) may be acute or chronic Acute Chronic Normocytic or slightly microcytic, orthochromic Reticulocytes + + Microcytic Hypochromic + or + Erythroblasts, polychromasla, and anisocytosis Van den Bergh reaction negative No urobilin in urine
	(C) Associated with disease of the blood	(C) Congenital defect—hemophilia Idiopathic diseases—thrombocytopenia	
	(D) Associated with parasitic infections	(D) Hookworm and bilharzia infection with loss from intestinal and urinary tracts	

11. Errors of Erythro-
genesis

11. Errors of Erythro- genesis	(A) Aplasia or hypoplasia of toxic or mechanical origin	(i) Unknown causes, i.e., pri- mary	(i) Idiopathic aplastic anemia	A large and varied group, but generally Normocytic Orthochromic Reticulocytes few Van den Bergh—negative No urobilin but in all aplastic states there may be a few areas of hyperplasia in the bone marrow	
		(ii) Bacterial and metabolic toxins	(ii) Anemia of chronic sepsis, influenza, etc. Anemia of chronic nephritis		
		(iii) Chemical poisons	(iii) Anemia due to Radium, X-rays, benzol, lead, etc.		
		(iv) Mechanical interference with blood formation	(iv) Carcinomatosis, Albers- Schonberg disease, possibly the anemia of kala-azar		
		(v) Exhaustion	(v) Terminal aplasia in almost any anemia, e.g., pernici- ous anemia and anemia of sprue		
	(B) Dysplasias—nutritional	(i) Iron deficiency	(i) Hypochromic anemia of infants and others		Microcytic Hypochromic Reticulocytes ± Urobilin — live Van den Bergh — live Normoblasts
		(a) Actual	(a) Hypochromic anemia		
		(b) Relative	(b) Hypochromic anemia of pregnancy and of hookworm infection		
		(c) Failure of absorption	(c) Simple achlorhydric anemia and anemia following gastric operations		
		(ii) Deficiency of hemopoietic principle	(a) Addisonian pernicious anemia		
		(b)	(a) (Not recognised clinically)	Macrocytic Hyperchromic Urobilin + Van den Bergh ++ Megaloblasts Reticulocytes ±	
		(b) Absence of extrinsic factor	(β) Tropical megalocy- tic anemia, asso- ciated with preg- nancy and splenic enlargement		
		(a) Actual	(c) Anemia of sprue		
		(β) Relative			
	(c) Failure of absorption of combination of extrinsic and intrin- sic factors, i.e., of the hemopoietic principle				

Main groups	Smaller groups	Examples of clinical syndrome	Generic characters of blood picture
III. Errors of Erythrolysis	(iii) Deficiency of (a) Vitamin C (b) Thyroxin	(iii) (a) Anæmia of scurvy (b) Anæmia of myxedema	Microcytic Hypochromic
	(A) Conditions affecting the red cells and rendering them more susceptible to normal lytic processes	(A)	
	(i) Abnormality of red cell structure (ii) Abnormality of physical condition of red cells, e.g., increased fragility (iii) Effect of toxins, snake venoms, chemical poisons, etc. (iv) Parasitization (c) Unknown causes	(i) Sickie-celled anæmia. (ii) Acholuric jaundice, paroxysmal hæmoglobinuria (iii) Anæmia associated with streptococcal and other bacterial infections, lead poisoning, novarsenobillon injections, etc. (iv) Malaria and Oroya fever (v) Acute hæmolytic anæmia of Lederer	Microcytic or normocytic Orthochromic usually, occasionally slightly hyper — or hypochromic Reticulocytes + + Urobilin + + + Van den Bergh + + Increased fragility of red cells
	(B) Conditions causing overaction of erythrolytic tissues	(B) Splenic anæmia, and probably chronic malaria and kala-azar	As above, but decreased red cell fragility

The Hæmorrhagic Syndromes

PRIMARY HÆMORRHAGIC DIATHESSES							
	HÆMORRHAGIC		ALLERGIC		HÆMOPHILIC		Secondary or Symptomatic Purpura
	Purpura Simplex	Essential Thrombopenia	Schonlein's Purpura	Hæmoch's Purpura	Hæmophilia	Hæmogenia (Female Hæmophilia)	
Characters of exudate or hæmorrhage	Red cells only. Crops of spots	Whole blood, spots, ecchymoses, and hæmorrhages from mucous membranes after slight trauma	Serum or whole blood. Spots, urticaria and localized oedemas	Serum or whole blood. Scanty spots, urticaria. Effusion in to joints. Blood in stools	Whole blood. External bleeding and joint effusions	Whole blood. Spots. Ecchymoses. Hæmorrhages from slight injuries	Infective, Ferrile, Cachectic, Chemical, Mechanical
Blood							
(1) Red corpuscles	Diminished. Reticulocytes present	Diminished Reticulocytes present	Normal	Normal	Diminished	Diminished	Icteric Avitaminotic Anæmie, etc.
(2) Platelets	Normal	Greatly reduced	Normal	Normal	Normal	Reduced in half the cases	...
(3) Coagulation time	Normal	Normal	Normal	Normal	Normal	Normal	...
(4) Bleeding time	Increased	Greatly increased	Normal	Normal	Greatly prolonged	Greatly increased	...
Age and sex chiefly affected	Children and young adults	Any age	Young adults males	Infants or adults	Age 2 to 20. Males only. Hereditary	Females 2: Males 1	...
Prognosis	Good	Good with correct treatment; Splenectomy (in remission stage only)	Runs prolonged course	Serious	Hopeless (death before 20)	Serious. Improves in adult life	...
Therapeutic indication	Arsenic		Calcium	Optum. Serum	Snake venom (viperine). Blood transfusion restores coagulation time for short period	Arsenic. Splenectomy always contra-indicated	...
Notes	Classified sometimes under Allergic group	...	Includes rheumatic purpura	..	Transmitted by females who do not suffer	Has no relation to hæmophilia and is only transmitted by actual sufferers	...

Typical Blood Counts of Various Blood Diseases

	Normal (average)	Idiopathic Hypo- chromic anemia and chlorosis	Pernicious anemia	Leucocytosis viz. Pneumonia	Chronic mye- loid leukemia	Chronic lym- phoid leukemia
Erythrocytes {	Male 5,800,000 { Female 4,800,000 }	4,850,000 (87%)	1,200,000 (24%)	4,655,000 (98%)	2,750,00 (55%)	2,500,000 (50%)
Hæmoglobin {	Male 16 gm. { Female 14 gm. }	56% (8.1 gm.)	37% (5.4 gm.)	90% (13.0 gm.)	50% (7.3 gm.)	45% (6.5 gm.)
Colour index	1	0.64	1.54	0.97 (90 t. 98%)	0.99	0.9
Leucocytes	7,000 per c. mm.	5,700	2,500	19,600	460,000	500,000
Lymphocytes	1,890 (27%)	2,508 (44%)	1,180 (45.2%)	1,960 (10%)	4,600 (1%)	495,000 (99%)

PHYSICAL CHARACTERISTICS OF BLOOD SERUM

	Normal	In Disease
Specific gravity	1'029 to 1'031	Lowered in nephritis with œdema, anæmia and marasmus.
Refractometer* value	1'348 to 1'350	Follows the protein content.
Freezing point	-0'56°C	Abnormally low in renal insufficiency and impending uræmia.

COMPOSITION OF BLOOD SERUM (per 100 c.cm.)

	Normal	In Disease
Dried residue ...	18 to 22 gm.	Diminished in nephritis with œdema, anæmia and marasmus.
Total nitrogen	1'04 to 1'2 gm.	Diminished in nephritis with œdema, anæmia and marasmus.
Protein ..	6'5 to 7'5 gm.	Diminished in nephritis with œdema, anæmia and marasmus.
Rest nitrogen ..	20 to 35 mg.	Increased in renal insufficiency and impending uræmia.
Urea ...	80 to 40 mg.	Increased in renal insufficiency and impending uræmia.
Uric acid ...	2'0 to 3'5 mg.	Increased in gout and renal insufficiency.
Creatinin ..	1'0 to 1'5 mg.	Increased in renal insufficiency.
Sugar ...	70 to 110 mg.	Increased in diabetes mellitus.
Chlorides ...	560 to 600 mg.	Increased in nephritis with œdema.
Calcium ...	9 to 11 mg.	Diminished in tetany and in severe nephritis.

WHITE BILE

White bile is sometimes found in the biliary tract when its contents have been dammed up by some obstruction. This secretion may be found, according to the actual site of the obstruction in the dilated gall bladder or in the dilated biliary ducts where these have been isolated from the gall-bladder. In every case bile salts and pigment were entirely absent; cholesterol was present only in small amounts, if at all; chlorides were present in approximately the same concentration as in the blood serum. Calcium was found in amounts corresponding with the blood levels. (*Med. Jour. Australia*, Vol. 1, No. 3, 1935).

ABNORMAL BLOOD CELLS IN THE PERIPHERAL CIRCULATION

Cells	Cytoplasm	Nucleus	REMARKS
Adult megalo- blasts (10 to 12 μ)	Deeply basophilic	Large. Occupies most of the cells. Stains lightly. Delicate threads of chromatin often with nucleoli	Cell outline often irregular very few present in normal marrow
Erythroblasts (8 to 10 μ)	Early forms : basophilic. Late forms : polychromatic	Smaller than that of megalo- blasts. Chromatin less reticulate and more deeply stained. May be cart wheel	
Normoblast (6 to 8 μ)	Polychromatic or eosinophilic (orthochromatic)	Dense chromatin deeply stained. Sometimes acen- tric	Nucleus may be lobed or clover leaf
Embryonic hæmoglobi- nised mega- loblast (Ehrlich) (10 to 14 μ)	Polychromatic or eosinophilic	Large clear and reticular but often much more mature	Large cells are known as giganto- blasts. Very mature forms may have pyknotic nucleus

COLLECTION OF BLOOD FOR DIFFERENT EXAMINATIONS

No preparation is usually necessary except that the blood for special cases should be drawn in the morning before the patient takes any food, it is essential, however, that the specimen is properly labelled and sent to the laboratory immediately after collection.

The following table gives an idea of the approximate quantity of blood required and the method of collection.

<i>Examination or estimation of :</i>	<i>Quantity of blood. in c.cm.</i>	<i>To be collected in :</i>
Sugar ...	2	Oxalated tube
Urea ...	2	" "
Non-protein nitrogen ...	5	" "
Cholesterol ..	3	" "
Calcium (in serum) ...	3	Sterile test tube

PRINCIPAL HILL STATIONS AND HEALTH RESORTS IN INDIA

Almora (United Provinces). Altitude 5,200 to 5,500 ft. District headquarters with contonment; six hours journey by car from Kathgodam, the terminus of R. & K. Ry.; situated on saddle shaped, bare ridge. Little vegetation, rocky soil, good natural drainage. Well reputed all over India as a resort for cases of tuberculosis of lungs; with leper asylum. Rainfall 42.55 in. Season—April to October.

Bangalore (Mysore State). Altitude 3,021 ft. Seat of Government of Mysore State and headquarters of Bangalore Brigade of Indian Army. A lively specimen of Hindu town. Climate noted for its salubrity, pleasant, cool, congenial for convalescents; wettest months generally September and October. Rainfall 36.57 in.; annual normal relative humidity 78 per cent.; annual normal maximum 84.5°F. and minimum 64.2°F.

Coomoor (Madras). Altitude 6,000 ft. At the south corner of Nilgiri plateau and 10 miles from Ootacamund on Nilgiri Railway. The Pasteur Institute of Southern India; one of the principal sanatoria of the Presidency and perhaps second only to Ootacamund in natural advantages, built on one of the loveliest sites in India. Flowers, fruits, and vegetables grow in profusion all the year round. Possesses cool and equable climate; rainfall 66.56 in., well distributed throughout the year but heaviest during the north-east monsoon; annual mean temperature, 60°F with an extreme variation not exceeding 15° either way.

Cox's Bazaar (Bengal). Subdivision in Chittagong district; well known health resort. Surrounding country hilly and very picturesque, with good game; excellent sea-bathing obtainable on fine sandy beach. Rainfall 145.77 in.; annual normal relative humidity 86 per cent.; annual normal maximum 84.9°F. and minimum 69.6°F.

Dalhousie (Punjab). Altitude 7,687 ft. In district Gurdaspur, 51 miles by road from Pathankot on N. W. Ry. Scenery compares favourably with that of any hill station in Himalayan range; very pretty, moderately sized hill station with Chamba only two stages beyond; hills consist of rugged granite. Rainfall 83.38 in. Season—May to October.

Darjeeling (Bengal). Altitude 6,000 to 7,800 ft. Summer headquarters of Bengal Government, served by D. H. Ry. Queen of Indian hill stations, picturesquely situated on a long narrow ridge, with magnificent views of snows from the observatory hill and abundant vegetation. Has well equipped sanatoria, several good educational institutions. Rainfall 123.27 in., principally from June to September when the climate is very damp, but very little during cold months; annual normal relative humidity 85 per cent.; annual normal maximum 59.3°F. and minimum 47.7°F. Best time before or after rains.

Dehra Dun (United Provinces). Altitude 2,233 ft. Cold season district headquarters, on main road from plains to hill station of Mussoorie. Pretty station with large number of retired Europeans and Anglo-Indians; headquarters of Trigonometrical Survey of India; with Forest Research Institute, Military College and a Public School. Soil rocky. Rainfall 83.16 in., abundant during monsoons; annual normal relative humidity 70 per cent.; extremes of heat and cold unknown. Season—October to March.

Dharamsala (Punjab). 16 miles north-east of Kangra in the midst of wild and picturesque scenery; with beautiful waterfalls within a short distance at Bhagsu Nath; well wooded with oaks and other forest trees. Rainfall 115.75 in., atmosphere peculiarly damp during 3 months of rainy season.

Gulmarg (Kashmir). Altitude 8,500 ft. One of the loveliest and most enjoyable hill stations in India, 28 miles from Srinagar; famous for golf course; plenty of picnic spots in the neighbourhood. Accommodation in well furnished, electrically lighted wooden huts mostly owned by the State, or in hotels both European and Indian. Season—June to middle of September.

Hazaribagh (Bihar). Altitude 2,000 ft. District headquarters; picturesquely situated on high central plateau of district in the midst of conical hills, with many fine lakes in the vicinity; motorable roads in and outside the town. Temperature moderate except during hot months of April to June. Rainfall 52.73 in.; annual normal relative humidity 63 per cent.; annual normal maximum 84.6°F. and minimum 65.7°F.

Kalimpong (Bengal). Altitude 4,200 ft. Headquarters of subdivision in Darjeeling district, 28 miles by road from Darjeeling or 12 miles from Gielle Kholā the D. II. Ry. terminus. Commands beautiful view of mountain, valley, and river scenery; has well equipped Charteris hospital, also St. Andrews Colonial Homes for education and training of poor European and Eurasian children. There is a proposal to start tuberculosis sanatorium here. Climate milder than Darjeeling. Rainfall 88.34 in.; annual normal relative humidity 84 per cent.; annual normal maximum 69.5°F. and minimum 57.6°F.

Karachi (Sind). Rapidly developing sea-port at extreme end of Indus delta, with modern architecture. Climate, owing to prevalence of sea breezes during 8 months, more healthy than at any other place in Sind; hottest months April to June. Rainfall about 5 in.; annual normal relative humidity 72 per cent.; annual normal maximum 93.4°F. and minimum 68.2°F.

Kasauli (Punjab). Altitude 6,335 ft. Cantonment and convalescent depot in Ambala district; situated on the crest of the hill overlooking Kalka valley, 9 miles by bridle path and 15 miles by motor road from Kalka on N. W. Ry.; good natural drainage; Pasture Institute of India. Rainfall 61.02 in. Season—April to October.

Kodaikanal (Madras). Altitude 7,688 ft. One of the largest sanatoria in the Presidency. On a plateau of the Palney hills, a spur of Ghats, in Madura district. Reached via Kodaikanal Road station on South Indian Railway. Much resorted to by Europeans throughout the year; temperature somewhat milder than Ootacamund. Rainfall lighter and atmospheric conditions more equable than those of Nilgiris; climate of the place one of the best in India. Round about are rolling downs, with beautiful little woods nestling in their hollows and perennial streams flowing through them; lake provides fine boating and fishing; noted for its dry gravelly soil. Rainfall 63.94 in.; annual normal relative humidity 69 per cent.; annual normal maximum 64.6°F. and minimum 51.1°F.

Lansdowne (United Provinces). Altitude 5,500 to 6,600 ft. Cantonment in Garhwal district, about half way between Mussoorie and Nainital; extends through beautiful pine and oak forests for more than 3 miles. Rainfall 78.98 in.

Mahabaleshwar (Bombay). Altitude 4,500 to 4,700 ft. Principal sanatorium of Bombay Presidency in Satara District; 39 miles from Wathar on Southern Mahratta Railway. Picturesque scenery and proximity to fresh sea breeze; spring and autumn retreat of Bombay Governor and officials; favourite season March to June, but this is not the time when it is most beautiful; in October, on cessation of monsoon, it is fall of flowers and verdure; excellent drives and walks in all directions. Monsoon sets early June and worst in July. Rainfall 265.6 in.

Maymyo (Burma). Altitude 3,545 ft. Principal hill station in Burma, district Mandalay, on Mandalay Lashio Railway; occupies un-

1724 HILL STATIONS AND HEALTH RESORTS

dulating plateau surrounded by hills covered with thin oak forests and bracken; enjoys temperate and on the whole salubrious climate. Rainfall 58.62 in., heaviest in May, June, September, and October; annual normal relative humidity 86 per cent.; annual normal maximum 76.6°F. and minimum 56.4°F.

Mount Abu (Rajputana). Altitude 3,945 ft. Eighteen miles from Abu Road on B. B. & C. I. Ry.; sanatorium and celebrated place of pilgrimage. Climate very healthy and delightfully cool. Polo, golf, cricket, and boating, etc., available. Rainfall 61.80 in.; annual normal relative humidity 54 per cent., annual normal maximum 75.9°F. and minimum 62.0°F.

Murree (Punjab). Altitude 7,507 ft. Hill sanatorium and headquarters of tahsil in Rawalpindi district, 89 miles from Rawalpindi on N. W. Ry.; commands magnificent view over forest-clad hill sides into deep valleys studded with villages and cultivated fields; admirable climate, suitable for children; sanatorium for tuberculosis of lungs recently started; has Lady Roberts Home for invalid officers and Murree Brewery. Rainfall 56.90 in.; annual normal relative humidity 56 per cent.; annual normal maximum 65.1°F. and minimum 50.2°F. Season—April to October.

Mussoorie (United Provinces). Altitude 6,000 to 7,500 ft. Hill station and sanatorium in Dehra Dun District, among beautiful and varied mountain scenery; two hours drive from Dehra Dun, important as an educational centre for European children; many excellent hotels and nursing homes; massage and electric treatment available. Rainfall 93.84 in.; annual normal relative humidity 65 per cent.; mean temperature 57.1°F.

Nainital (United Provinces). Altitude 6,400 ft. Summer headquarters of the Government of United Provinces, with contonment; 21 miles from Kathgodam the R. K. Ry. terminus. Cup-shaped station with pear-shaped lake in the middle, a little more than 2 miles in circumference, with good boating arrangements, unless accommodation obtained near top, it cannot be said to be healthy. Ramsay Hospital for Europeans with large maternity block. Rainfall 97.94 in. Season—April to October.

Ootacamund (Madras). Altitude 7,327 ft. Headquarters of Nilgiri district and summer seat of Madras Government, chief sanatorium of the Presidency and one of the most beautiful hill stations in India; standing on the Nilgiri plateau, Nilgiri Railway. Station reposes in an amphitheatre surrounded by 4 hills; flowers blossom in profusion all the year round. Rainfall 52.14 in.; annual normal relative humidity 68 per cent.; annual normal maximum 65.5°F. and minimum 49.2°F.

Pachmarhi (Central Provinces). Altitude 3,528 ft. Sanatorium in Hosangabad district, summer resort of C. P. Government; 32 miles from Pipariya station on G. I. P. Ry. Stands on plateau of Satpura hills, forest growth generally thin, interspersed with numerous grass glades of park-like appearance; affords slight relief from heat of plains, May the hottest month but not oppressive; climate delightfully cool and bracing in second half of September and October. Rainfall 76.89 in., heaviest in June to September; annual normal relative humidity 60 per cent.; annual normal maximum 79.8°F. and minimum 61.0°F.

Pahalgam (Kashmir). Altitude 7,200 ft. Sixty miles from Srinagar by motor road; admirably situated beside Lidder tributary of Jhelum river, coniferous forests all round, drinking water from several good springs. Climate salubrious, cool, congenial for convalescents, less rainy than Gulmarg. Much resorted to by Indians; accommodation chiefly in tents available locally on moderate charges. Season—June to September.

Parachinar (North West Frontier Province). Headquarters of Kurum Agency. Three hours drive from Thal station on N. W. Ry.; in the midst of wide open valley encircled by hills. Climate cold—except in mid-summer—and dry, very healthy, suitable for convalescents. Some of the best varieties of fruits available. Rainfall 28.39 in.; annual normal relative humidity 55 per cent.; annual normal maximum 70.1°F. and minimum 48.0°F. Season—May to October.

Puri (Orissa). Headquarters of Puri district; popular health resort with good sea-bathing, on B. N. Ry., celebrated for Jagannath temple; has several hotels. The site is salubrious and monsoon blows fresh and cool from sea, less healthy during rains. Rainfall 53.99 in.; annual normal relative humidity 83 per cent.; annual normal maximum 86.3°F. and minimum 74.6°F.

Quetta (Baluchistan). Altitude 5,502 ft. Capital of Baluchistan and important military station on N. W. Ry., now in ruins on account of the 1935 earthquake; has severe winter and suffers from blizzards, dust-storms frequent in summer; well-known for fruits, has fine turfed polo and cricket grounds. Rainfall 9.37 in.; annual normal relative humidity 58 per cent.; annual normal maximum 73.6°F. and minimum 44.3°F.

Ranchi (Bihar). Altitude 2,128 ft. Summer seat of Bihar Government; situated on Chota Nagpur plateau on B. N. Ry. Much used by Europeans as health resort in cold-weather months; has mental hospitals for Indians and Europeans. Rainfall 54.72 in.; annual normal relative humidity 66 per cent.; annual normal maximum 84.2°F. and minimum 65.5°F.

Ranikhet (United Provinces). Altitude 5,983 to 6,942 ft. Military sanatorium in Almora district, 52 miles from Kathgodam by motor; more or less on flat so that horse conveyances and motors can be used; has a good golf course and extensive pine woods. Rainfall 52.13 in.; annual normal relative humidity 67 per cent.; mean temperature 60.3°F. Season—April to October.

Shillong (Assam). Altitude 4,920 ft. Headquarters of Assam Government; 67 miles by road from Gauhati on Assam Bengal Railway, situated on a plateau in Khasia Hills. Town laid out with great judgment and taste among pine woods, surrounded with rolling downs; visitors can enjoy riding, driving, polo, golf, and cricket; excellent climate, temperature more equable than that of any hill station in India, seldom above 80°F. in hottest weather. Rainfall 81.08 in.; annual normal relative humidity 74 per cent.; annual normal maximum 69.9°F. and minimum 53.4°F.

Simla (Punjab). Altitude 7,232 ft. Summer Headquarters of Governments of India and the Punjab; on N. W. Ry., Kalka-Simla section. Ripon hospital for Indians and Walker for Europeans; electric treatment obtainable; some near localities recommended for invalids; several excellent hotels. Rainfall 63.07 in.; annual normal relative humidity 57 per cent.; annual normal maximum 60.9°F. and minimum 49.7°F. Season—April or May to October.

Srinagar (Kashmir). Altitude 5,204 ft. Capital of Kashmir State; 196 miles from Rawalpindi or about similar distance from Jammu on N. W. Ry.; admirably situated on banks of navigable river Jhelum, with lovely Moghul gardens in the neighbourhood; accommodation principally in well furnished, electrically lighted house boats. Rather warm during June to August, but cooler places within easy reach; winter months very sunless. Has Cottage Hospital for the Europeans and large Mission Hospital for Indians. Rainfall 25.73 in.; annual normal relative humidity 82 per cent.; annual normal maximum 66.1°F. and minimum 44.1°F. Season—April to June, and September to November.

1726 CLASSIFICATION OF MINERAL WATERS

CLASSIFICATION OF MINERAL WATERS

The mineral waters available in the Western Countries are classified below according to their constituents. The mineral waters and springs found in India are also grouped in a tabular form for convenience.

Class	Spa	Characteristics
(1) Thermal Radio active of Low Mineralisation	... Buxton	... Warm, 82°
	... Bath	... Hot, 104° to 120°
	... Wildbad	... 91° to 105°
	... Plombières	... 77° to 155°, arsenical
	... Aix-les-Bains	... 108° to 122°, H ₂ S
(2) Muriated : Simple	Droitwich	} Hypertonic, 30 per cent. NaCl, external use only
	Nantwich	
	Woodhall Spa	... Contains Br and I
	Langammarch	... Contains barium
	Wiesbaden	... Isotonic or hypotonic
Alkaline	... Cheltenham (Pittville)	... Internal use
	... Ems	... 116°, CO ₂
	... Royat	... 95°, CO ₂
	... Hamburg	...
	... Nauheim	... Hot effervescing
	... Kissingen	...
Sulphated	... Cheltenham	... Internal use
	... Leamington	... Internal use
Alkaline	... Karlsbad	... Hot, internal use
Sulphated	... Marienbad	... Cold, internal use
(3) Sulphated (pure)	Apenta	} Bottled
	Rubinät	
	Hunyadi Janos	
(4) Alkaline : Carbonated	... Vichy	...
(5) Sulphur : Simple	Strathpeffer	...
	Isanwtyd Wells	...
Muriated	... Harrogate	...
	... Isandrindod	...
	... Helouan	... Hot
	... Rotoura	... Hot
	... Aachen	...
(6) Arsenical	... Levico	... Bottled
	... Mont Dore	... Low mineralisation
	... La Bourboule	... Muriated
(7) Calcareous	... Bath	... Hot
	... Contrexeville	... Cold
	... Wildungen	...

(8) Chalybeate :				
Ferrous	car-			
bonate	...	Strathpeffer	...	
		Buxton	...	
		Harrogate	...	
		Tunbridge Wells	...	
		Spa	...	CO ₂ , effervescent
Ferrous	sul-			
phate	Muriat-	Trefriw	...	
ed. FeCl	...	Harrogate	...	

MINERAL WATERS IN INDIA

Places	Temperature of the water	Characteristics
ASSAM.		
Cachar :— <i>Kopili</i> ...	128° to 130°F	Strongly saline.
Sibsagar :— <i>Namboo</i> ...	95° to 98°F	Water slightly sulphurous. Gas slightly sulphuretted.
BALUCHISTAN.		
Bolan Pass :— <i>Kirtla</i>	Hot sulphurous.
Las Bela :— <i>Kan Berar</i>	Strongly sulphurous.
Kachhi :— <i>Lakha</i>	Intensely saline and sulphurous.
Sibi :— <i>Khattan</i> ...	109°F	Sulphurous.
BENGAL.		
Birbhum :— <i>Tantipara</i> ..	128° to 162°F	Sulphuretted hydrogen.
Chittagong :— <i>Babu or Bharat-Khund</i>	Sulphurous and chalybeate.
<i>Balwa-Khund</i>	Diuretic and aperient.
<i>Kauri-Khund</i> ...	very hot	Saline, sulphurous and chalybeate.
<i>Brahma-Khund</i>	Saline, slightly chalybeate.
Darjeeling :— <i>Mechi</i>	Carbonated, sulphurous and chalybeate.
Jessore :— <i>Khajura</i> ..	82°F	Carbonate of lime and magnesia with a small proportion of iron.
BEHAR AND ORISSA.		
Atymallik :— <i>Deolghati</i> ...	134°F	Slightly saline and sulphuretted hydrogen.
Cuttack :— <i>Atari</i> ...	138°F	Quantity of sulphuretted hydrogen.
** Hazaribagh :— <i>Belkapi or Surja-Khund</i> ...		
	169°, 170°, 190°F	Chloride and sulphate of soda

<i>Doari</i> ...	110° to 115°F	Sulphurous and slightly saline
<i>Indra jurba</i> ...	Tepid	Sulphurous.
<i>Katkamsandi</i> ...	110°F	Sulphuretted hydrogen, silica, alkaline chlorides, sulphate and iron.

Mambhum :—

<i>Tatlul or Tantolya</i> ...	190°F	Sulphurous and slightly clayey beate.
-------------------------------	-------	---------------------------------------

Monghyr :—

<i>Bhimband</i> ...	145° to 150°F	Limpid and tasteless.
<i>Lachmi-Khund</i> ...	144°F	Not sulphurous.
<i>Panchbhur</i> ...	85.4°F	Not sulphurous.
<i>Sita Khund</i> ...	140°F	Slight odour of sulphuretted hydrogen.

Palamau :—*Jarum* .

<i>Thatha</i> ...	132°F	Sulphuretted hydrogen.
	151°F	Slightly impregnated with sulphuretted hydrogen.

Patna :—*Rajghir* ...

<i>Santhal-Parganas :—</i>	100° to 110°F	Water clear and tasteless.
<i>Baramasia</i> ...	93°F	Not sulphurous.
<i>Dumka</i> ...	82°F	Not sulphurous.
<i>Jhariya or Jherwa</i>		
<i>Pani</i> ...	93°F	Not sulphurous.
<i>Sibpur</i> ...	122°F	Profuse discharge of gas slightly sulphuretted.
<i>Nunbil</i> ..	119.5°F	Sulphuretted gas.
<i>Tatloi</i> ...	148°F	Slightly sulphurous.

BOMBAY.

<i>Kaira :—Lasundara</i> ...	100° to 122°F	Strongly sulphurous and saline.
------------------------------	---------------	---------------------------------

Panch Mahals :—

<i>Tuwa or Tul</i> ...	Near boiling point	
------------------------	--------------------	--

<i>Ratnagiri :—Arauli</i> .	105°F	Sulphurous vapour. Strongly impregnated with sulphur.
<i>Rajpur</i> ...	90°F	Alkaline. Traces of common salt and sulphate of lime.
<i>Sangameswar</i> ...	105°F	Slightly sulphurous.
<i>Rafivall</i> ..	110°F	Slightly sulphurous.
<i>Manga</i> ...	99° to 117°F	Chalybeate when fresh and sulphurous on issuing.

Surat :—

<i>Anaral</i> ...	115° to 120°F	Sulphurous gas.
<i>Vicrabhi</i> ...	110° to 136°F	Sulphuretted hydrogen.

CENTRAL PROVINCES.

Chhindwara :—

<i>Anhoni</i> ...	134°F	Strongly sulphurous.
-------------------	-------	----------------------

Hoshangabad :—

<i>Anhoni Samoni</i> ...	114°F	Abundant discharge of sulphuretted hydrogen.
--------------------------	-------	--

Surguja :—

<i>Talapani</i> ...	130° to 190°F	Strong odour of sulphuretted hydrogen.
---------------------	---------------	--

KASHMIR.

Baltistan :—

<i>Asholt</i>	...	104.5°F	Sulphuretted hydrogen.
<i>Bistlo Behitsil</i>	..	160°F	Sulphuretted hydrogen.
<i>Duchin</i>	...	154°F	Slightly chalybeate.
<i>Khorkan</i>	...	185°F	Sulphurous.

Changchengmo :—

<i>Gokra</i>	...	120° to 150°F	Carbonic acid gas.
<i>Pampun</i>	...	70°F	Sulphuretted hydrogen.

Nubar :—

<i>Chausan</i>	..	167°F	Faintly sulphurous.
----------------	----	-------	---------------------

Rupshu :—

<i>Puga</i>	...	80° to 174°F	Sodium chloride and sulphuretted hydrogen.
-------------	-----	--------------	--

MADRAS.

Godavari :—

<i>Gondala</i>	..	140°F	Slight odour of sulphuretted hydrogen.
----------------	----	-------	--

PUNJAB.

Gurgaon :—

<i>Sohna</i>	...	108°F	Strongly sulphuretted.
Kufu :— <i>Bashisht</i>	...	138°F	Sulphuretted hydrogen.
<i>Khclat</i>	...	104°F	Sulphurous
<i>Manikara</i>	...	106.5° to 202°F	Sulphuretted hydrogen.

Spiti :—

<i>Changhtsang</i>	...	117.5°F	Sulphuretted hydrogen.
--------------------	-----	---------	------------------------

Mianwali :—

<i>Bakh Ravine</i>	...	94°F	Sulphuretted hydrogen.
--------------------	-----	------	------------------------

Simla Hill States :—

<i>Jaori</i>	...	130.5°F	Sulphurous and Saline
Bhajji :— <i>Sunl</i>	...	135°F	Strongly sulphurous.

RAJPUTANA.

Mewar (Udaipur)

<i>Gangar</i>	...	80°F	Slightly saline and sulphurous.
---------------	-----	------	---------------------------------

SIKKIM.

<i>Momai</i>	..	110° to 116°F	Strongly sulphurous.
<i>Yeumtong</i>	..	112.6°F	Sulphuretted hydrogen. Chloride and sulphate of soda.

UNITED PROVINCES.

<i>Sahasradhara</i>	...	72°F	Strongly impregnated with sulphuretted hydrogen.
<i>Gauri Khund</i>	..	130°F	Carbonate of lime and iron.
<i>Gauri Khund</i>	...	72°F	Saline and strongly chalybeate.

NOTIFIABLE DISEASES

The following is a list of notifiable diseases in America, Great Britain, Ireland, India (Br.), and French and Portuguese territories in India.

Actinomycosis (A.)	Miliary fever (A., Fr. I.)
Adinitis, acute infectious (A.)	Mumps (A., I.)
Ankylostomiasis (A.)	Paragonimiasis (A.)
Anthrax (A.)	Paratyphoid (A., Fr. I., G.B. & Ir.)
Beri-beri (A.)	Pediculosis (A.)
Bilharziasis (A.)	Pellagra (A.)
Black-water fever (A.)	Pemphigus (A.)
Broncho-pneumonia (A.)	Pemphigus neonatorum (E. & W.)
Cancer (A.)	Plague*
Chancres, soft (A.)	Pneumonia (A., Fr. I., Sc.)
Chicken-pox (A., G.B., Ir., I.)	Poliomyelitis (A., G.B. & Ir.)
Cholera *	Psittacosis (A.)
Coccidiodal Granuloma, infectious (A.)	Puerperal fever (Sepsis) *
Continued fever (A., G.B., Ir.)	Rabies (A., E. & W.)
Dengue (A.)	Rat-bite fever (A.)
Diarrhoea and Enteritis (A., I., Ir.)	Relapsing fever *
Diphtheria and croup.*	Rheumatic fever (A.)
Distomiasis (A.)	Ring worm (A.)
Dysentery, Amoebic (A., Fr. I.)	Rocky mountain spotted fever (A.)
" Bacillary (A., Fr. I.)	Rubeola (A., E. & W.)
" unspecified (A.)	Scabies (A.)
Echinococcus infection (A.)	Scarlet fever *
Encephalitis, Epidemic lethargic (A., G.B. & Ir.)	Scurvy (A.)
Erysipelas (A., G.B. & Ir.)	Septic sore throat (A.)
Favus (A.)	Small-pox *
Filariasis (A.)	Syphilis (A.)
Food poisoning (A.)	Tetanus including infantile A., Sc.)
Foot and Mouth Disease (A.)	Tick fever (A.)
Glanders (A., E. & W.)	Trachoma (A., Sc.)
Goitre (A.)	Trench fever (Ir.)
Gonorrhoea including ophthalmia neonatorum (A.)	Trench mouth (A.)
Impetigo contagiosa (A.)	Trichinosis (A.)
Influenza *	Trypanosomiasis (A., Fr. I.)
Jaundice, infectious (A., Sc.)	Tuberculosis, pulmonary *
Leishmaniasis (A., I.)	Tuberculosis, nonpulmonary *
Leprosy (A., I., Fr. I., Pr. I.)	Tularæmia (A.)
Malaria (A., G.B. & Ir.)	Typhoid *
Malignant cedema (A.)	Typhus fever (Exanthematic) *
Measles (A., Fr. I., G.B. & Ir.)	Typhus, Benign Epidemic (A.)
Meningitis, epidemic cerebro-spinal *	Undulant fever (A., Fr. I.)
	Vincent's Angina (A.)
	Whooping cough *
	Yellow fever (A., I., Ir.)
	Yaws (A.)

* America, Great Britain, Ireland, India (Br.), and French and Portuguese settlements in India.

A.—America

E. & W.—England and Wales

Sc.—Scotland

Fr. I.—French territories in India

G. B.—Great Britain

Ir.—Ireland

I.—India (Br.)

Fr. I.—Portuguese territories in India

..

INDEX

- Acalypha indica*, 329
Acanthosis nigricans, 1181
 treatment, 1182
Acetanilide, 213
Acetarsones, 409, 668
Acetophenatidin, 213
Acetylarsan, 472, 672
 Acid-fast organisms, 938
Acidophilus bacillus, 1552
Acidosis, 69
 after anaesthesia, 74
 degree of, 72
 in children, 74
 in cholera, 75
 in diabetes, 73
 in malaria, 75
 in nephritis, 73
 non-gaseous, 72
 treatment of, 72
Achlorhydria, 1359
Acne scrofulosorum, 1171
 vulgaris, 787, 1158
Acnitis, 1171
Acorus calamus, 419
 chemistry of, 419
 therapeutics of, 419
Acridine dyes, 766
Acrodermatitis perstans, 1201
 treatment of, 1201
Actinomycosis
 of nails, 1159
 of skin, 1159
 treatment of, 1159
 Acute abdomen, 1125
Adexolin, 200
Adipositas dolorosa, 1054
 Administration, modes of, 25
 on mucous membranes, 27
 oral, 28
 rectal, 28
 sprays, 27
 subdural, 33
 sublingual, 33
 subnasal, 33
Adrenalin, 250
Adrephrine, 1436
 therapeutics of, 418
Aegle marmelos, 418
Afridol, 729
 violet, 78
Agomensin, 1440
Agranulocytosis, 1230
Aihum, 1232
Ajowan, 313
Akri, Akti : see *Vicia sativa*
Albumin water, 1343
Alcohol, 165, 238
 in fever, 169
 protective action of, 165
Alepol, 927
Alkalosis, 69, 75
 symptoms of, 75
 treatment of, 76
Alkresta ipecac, 381
Allergy, 1232
 non-specific desensitisation, 1239
 protein shock therapy, 1239
 protein skin tests, 1234
 treatment, 1237
Allium sativum, 329
Alopecia areata, 1220
Amidopyrin, 213
 Amino-acid deficiency, 1031
Amino-arsenophenol, 673
Amino-stiburea, 444
Amoebiasis, 356, 1241
 causative organisms, 356
 carriers, 358
 diagnosis of, 357
 diet in, 359
 incidence of, 356
 latent infection, 358
 mercury compounds in, 412
 organic arsenicals in, 409
 palliative remedies in, 415, 421
 problem of cure, 357
 total alkaloids of *ipecacuanha* in, 388
 treatment of, 1241
Amoebic dysentery
 bismuth in, 713
 stovarsol in, 669
 treatment of, 399, 406
Amytal, 230
Anabolin, 1301
Anæmia, 1241
 arsenic in, 646, 1248
 classifications of, 1241, 1714
 microcytic hypochromic, 1247
 arsenic in, 1248

- microcytic hypochromic anæmia
(*contd.*)
 blood transfusion in, 1249
 copper in, 1248
 iron in, 1247
 radium in, 1248
 splenectomy in, 1249
 treatment of, 1247
 pernicious, 1243
 blood picture in, 1243
 diagnosis of, 1243
 hydrochloric acid in, 1246
 iron in, 1246
 liver therapy in, 1244
 stomach preparations in, 1246
 treatment of, 1244
- Anæsthetics intravenous, 62
 evipan-sodium, 63
 magnesium sulphate, 62
- Anaphylaxis, 797
- Anatomical standards, 1711
- Anayodin, 409
- Angina pectoris, 1249
- Angiography, cerebral, 67
- Angioxyl, 1443
- Aniline dyes
 as anthelmintics, 345
 in leprosy, 936
- Ankylostoma duodenale, 268
- Anthelmintics
 administration of, 256
 choice of, 263
 investigation of, 264
 miscellaneous, 326
 antiseptics, intestinal, 326
 azadirach, 327
 butea frondosa, 327
 corsican moss, 327
 embelia, 327
 figus laurifolia, 328
 geraniol, 329
 heavy metals, 327
 mucana, 327
 purgatives, 326
 quassia, 328
 rotylon, 329
 spigelia marilandica, 328
 verona anthelmintica, 329
- on cestodes, 271
 arecanut, 281
 aspidium, 271
 carbon tetra-chloride, 283
 cocoanut, 283
 cusso (kouso), 276
 kamala, 278
 masenna, 283
 pepo, 283
- Anthelmintics (*contd.*)
 pomegranate, 279
 on nematodes, 284
 absinthi oil, 305
 anisi oil, 306
 beta-naphthol, 319
 betel oil, 305
 cajuput oil, 304
 carbon tetra-chloride, 284
 caryophylli oil, 305
 chenopodium oil, 298
 chloroform, 293
 cinnamomi oil, 306
 copaiba oil, 306
 eucalyptus oil, 294, 303
 heptyl resorcinol, 324
 hexyl resorcinol, 322
 rutæ oil, 306
 santonin, 307
 sassafras oil, 305
 tanceti oil, 305
 tetrachlor-ethylene, 294
 thymol, 311
 turpentine oil, 304
 on somatic parasites, 330
- Anthrax, 1166, 1251
- Antibody, production of, 102
- Antilebrine, 930
- Antileprol, 923, 930
- Antimonv, 429
 aniline tartarate, 456
 aromatic compounds of, 456
 chemotherapy of, 108, 454
 cumulative action, 463
 derivatives of, 429, 454, 459
 fastness, 446
 in filariasis, 343
 in flukes, 343
 in framboesia, 448
 in granuloma inguinale, 448, 1014
 in helminthic diseases, 339
 in kala-azar, 436
 in leprosy, 934
 in malaria, 448
 in pregnancy, 446
 in rat-bite fever, 449
 in schistosomiasis, 339
 in syphilis, 448
 in trichinosis, 343
 in trypanosomiasis, 449
 organic aromatic compounds of
 440, 456
 action of, 433
 pentavalent compounds, 456, 458
 complications after injection of,
 461
 dosage of, 441

- Antimony (*contd.*)
 pharmacology of, 430
 therapeutics of, 436
 tolerance, 433
 toxic effects of, 434, 459, 460
 trivalent compounds of, 456
 Antimonyl tartarate, 460
 Antimosan, 342
 Antineuritic vitamin, 192
 Antipellagra vitamin, 194
 Antipyretic drugs, 212
 analgesic action, 214
 habit formation, 215
 in fever, 119
 therapeutics of, 216
 toxic effects, 215
 Artipyrin, 213
 Antisera, dosage of, 799
 preparations, 792
 Anti-scorbutic vitamin, 196
 Anti-sterility vitamin, 190
 Antivenin, 805
 Antivirus, 779
 Areca, nut, 281
 Arecoline, 281
 dihydrobromide, 282
 dihydrochloride, 282
 pharmacology of, 281
 toxicity of, 282
 Aristochin, 583
 Arsacetin, 661
 Arsemetine, 387
 Arsenic, 239
 administration of, 657
 as anthelmintic, 647
 derivatives of, 635
 in chemotherapy, 110
 in dengue, 650
 in eruptions, 694
 in framboesia, 655
 in intestinal protozoa, 651
 in leprosy, 935
 in malaria, 647
 in rat-bite fever, 652
 in syphilis, 653
 in trypanosomiasis, 648
 in vincent's angina, 656
 organic compounds, 640
 absorption of, 641
 classes of, 643
 excretion of, 642
 pharmacology of, 635
 poisoning, 685
 therapeutics of, 646
 toxicity of, 685
 trivalent compounds, 673
 Arsenical
 dermatitis, 695
 eruptions, 692
 jaundice, 697
 organic, 680
 mode of action, 680
 poisoning, 686
 toxicity of, 686
 reactions, 687, 690
 Arsenobenzene, 678
 Arsenobillon, see Salvarsan
 Arsen-phenolamine, see Salvarsan
 Arsphenamine, see Salvarsan
 Artemisine, 312
 Arteriosclerosis, 1535
 Arthritis, 1251
 classification of, 1251
 treatment of, 1253
 aurotherapy, 1258
 diet therapy, 1255
 drug therapy, 1257
 fever therapy, 1256
 haemotherapy, 1256
 histamine therapy, 1259
 local, 1254
 non-specific protein therapy, 1255
 physical therapy, 1254
 vaccine therapy, 1256
 Arthropod vectors, 1608
 Ascaridole, 308
 Ascaris lumbricoides, 268
 Aschheim-Zondek test, 1454
 Ascitis, 1260
 treatment of, 1262
 Aspidium, 271
 administration of, 272
 anthelmintic effects, 273
 chemical composition, 271
 pharmacology of, 272
 poisoning, 274
 preparations of, 276
 Asthma, 789, 1262
 Atebrin, 602, 1519
 for prophylaxis, 607, 1521
 in black water fever, 608
 in labour forces, 1519
 pharmacology of, 602
 toxicity of, 606, 1522
 Atophan, 214
 Atoxyl, 472, 661
 therapeutics of, 662
 toxicity of, 663
 Aur-emetine, 386
 Autolysates, 778
 Avenyl, 753
 in leprosy, 934
 Azadirach, 327

- Bacillary dysentery, 840
 bacteriophage, 844
 carriers of, 842
 lactose in, 844
 treatment of, 842
 Bact. coli infection, 59
 Bact. pseudo carolinus infection, 846
 Bacteria, pathogenic, 1594
 Bacterial diseases
 channels of infection in, 763

 Razin's disease, 1167
 Bed sore, 1499
 Bee sting, treatment of, 1112
 Bee venom therapy, 1104
 Remax, 200
 Reprochin, 590
 Beri-beri, 193, 1018
 adrenalin effect in, 1021
 dry type, 1018
 evlunis in, 1022
 marmite in, 1022
 oryzanin in, 1022
 oryza toxin in, 1020
 prophylaxis and treatment of, 1021
 rice, 1020
 tikitiki in, 1018, 1022
 wet type, 1018
 Beta-naphthol, 319
 anthelmintic effect, 320
 pharmacology of, 319
 preparations of, 321
 toxicity of, 321
 Beverages, 1647
 Phang, 1120
 Bile, white, 1719
 Bile-pigments, formation of, 99
 Biloposol, 725
 Biquinyi, 725, 726
 Bird malaria, tests on, 549
 Bisantol, 724
 Bismarsen, 679, 725
 Bismocymol, 724
 Bismogenol, 724
 Bismol, 723
 Bismolnol, 724
 Bismostab, 722
 Bismuth, 703
 administration of, 715
 in amoebic dysentery, 718
 in leprosy, 935
 in lupus erythematosus, 714
 in neurosyphilis, 711
 in syphilis, 708
 in yaws, 712
 pharmacology of, 704
 preparations of, 721
 therapeutic uses, 708
 toxicity of, 717
 Bismutho-yatren, 726
 Bismuthyl, 722
 Bismuthyl gluconic acid, 724
 Bismuthyl tartrates, 723
 Bismutol, 724
 Disene, 724
 Bistovol, 726
 Bivatol, 725
 Black water fever, 574, 1270
 Black widow: see Latrodectus
 mactans
 Blazan, 725
 Blood, 1271
 arneth count, 1265
 bleeding time, 1284
 chemistry of, 1272
 coagulation time, 1284
 collection of, 1720
 examination of, 1286
 flukes, 332
 groups, 54
 leucocyte count, 1274
 parasites of, 1287
 platelets, 1282
 pressure, 1290
 method of determination, 1292
 diet therapy in, 1296
 opotherapy in, 1301
 treatment of, 1297
 red cell count, 1279
 sedimentation test, 1284

- Blood (*contd.*)
 specific gravity of, 35
 transfusion, 49
 animal to man, 53
 complication of, 53
 direct, 52
 in different diseases, 50
 technique of, 52
 whole blood, 52
 viscosity of, 1271
